It should perhaps be noted that if Λ be plotted against $C^{1/2}$—a procedure frequently employed in the past, for example by Barak and Hartley[4]—the plot is definitely S-shaped. To take the case of NaCl as an example, a "best" straight line can be drawn representing the experimental data within 0.05 conductance unit or so, but the extrapolated Λ_0 is 42.35, a fifth of a unit in error. The result so obtained, however, agrees probably as closely as can be expected with Barak and Hartley's 42.5, and the slope, 190, is in reasonable agreement with the value, 197, quoted in their Table IV. Nevertheless, one must question the validity of conclusions as to ion-pair formation, etc., based on such a procedure.

If the values of Λ_0 for NaCl and LiCl be combined with the l^0 of the preceding paper,[1] one obtains 21.87 and 21.82, respectively, as the limiting conductance for chloride ion. The agreement is not as close as was obtained with methanol as solvent,[5a] but the mean, 21.85, is probably reliable to ±0.02 or 0.03 conductance unit. The corresponding λ^0_+ for the cations are summarized in Table III. Smisko and Dawson[22] have reported a limiting conductance for K^+ of 23.4; this is based on their value of l^0_+ for KCNS of 0.4612 and a Λ_0 for the salt of 50.8, computed by them from Barak and Hartley's data[4] by means of a Shedlovsky extrapolation; their result probably agrees with ours as closely as can be expected in view of the uncertainties of the conductance data they were forced to employ.

Discussion

Table III gives the limiting conductances and the conductance–viscosity products for the four ions.[23] It is at once apparent that while the Walden rule (as might be expected) is not obeyed, the variation in the product on passing from methanol to ethanol is considerably less than on passing from water to methanol, and is moreover not as great for the three cations as for chloride.

In Table IV are the limiting conductance ratios for the ions in water at 25 and 45° and in the two alcohols. It was earlier pointed[5b] out that viscosity effects on passing from one solvent to another should cancel to some extent in the ratio, if the ions compared were of the same sign and charge. A glance at Table IV shows at once, however, that no simple generalization as to the conductance ratio can be made. In all cases, there is an increase in the ratio of the conductance of the slower to the faster cation with rise in temperature, *i.e.*, with decrease in dielectric constant, and the same is true on going from water to methanol. On passing from methanol to ethanol, a solvent of still lower dielectric constant, however, the Na^+/K^+ ratio is unaltered, while that for Li^+/Na^+ actually decreases. Thus there does not seem any obvious dependence of the ratio on solvent dielectric constant, and this of itself would seem to bargain out any purely electrostatic picture of solvent dipole–cation interaction. It is true that the use of the macroscopic dielectric constant[24] as a rough measure of solvent–ion interaction and consequently of the ion size effective in transport is a gross and possibly unjustifiable simplification. A more sophisticated treatment such as that used by Gilkerson[25] in his recent study of the effect of solvent properties, in particular the dipole moment, on the ion-pair dissociation constant, however, does not seem hopeful, since it would involve assumptions as to the local dielectric constant effective in the interaction between the ion and the innermost layer of solvent dipoles. It should also be noted that while there is a definite trend in the ratio Na^+/Cl^-, this is not the case for K^+/Cl^-. If as relatively simple a quantity as the limiting conductance ratio for a pair of noble gas type ions, shows such individualistic behavior with three solvents as closely related as water and the two alcohols, it indicates (we believe) that any satisfactory answer to the problem of ionic mobility as a function of solvent properties is still remote.

Finally, it should be noted, however, that the ion-pair dissociation constants for the three salts lie in the order expected, *i.e.*, the salt with the smallest crystallographic and consequently the largest solvated radius for the cation shows the smallest tendency toward ion-pair formation.

In conclusion, we wish to express our thanks to the National Research Council of Canada for the award of studentships to J. R. G. and G. S. K.

Adsorption Kinetics and Electrode Processes

BY PAUL DELAHAY AND ISAAC TRACHTENBERG[1,2]

RECEIVED DECEMBER 11, 1956

The kinetics of adsorption on electrodes is studied for substances which are not reduced or oxidized at the electrode. Adsorption rates are derived for the plane electrode with control by semi-infinite linear diffusion, the streaming mercury electrode, and electrodes in stirred solution. Adsorption at the dropping mercury electrode is also considered briefly. To simplify the treatment it is assumed either (a) that the concentration of adsorbate is so low as to allow linearization of the isotherm, or (b) that the concentration of adsorbate is so large as to correspond to full coverage. In the range of concentrations in which the isotherm can be linearized, adsorption with diffusion control is a slow process and the equilibrium surface concentration is reached only after a long time (perhaps 30 min.). This conclusion is verified experimentally by differential capacity measurements for the adsorption of *n*-hexyl alcohol on a hanging mercury drop in 1 *M* potassium nitrate. Conversely, the streaming mercury electrode is essentially free of adsorbate. Implications are discussed for double layer capacity measurements, electrocapillary curves studies, electrochemical kinetics and polarography. Maxima and minima and other features of current–time curves during drop life in polarographic reductions in presence of an adsorbable species are accounted for; and the dependence of limiting currents on the head of mercury is interpreted. Experimental results are given for the reduction of Cu(II) in 0.5 *M* sodium citrate in presence of quinoline. Experimental methods are discussed, and a simple and accurate bridge for differential capacity measurements without isolation transformer is described.

Introduction

The characteristics of electrode processes often are affected by the adsorption of substances not directly involved in the electrode reaction. For instance, the exchange current and the transfer coefficient for the discharge of cadmium ion on cadmium amalgam vary when hexyl alcohol is added to the cadmium ion solution. The partial coverage of the electrode by the adsorbed substance causes an increase in actual current density and a concomitant increase in overvoltage. The variation of kinetic parameters and the increase in actual current density account for the distortion of current–potential curves which results from the addition of an adsorbable species such as a polar organic substance. If the exchange current is large enough, current–potential curves may not be altered because the decrease in the rate of the electrochemical reaction is not sufficient to cause a

departure from so-called reversible behavior.[3] Another effect of adsorption of polar organic substances is the decrease of limiting currents which otherwise would be mass transfer controlled.

These effects have been studied in detail[4-13] but, if one excepts studies of adsorption by electrolysis with superimposed alternating current[14-16] (no claim to a comprehensive literature survey is made), mass transfer of the adsorbate has generally not been considered, and it has been assumed tacitly that there is no concentration "polarization" of the adsorbate. In other words it is generally assumed that the surface concentration has the equilibrium value corresponding to the concentration of adsorbable substance in the bulk of the solution far from the electrode. This assumption often cannot be made[17] as will be apparent from this work, and a study of the kinetics of adsorption with mass transfer control is of interest. This study is reported here (a) for control by linear diffusion, (b) for the dropping mercury electrode, (c) for the streaming electrode and (d) for stirred solution. Implications in double layer capacity measurements, electrocapillary curve studies, electrochemical kinetics, and polarography are considered.

Control by Semi-infinite Linear Diffusion

Boundary Value Problem.—We consider the adsorption of a substance on a plane electrode with mass transfer controlled by semi-infinite linear diffusion. The surface of the electrode is supposed to be uncovered initially; the modification in treatment for a partially covered electrode at time zero is trivial. The surface concentration Γ of adsorbable substance at time t is obtained by integrating the flux of adsorbate from 0 to t, *i.e.*

$$\Gamma = \int_0^t D(\partial C/\partial x)_{x=0}\, dt \qquad (1)$$

where D is the diffusion coefficient of the adsorbate, C the concentration of this substance, and x the distance from the electrode. If it is assumed that the adsorption process is so rapid that there is solely diffusion control, the surface concentration Γ is related to the volume concentration at the electrode surface, $C_{x=0}$, by the adsorption isotherm. This simplification is quite justified since it has been found by the alternating current method[14-16] that the adsorption of many polar organic substances on a mercury electrode is purely diffusion controlled. For other metals there might be partial control by the kinetics of adsorption, but this complication will not be considered here. Thus

$$\Gamma = \frac{\Gamma_m C}{a + C} \qquad (2)$$

where Γ_m is the surface concentration for maximum coverage, and a is a parameter which is characteristic of the isotherm.

The combination of (1) and (2) yields the boundary condition for which Fick's equation must be solved. Furthermore, one has $C = C^0$ for $x \geqslant 0$ and $t = 0$; and $C \to C^0$ for $x \to \infty$ and $t \geqslant 0$, C^0 being the bulk concentration of adsorbate.

Solutions are discussed below for the following two cases: (a) The adsorption isotherm can be linearized,[18] *i.e.*

$$\Gamma = KC \text{ with } K = \Gamma_m/a \qquad (3)$$

and (b) the case in which C^0 is so large that $\Gamma \approx \Gamma_m$ even when $C_{x=0} \ll C^0$. The general case is not treated because of mathematical difficulties. A general solution could be obtained by means of computer calculations, but the essential ideas can be presented in a simple treatment.

Variations of Concentration for the Linearized Isotherm.—The ratio of concentrations C/C^0, as obtained by Laplace transformation[19] is

$$\frac{C}{C^0} = 1 - \exp\left[\frac{x}{K} + \frac{Dt}{K^2}\right] \operatorname{erfc}\left[\frac{x}{2D^{1/2}t^{1/2}} + \frac{D^{1/2}t^{1/2}}{K}\right] \qquad (4)$$

where "erfc" represents the complement of the error function. Variations of C/C^0 with the distance from the electrode are shown in Fig. 1 for different times after the beginning of the adsorption process and for the values $D = 0.5 \times 10^{-5}$ cm.^{2} sec.$^{-1}$ and $K = 5 \times 10^{-3}$ cm. (see Experimental Verification). The concentration in the immediate vicinity of the electrode approaches the bulk concentration C^0 only after a long time (1000 sec. or more), and *adsorption equilibrium is slowly attained.* The qualitative interpretation is simple: the gradient of concentration of adsorbate decreases continuously as adsorption proceeds, and the rate of diffusion drops accordingly.

(3) Reversible waves are observed in polarography when the rate constant at the standard potential for the electrode reaction is larger than 10^{-2} cm. sec.$^{-1}$. See P. Delahay, THIS JOURNAL, **75**, 1430 (1953); P. Delahay, "New Instrumental Methods in Electrochemistry," Interscience, New York, N. Y., 1954, pp. 83–85.

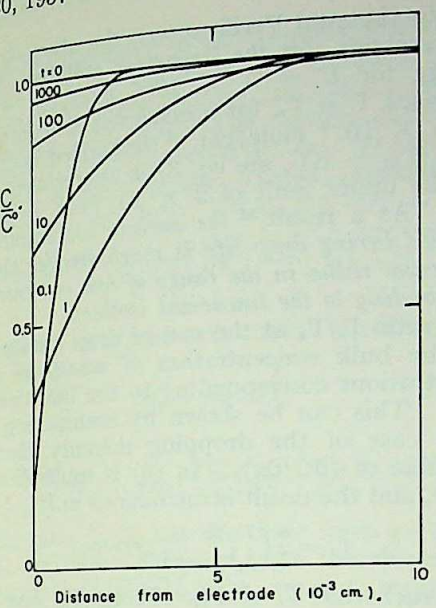

Fig. 1.—Variations of C/C^0 with distance from electrode for different times (in seconds) after the beginning of adsorption and for control by semi-infinite linear diffusion (data in text).

The surface concentration Γ_t at time t is readily obtained from (4) by noting that, according to (3), $\Gamma_t = KC_{x=0}$. Thus

$$\frac{\Gamma_t}{\Gamma_e} = 1 - \exp\left(\frac{Dt}{K^2}\right)\operatorname{erfc}\left(\frac{D^{1/2}t^{1/2}}{K}\right) \qquad (5)$$

where Γ_e is the equilibrium surface concentration for the bulk concentration C^0, *i.e.*, $\Gamma_e = KC^0$ (see eq. 3). The function in (5) is tabulated in Carslaw and Jaeger.[20] The ratio Γ_t/Γ_e, which is equal to zero for $t = 0$, approaches unity as t tends to infinity. The value of the argument for which there is virtually complete coverage is readily deduced from (5). For instance, $\Gamma_t/\Gamma_e \geq 0.99$ when $D^{1/2}t^{1/2}/K \geq 56.5$; *i.e.*, for $t > 1.6 \times 10^4$ sec. for the data of Fig. 1. Actually, convection interferes and shortens the time necessary to attain adsorption equilibrium.

The ratio Γ_t/Γ_e given by (5) is independent of the bulk concentration of adsorbable substance because the adsorption isotherm is linearized in this treatment. Thus, the rate of diffusion is doubled when C^0 is changed to $2C^0$, but Γ_e is also doubled and, consequently, Γ_t/Γ_e is independent of C^0. Actually, one would find that the time required to reach a given value of Γ_t/Γ_e decreases as C^0 increases if the *complete* adsorption isotherm (equation 2) were used.

Variations of Concentration for the Case in which $\Gamma_e \approx \Gamma_m$ even for $C_{x=0} << C^0$.—This case can be treated readily by the Ilkovic equation, as written for the case of semi-infinite linear diffusion.[21,22] It is assumed that the rate of diffusion is the same as for a process in which $C_{x=0} = 0$ for $t > 0$ and $C_{x=0} = C^0$ for $t = 0$. This major *simplification* is justified when the bulk concentration of adsorbate, C^0, is so large that the maximum coverage Γ_m is reached even when the volume concentration of adsorbate at the electrode surface is much smaller than C^0. One then has[23] per unit area

$$\left(\frac{\partial C}{\partial x}\right)_{x=0} = \frac{C^0}{(\pi Dt)^{1/2}} \qquad (6)$$

and in view of (1)

$$\Gamma_t = \frac{2D^{1/2}C^0}{\pi^{1/2}}t^{1/2} \qquad (7)$$

Equation 7 holds only for values for t for which $\Gamma_t \leq \Gamma_m$. The time τ at which $\Gamma_t = \Gamma_m$ is readily computed from (7). Actually, the value Γ_m is approached asymptotically and τ should be infinite, but a finite value is obtained in this very approximate derivation. Note that τ is inversely proportional to the square of the bulk concentration C^0.

Experimental Verification.—The differential capacity of an electrode is markedly changed by the adsorption of polar organic substances. The double layer can be represented by an equivalent circuit composed of two capacities in parallel: one capacity for the covered fraction of the electrode, and the other capacity for the uncovered fraction. On the basis of this model one can write

$$C = C_{\theta=1} + (C_{\theta=0} - C_{\theta=1})(1 - \theta) \qquad (8)$$

θ being the electrode coverage. Equation 8 holds for the range of potentials in which $c_{\theta=0} > c_{\theta=1}$. At time t, one has $\theta = \Gamma_t/\Gamma_m$, Γ_m being the maximum surface concentration of adsorbate. Likewise, $\theta = \Gamma_e/\Gamma_m$ for $t \to \infty$. Hence

$$\frac{\Gamma_t}{\Gamma_e} = \frac{C_{\theta=0} - C_t}{C_{\theta=0} - C_{t\to\infty}} \qquad (9)$$

Relationship 9 was applied to the adsorption of *n*-hexyl alcohol on a mercury hanging drop in 1 *M* potassium nitrate. Differential capacities were measured with an a.c. bridge (see Experimental). Values of $c_{t\to\infty}$ measured at -0.700 v. (*vs.* S.C.E.) are shown in Fig. 2. These values were

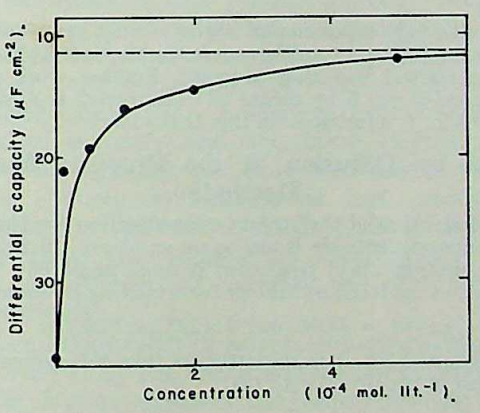

Fig. 2.—Differential capacity of hanging mercury drop in 1 *M* potassium nitrate with varying amounts of *n*-hexyl alcohol. Capacities were measured at -0.700 v. (*vs.* S.C.E.) and 25°.

reached after 30 to 60 minutes. The curve and the asymptote were traced to fit a Langmuir isotherm ($\Gamma_m = 8 \times 10^{-10}$ moles cm.$^{-2}$, $a = 2 \times 10^{-8}$ moles cm.$^{-3}$, see eq. 2). The capacity c_t was followed during adsorption, and the corresponding values of Γ_t/Γ_e (Fig. 3) were computed from (9).

The theoretical curve deduced from eq. 5 is also traced in Fig. 3 for the value $D^{1/2}/K = 0.05$ sec.$^{-1/2}$, *i.e.*, for $K = 4 \times 10^{-2}$ cm. with $D = 0.4 \times 10^{-5}$ cm.^{2} sec.$^{-1}$. This value of K corresponds to $\Gamma = \Gamma_m$ for $C = 2 \times 10^{-8}$ moles cm.$^{-3}$ for the linearized isotherm (Fig. 2). The value $\Gamma_m = 8 \times 10^{-10}$ mole cm.$^{-2}$, used in the calculation of K, was computed from the coverage of 21×10^{-16} cm.^{2} per molecule quoted by Adam[24] for the adsorption of an aliphatic alcohol with no compression of the film.

The marked departure from theory in Fig. 3 is to be expected since the theoretical curve corresponds to linear dif-

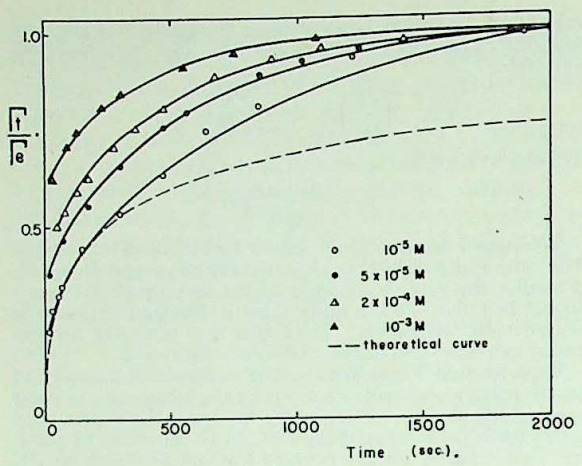

Fig. 3.—Variations of Γ_t/Γ_e with time for the conditions of Fig. 2. The theoretical curve is for the plane electrode.

fusion whereas the experimental results were obtained with a spherical electrode. The disagreement is in the right direction since the rate of diffusion for a spherical electrode is higher than for a plane electrode, all other conditions being the same. Convection also increased the rate of mass transfer of *n*-hexyl alcohol. Similar experiments were made with a mercury pool electrode, but the results were unreliable probably because of wetting of the mercury in contact with the wall of the container.

Figure 3 also shows that Γ_e is reached more rapidly when the bulk concentration of adsorbate is increased, *e.g.*, when the isotherm departs markedly from the linearized form (Fig. 2).

Although this experimental study is only semi-quantitative it definitely bears out the conclusion that adsorption with diffusion control is a slow process. Further work on the verification of eq. 5 by means of radiotracers is now being done by Mr. J. Truemper in this Laboratory.

Control by Diffusion at the Dropping Mercury Electrode

The derivation of the surface concentration for the dropping mercury electrode is the same as above, in principle, but the mathematical treatment is more involved. Fick's equation, as modified by Ilkovic for a moving boundary[23b]

$$\partial C/\partial t = D\partial^2 C/\partial x^2 + (2/3)(x/t)\partial C/\partial x \qquad (10)$$

is applied, and eq. 1 is rewritten to take into account the expansion of the drop (with $t^{2/3}$)

$$\Gamma = \frac{1}{t^{2/3}} \int_0^t Dt^{2/3}(\partial C/\partial x)_{x=0}\, dt \qquad (11)$$

This problem possibly could be solved by computer calculations or by making the same transformations that Smutek[25] used in his elegant treatment of irreversible polarographic waves. Calculations would be laborious, and only a simple analysis will be made here.

The rate of diffusion is increased because of the expansion of the drop, and Γ_t/Γ_e approaches unity more rapidly than eq. 5 predicts for linear diffusion. However, the time required to reach a given Γ_t/Γ_e should be of the same order of magnitude in both cases. From (5) one deduces that $\Gamma_t/\Gamma_e \approx 1$ for $(Dt)^{1/2}/K > 20$, *i.e.*, $D^{1/2}/K > 10$ sec.$^{-1/2}$ for a normal drop time of 4 sec. Since D is of the order of 0.5×10^{-5} cm.^{2} sec.$^{-1}$ in most cases (not for polyelectrolytes), the preceding condition becomes $K < 2 \times 10^{-4}$ cm. If one takes the realistic approximate value of $\Gamma_m = 10^{-9}$ mole cm.$^{-2}$ (see Experimental Verification), the above limit of K corresponds, *for the linearized isotherm*, to full coverage for $C = 5 \times 10^{-6}$ mole/cm.$^{-3}$. In most cases, $\Gamma \approx \Gamma_m$ for much lower concentrations than 5×10^{-6} mole/cm.$^{-3}$ (linearized isotherm), and K ($\Gamma_m = KC$, see eq. 3) is appreciably larger than the upper limit of 2×10^{-4} cm. prescribed above. As a result,[26] *the surface concentration of adsorbate during drop life is much smaller than the equilibrium value in the range of low concentrations corresponding to the linearized isotherm.*

The ratio Γ_t/Γ_e at the end of drop life increases with the bulk concentration of adsorbate above concentrations corresponding to the linearized isotherm. This can be shown by transposing eq. 7 to the case of the dropping mercury electrode. The value of $(\partial C/\partial x)_{x=0}$ in (6) is multiplied[23] by $(7/3)^{1/2}$, and the result is introduced in (11). Thus

$$\Gamma_t = \frac{6}{7}\left(\frac{7}{3}\right)^{1/2} \frac{1}{\pi^{1/2}} C^0 D^{1/2} t^{1/2} \qquad (12)$$

with t such that $\Gamma_t \leqslant \Gamma_m$. From (12) one calculates that the time τ at which $\Gamma_t = \Gamma_m$ is 0.3 sec. for $D = 0.4 \times 10^{-5}$ cm.^{2}/sec.$^{-1}$ and $C^0 = 10^{-4}$ mole/cm.$^{-3}$. This calculation which is *very* approximate corresponds to the most favorable conditions for equilibrium attainment.

Control by Mass Transfer at the Streaming Mercury Electrode

The electrode surface is continuously renewed at the streaming mercury electrode, and it is of interest to determine to what extent the mercury surface is free of adsorbable substance and can be regarded as "clean" in applications in electrochemical kinetics.

The surface concentration of adsorbate will be derived by adaptation of the result for linear diffusion as was done by Koryta[27] in his treatment of the limiting current for the streaming mercury electrode. On the basis of the assumptions listed below, Koryta obtained the simplified form of the equation for the limiting current which had been derived more rigorously by Rius and co-workers.[28,29]

The following assumptions are made: (a) the layer of solution which is adjacent to the mercury column moves at the same velocity as mercury; (b) this layer is thicker than the diffusion layer; (c) there is virtually no concentration gradient in this layer in the direction parallel to the axis of the mercury jet; (d) diffusion in the layer in the immediate vicinity of the mercury column is treated by Fick's equation for linear diffusion.

The number of moles adsorbed on the electrode is

$$N = \int_0^L D\left(\frac{\partial C}{\partial x}\right)_{x=0} 2\pi r\, dl \qquad (13)$$

where L is the length of the mercury column (supposed to be cylindric), l is the distance from the

(26) One deduces from (5) that $\Gamma_t/\Gamma_e = 0.10$ for $D^{1/2}/K = 0.05$ sec.$^{-1/2}$ and $t = 4$ sec. This corresponds to the data used in the calculation of the theoretical curve in Fig. 3.

tip of the capillary to the annular zone of height dl and r is the radius of the mercury jet. The gradient of concentration $(\partial C/\partial x)_{x=0}$ in (13) is evaluated from (4). The latter contains the variable t which is converted to l by noting that $t = l/v$ where v is the velocity (assumed to be uniform) of mercury. Thus, for $l = L$ one has

$$N = 2\pi rLKC^0\left\{1 - \exp\left(\frac{DL}{K^2v}\right)\operatorname{erfc}\left[\frac{1}{K}\left(\frac{DL}{v}\right)^{1/2}\right]\right\} \quad (14)$$

The value of N_e for adsorption equilibrium is in view of (3)

$$N_e = 2\pi rLKC^0 \quad (15)$$

and

$$\frac{N}{N_e} = 1 - \exp\left(\frac{DL}{K^2v}\right)\operatorname{erfc}\left[\frac{1}{K}\left(\frac{DL}{v}\right)^{1/2}\right] \quad (16)$$

The ratio N/N_e has the same form as the value Γ_t/Γ_e for linear diffusion, and the dimensionless parameter $(1/K)(DL/v)^{1/2}$ simply replaces the group $(Dt)^{1/2}/K$.

Because of the assumptions underlying eq. 16, this formula is only approximate but the order of magnitude of N/N_e can be evaluated from it. One has $N/N_e = 0.6\%$ for $D^{1/2}/K = 0.05$ sec.$^{-1/2}$ (see experimental part above), $L = 0.5$ cm., and $v = 50$ cm. sec.$^{-1}$. The electrode is thus essentially free of adsorbate. This could be advantageous in electrochemical kinetics where contamination of electrodes (even mercury or amalgam electrodes) is a serious obstacle to the precise determination of kinetic parameters for electrode processes.

The case in which the bulk concentration of adsorbable substance is so large as to correspond to virtual saturation of the electrode surface can be analyzed by following the same procedure as for linear diffusion. Details will not be given here because the result is of little practical value.

Control by Mass Transfer in Stirred Solution

The surface concentration of adsorbate is easily obtained on the basis of the concept of the Nernst diffusion layer. Thus

$$(\partial C/\partial x)_{x=0} = (C^0 - C_{x=0})/\delta \quad (17)$$

where δ is the thickness of the diffusion layer. By substituting in eq. 1 the gradient from (17) and by differentiating the result with respect to t, there follows a differential equation. The solution is

$$C = C^0\left[1 - \exp\left(-\frac{Dt}{K\delta}\right)\right] \quad (18)$$

Hence (see eq. 3), one has for the linearized isotherm

$$\frac{\Gamma_t}{\Gamma} = 1 - \exp\left(-\frac{Dt}{K\delta}\right) \quad (19)$$

The electrode is rather rapidly covered: $\Gamma_t/\Gamma_e = 0.98$ for $t = 120$ sec. and $D^{1/2}/K = 0.05$ sec.$^{-1/2}$ (see experimental part above), *i.e.*, for $D = 0.4 \times 10^{-5}$ cm.^{2} sec.$^{-1}$, and $\delta = 0.003$ cm. (an order of magnitude for not too vigorous a stirring).

Implications

Double Layer Capacity Measurements.—Double layer capacity measurements are somewhat in error when adsorption equilibrium is not attained for adsorbable species. This is the case in the study of the adsorption of polar organic molecules on mercury, when the differential capacity is measured with a dropping mercury electrode and the concentration of the organic substance is low. The correct dependence of the differential capacity on frequency is nevertheless obtained because the diffusion layer is much thicker than the layer in which the concentration of adsorbate varies periodically with time. However, the surface concentration of adsorbate is smaller than the equilibrium value corresponding to the bulk concentration. It is observed that the characteristic two desorption peaks in the curve differential capacity against potential disappear as the concentration of adsorbate is decreased. When adsorption equilibrium is not attained with the dropping mercury electrode, the peaks should disappear at higher concentrations than for curves obtained with the hanging mercury drop.

Likewise, differential capacities measured with the dropping mercury electrode for *low* electrolyte concentration (10^{-3} M or less) could be somewhat erroneous when the anion (or cation) is adsorbed. The theoretical analysis made above does not apply to this case because of complications resulting from migration and the structure of the double layer, but the conclusion about the slowness of adsorption is still qualitatively valid. The same comment can be made for polyelectrolytes.[30] Fortunately, most measurements of differential capacity for pure electrolytes are made at concentrations at which adsorption equilibrium is attained.

The value of the parameter $(Dt)^{1/2}/K$ for the system being investigated can serve as a guide in deciding whether adsorption equilibrium is attained: the condition $(Dt)^{1/2}/K > 20$ should be fulfilled (see eq. 5). A simpler test is to change the head of mercury and determine whether the differential capacity per unit area varies with drop time. When equilibrium is not attained, the coverage at the end of the drop life decreases with drop time (see section on Polarography below), and the differential capacity per unit area varies accordingly.

Non-attainment of adsorption equilibrium could be avoided by the use of a stationary mercury electrode, but progressive contamination of the electrode by traces of impurities might be very difficult to avoid. The hanging mercury drop is preferable to the mercury pool[31] because of better reproducibility of area. Another possible solution is the use of the rotating dropping mercury electrode developed for voltammetric studies by Stricks and Kolthoff.[32] However, the use of this electrode in precise measurements of differential capacities might not be practical.

Electrocapillary Curves.—The foregoing considerations can be transposed to the "drop weight" method for the determination of electrocapillary curves. Somewhat erroneous results can be expected particularly in studies at low concentration of electrocapillary active substances. Although results are then affected by a systematic error, they

can be precise and analytical application is possible.[22]

Electrochemical Kinetics.—In general, traces of adsorbed impurities strongly affect kinetic parameters for electrode processes (exchange current and transfer coefficient). This source of error often cannot be entirely eliminated by careful purification of solution, and electrodes in which contamination is minimized are advantageous. The streaming mercury electrode is the best in this respect, but it is not very practical. The dropping mercury (amalgam) electrode is better than the hanging mercury drop because of the short duration of measurements and the continuous renewal of the mercury surface. It is suggested that kinetic parameters be measured for different times of the drop life (synchronization system), and that results be extrapolated to zero time to minimize the effect of impurity adsorption. This procedure should prove useful in the application of relaxation methods (potential- or current-step methods, electrolysis with superimposed a.c. component). The extrapolation method probably would fail for electrode reactions with gas evolution (hydrogen or oxygen overvoltage) because of the necessity of attainment of a steady state for the electrode coverage by gas. The dropping mercury electrode cannot be utilized in such a case anyhow.

The advantage of the dropping mercury electrode over the hanging mercury drop can be inferred from the recent work of Gerischer and Staubach[33] on the kinetics of the mercurous ion–mercury electrode. These authors observed that exchange currents obtained with a dropping mercury electrode for different concentrations of mercurous ion were about three times larger than the values for the hanging mercury drop. Two different methods, a.c. electrolysis and the potential-step method, were applied in these two sets of measurements and this might account for the discrepancy on the exchange current values. However, the lesser contamination of the dropping mercury electrode may well be the explanation of the difference between the two sets of results.

Polarography.—The departure from adsorption equilibrium (with respect to the bulk concentration) at the dropping mercury electrode may be relevant in a variety of polarographic studies: maximum suppressors, catalytic waves of alkaloids, distortion of waves, and depression of limiting currents by adsorption of foreign substances, etc. Implications will be considered here for current–time curves for electrode reactions in presence of an adsorbable organic substance that is not reduced or oxidized. This study was made for the reduction of Cu(II) in 0.5 *M* sodium citrate in presence of quinoline. Tracings of current–potential curves (maximum current during drop life) are given in Fig. 4. The range of markedly cathodic potentials at which quinoline should be desorbed could not be explored because of reduction of this substance.[34] Current–time curves during drop life are shown in Fig. 5 with the pertaining data in Table I. The following effects will be discussed: effects of drop time, quinoline concentration, and potential.

Since the area of the mercury drop (sphere) increases with $t^{2/3}$, t being the time during drop life, the rate of drop growth depends on $t^{-1/3}$ and decreases continuously. In the initial stage of the drop life, the drop grows too rapidly to be fully covered and the faradaic current is not too markedly hindered. The drop becomes progressively covered with adsorbate, and the current decreases at the end of the drop life (Fig. 5A). If the drop time is long enough (perhaps 10 sec.), the decrease in current is soon over-compensated by the increase in area, and the current increases again (Fig. 5B).

The rate of adsorption increases with the volume concentration of adsorbate. Hence, the minimum in current–time curves is shifted toward shorter times as the concentration of adsorbate increases (Fig. 5C and 5D). The minimum in current–time curves disappears at large concentrations of adsorbable species.

The electrode coverage can be adjusted at will by variation of the potential,[35,36] all other conditions being identical; and the shape of current–time curves changes with potential.[37] If the potential is sufficiently close to one of the two desorption peaks of the differential capacity curve, the coverage is small, and the minimum in the current–time curves disappears (Fig. 5E). Compare plates B, D and E of Fig. 5 which were obtained under identical conditions except that the potential was changed.

If the limiting current is relatively small in comparison with the diffusion current which would be observed in the absence of adsorbed substance, "blocking" by the film primarily controls the current. There is little concentration polarization for the reducible substance, and the limiting current is essentially proportional to the electrode area. The limiting current then is practically independent of the head of mercury.[38] Conversely, when the limiting current is almost equal to the diffusion current, mass transfer is rate determining, and the limiting current virtually obeys the Ilkovic equation. Under these conditions, the limiting current is essentially proportional to the square root of the head of mercury. The intermediate behavior is more complex and corresponds to current–time curves with a minimum.

The foregoing conclusions are borne out experimentally, and it is observed that the relationship between maximum current during drop life and the head of mercury depends on the concentration of adsorbable substance (Fig. 6). Limiting currents of Fig. 6 were measured at the minimum of current–potential curves (see Fig. 4).

Experimental

Cell, Solutions and Procedure for Differential Capacity Measurements.—A hanging mercury drop similar to that developed by Gerischer was utilized.[39,40] Mercury drops were collected in a glass spoon and then, by rotation of the spoon, hung on a fine gold-plated platinum wire[41] sealed in a

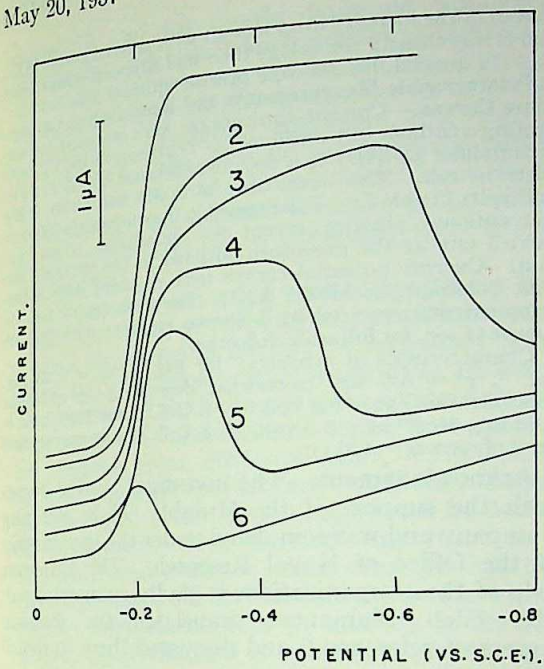

Fig. 4.—Polarograms of 1 millimolar Cu(II) in 0.5 *M* sodium citrate with varying amounts of quinoline. Millimolar concentrations of quinoline are: (1) 0; (2) 0.1; (3) 0.5; (4) 1; (5) 2.5; (6) 5; temperature, 25°.

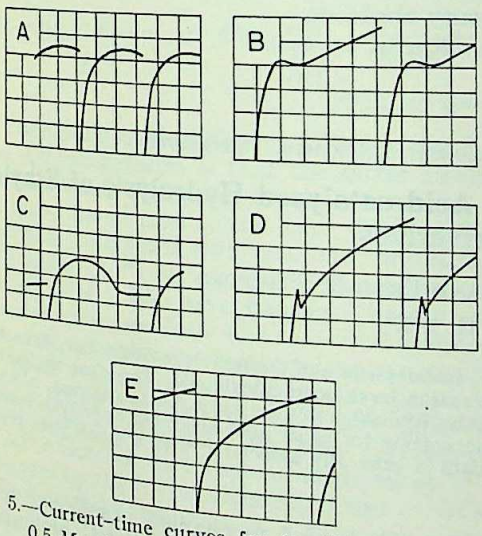

Fig. 5.—Current-time curves for 1 millimolar Cu(II) in 0.5 *M* sodium citrate. See data in Table I.

drawn-out glass tube. This method proved more practical than the one used by Gerischer. The tip of the glass tube was drawn out to avoid shielding of the mercury drop and the resulting dispersion of differential capacity with frequency. The cell was quite similar to that devised by Grahame.[42] The mercury drop was surrounded by a cylinder of platinum foil (diameter, 1 cm.; length 1.5 cm.) which was connected to the a.c. bridge. The potential of the mercury drop was adjusted against a saturated calomel electrode. Solutions were freed of oxygen by nitrogen. To avoid evaporation of the substance being adsorbed on the electrode (*n*-hexyl alcohol), the pure electrolyte was first freed of oxygen, and a small volume (1 ml. in general) of an aqueous solution of *n*-hexyl alcohol was added afterwards. No nitrogen was passed through the solution after the addition of *n*-hexyl alcohol. Solutions were prepared with bidistilled water because traces of organic impurities interfered, especially at low concentrations (10^{-5} *M*) of *n*-hexyl alcohol.

(42) D. C. Grahame, THIS JOURNAL, **71**, 2975 (1949).

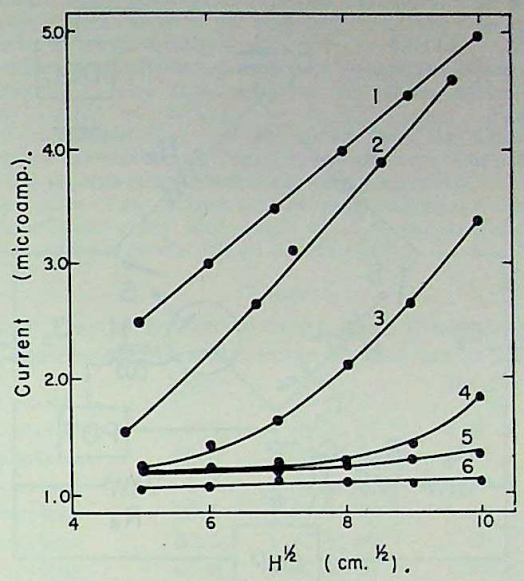

Fig. 6.—Limiting current at 25° against head of mercury for the reduction of 1 millimolar Cu(II) in 0.5 *M* sodium citrate in presence of quinoline. Millimolar concentrations of quinoline are: curve (1), 0; (2) 0.3; (3) 0.4; (4) 0.6; (5) 1; (6) 3.

The procedure was as follows. After preparation of the solution in the cell and proper setting of the potential of the mercury drop electrode (see bridge below), a mercury drop was rapidly hung and the differential capacity was measured within 20–30 sec. The bridge was set approximately at the correct resistance and capacity in advance to speed up measurements. The differential capacity was followed until a steady reading was obtained. This required at least 30 min. with the more dilute solution of hexyl alcohol.

Bridge.—The bridge of Fig. 7 was utilized.[43-45] It is described here because it is simpler than bridges with isolation transformers (in the input and detector circuits) often utilized in differential capacity measurements.[42]

Components were as follows: R_1 and R_2, matched 100 ohm resistances; R_3 and R_4, 1 megohm; R_5, 0–999.9 ohms decade box; R_6, 0–1 megohm variable resistance; C_1, 0.5 microfarad; C_2 and C_3, 0.05 microfarad; C_4, 0–11 microfarad decade box in 0.001 microfarad steps; C_5, 0–500 microfarads, adjustable; H, 32 henry inductance; POT, Leeds and Northrup student potentiometer; OSC, Hulett–Packard oscillator, Model 650A; AMP, Tektronix preamplifier, Model 122; CRO, Dumont oscilloscope, Model 304A; FIL, General Radio filter, Model 1231-P5.

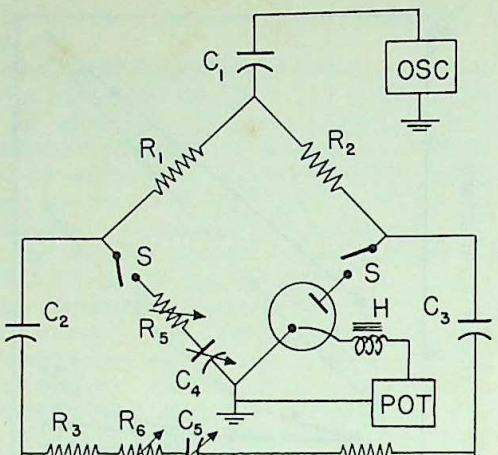

Fig. 7.—Bridge for differential capacity measurements.

The procedure was as follows: the voltage (peak voltage) applied to the bridge was set approximately at 5 mv. at 2000 c.p.s.; the earth compensation was first adjusted with R_6 and C_5 to achieve balance, switch S being open; the potential of the mercury drop was set with potentiometer POT, and S was closed; the bridge then was adjusted with R_5 and C_4. In general, results were precise within 0.1%.

Polarographic Measurements and Recording of Current-Time Curves.—Current–time curves were recorded by connecting a cathode-ray oscilloscope (Tektronix model 531 with preamplifier 53-54D) to a decade resistance box R in series with the cell. The ohmic drop in R did not exceed a few millivolts (Table I). Polarographic measurements followed conventional practice except for deaeration which was carried out by the procedure outlined in the previous section. Current–potential curves were recorded with a Sargent polarograph, Model XXI. The recorder of this instrument was replaced by a Brown recorder with fast response (1 sec. for full scale deflection).

Characteristics of capillary: for Fig. 4, m = 1.23 mg. sec.$^{-1}$, τ = 5.0 sec. (somewhat dependent on quinoline concentration) at −0.8 volt (*vs.* S.C.E.); for Fig. 6, m = 2.23 mg. sec.$^{-1}$ at −0.8 volt (*vs.* S.C.E.) for an uncorrected head of mercury of 81 cm.

Acknowledgment.—The investigation was begun with the support of the Humble Oil & Refining Company and was completed under the sponsorship of the Office of Naval Research. The generous help of these organizations is gladly acknowledged. Mr. Gleb Mamantov translated the Russian papers of reference 9 and discussed them in detail with us.

ADDED IN PROOF.—Arrangements have been made with the Oak Ridge Institute of Nuclear Studies to carry out computer calculations for the complete isotherm for the plane electrode and the dropping mercury electrode.

Entropies of Activation and Mechanism for the Acid-catalyzed Hydrolysis of Ethylene Oxide and its Derivatives[1]

BY F. A. LONG, J. G. PRITCHARD AND FRED E. STAFFORD

RECEIVED JANUARY 17, 1957

The rates of the acid-catalyzed hydrolysis of ethylene, propylene, isobutylene and trimethylene oxides have been measured at several temperatures and the energies and entropies of activation have been calculated. The close similarity in the entropy of activation values strongly suggests that all of the oxides hydrolyze by the same A-1 mechanism, which has been proposed previously for epoxides. A survey of entropies of activation for other acid-catalyzed hydrolysis reactions indicates that within similar classes of compounds the A-1 mechanism is generally associated with a much more positive entropy of activation than the A-2 mechanism.

Recent studies on the acid-catalyzed hydrolysis of epoxides have led to the conclusion that this reaction follows an A-1 mechanism in which the rate-determining step is the formation of a carbonium ion.[2–4] In the case of 1,1-disubstituted oxides, the evidence for the A-1 mechanism is sufficient to exclude all others. Thus: (a) the preliminary equilibrium step (1) is established[4] from rate studies in deuterium oxide; (b) the rate-determining spontaneous opening of the epoxide ring in step (2) is shown by the fact that the rates of reaction of several epoxides in strong aqueous solutions of perchloric acid show a good correlation[3] with the Hammett acidity function, h_0; (c) H_2O^{18} has been shown to enter the isobutylene oxide molecule in the tertiary position in accord with step (2)[2]; and (d) the reaction rate is significantly faster for epoxides having electron releasing substituent groups R_1 and R_2, and slower for those with electron withdrawing groups. The same points of evidence have also been established for monosubstituted oxides (R_2 = H). However, for the symmetrical parent compound, ethylene oxide (R_1 = R_2 = H), only items (a) and (b) have been established since

items (c) and (d) clearly have no application. Hence, the only significant evidence in favor of the formation of a primary carbonium ion during the acid-catalysed hydrolysis of ethylene oxide is the h_0 correlation.[3] (Actually, regarding (d), the rate for ethylene oxide does lie intermediate between the rates for monosubstituted oxides have electron withdrawing and electron releasing group substituents, respectively, as is *consistent* with a single mechanism.)

It is generally accepted that (other things being equal) the order of stability of carbonium ions of various structures is tertiary > secondary > primary, and very few examples of the latter are known. The presence of the hydroxyl group at the β-position with respect to the carbonium center in the primary ion derived from ethylene oxide, $CH_2OHCH_2^+$, should render it particularly unstable. Indeed, the existence of such an ion might well be doubted on this ground. It is therefore important to obtain additional evidence concerning the acid catalyzed hydrolysis of ethylene oxide to decide whether the A-1 mechanism, steps (1) and (2), or the alternative A-2 mechanism is operative. In the latter mechanisms, steps (1) and (3), no carbonium ion would be involved since the rate-determining step would be a simple nucleophilic attack of the solvent molecules on the conjugate acid of the oxide.

$$CH_2(OH^+)-CH_2 + H_2O \xrightarrow{\text{slow}} CH_2(OH)-CH(OH_2^+) \xrightarrow{\text{fast}} \xrightarrow[via\ H_2O]{} \text{Glycol} + H^+ \quad (3)$$

The characteristic difference between the A-1 and the A-2 mechanisms is that the latter involves a specific water molecule in the transition state whereas the former does not. This difference should be reflected in a difference in the entropies of activation (ΔS^*) for the two mechanisms as discussed later. We have therefore measured ΔS^* values for the perchloric acid catalyzed hydrolysis of ethylene, propylene and isobutylene oxides in order to make a comparison for a primary, a secondary and a tertiary epoxide to see if any difference in mechanism is indicated. We have also determined a ΔS^* value for trimethylene oxide since, if it hydrolyzes by the A-1 mechanism,[5,6] this oxide should afford another example of a primary carbonium ion, $CH_2OH{\cdot}CH_2{\cdot}CH_2^+$, and should be of interest for comparison with the results for the epoxides.

Experimental

Rates were measured dilatometrically using the procedures previously described.[3] Chemicals were of reagent grade and all experiments were carried out in water-baths whose temperatures were controlled to $\pm 0.01°$. In the experiments with the very reactive isobutylene oxide, rate measurements were made at 0 and 25° using concentrations of perchloric acid varying between 10^{-2} and 10^{-5} molar, as determined with a standardized Beckman pH meter at the end of each dilatometric run. A value of k_{H+} for $C_{H+} = 10^{-3}$ molar at each temperature was then obtained by graphical interpolation. For each of the other three oxides, a single stock solution of aqueous perchloric acid was prepared, standardized at 25° and used for all the rate measurements, at temperatures ranging from *ca.* 0 to 40°. (Changes in acid concentrations caused by temperature changes were neglected.) The rate equation for these hydrolyses is $-dC_{oxide}/dt = k_1 C_{oxide} = k_{H^+} C_{H^+} C_{oxide}$. First-order rate-coefficients (k_1) were calculated from the dilatometric data by the method of Guggenheim and were then converted to the second-order coefficients (k_{H+}) recorded in Table I. The values of k_{H+} shown are the mean values of at least four determinations for each oxide at each temperature. The results were reproducible to within ±2%.

(5) L. Smith, G. Wode and T. Widhe, *Z. physik. Chem.*, **130**, 154 (1927).

(6) J. G. Pritchard and F. A. Long, to be published. An excellent correlation between the first-order reaction rate and h_0 has been found for the acid-catalyzed hydrolysis of trimethylene oxide in 1 to 4 molar aqueous perchloric acid.

TABLE I

MEAN VALUES OF SECOND-ORDER RATE COEFFICIENTS FOR PERCHLORIC ACID-CATALYZED HYDROLYSIS OF OXIDES

Oxide	Temp. (°C.)	C_{H+} (M)	k_{H+} (l. mole^{-1} sec.$^{-1}$)
Isobutylene	0.0	1.00×10^{-3}	3.80×10^{-1}
Isobutylene	25.0	1.00×10^{-3}	4.60
Propylene	1.0	1.97×10^{-2}	2.79×10^{-2}
Propylene	10.1	1.97×10^{-2}	8.46×10^{-3}
Propylene	30.0	1.97×10^{-2}	7.45×10^{-2}
Propylene	40.0	1.97×10^{-2}	1.99×10^{-1}
Ethylene	1.0	9.45×10^{-2}	5.79×10^{-4}
Ethylene	10.1	9.45×10^{-2}	1.84×10^{-3}
Ethylene	30.0	9.45×10^{-2}	1.69×10^{-2}
Ethylene	40.1	9.45×10^{-2}	4.36×10^{-2}
Trimethylene	1.0	7.02×10^{-1}	7.20×10^{-5}
Trimethylene	10.1	7.02×10^{-1}	2.42×10^{-4}
Trimethylene	30.0	7.02×10^{-1}	1.93×10^{-3}
Trimethylene	35.1	7.02×10^{-1}	4.72×10^{-3}
Trimethylene	40.1	7.02×10^{-1}	7.71×10^{-3}

Values of the Arrhenius energy of activation (E) were obtained in the usual fashion from the gradients of plots of log k_{H^+} *vs.* the reciprocal of the absolute temperature. In all cases, the data were well fitted by straight lines. Values of ΔS^* were calculated from the Eyring equation 4 where the logarithms are to the natural base "e" and the other symbols have their usual significance.

$$\ln k_{H^+} = \ln (ekT/h) + \Delta S^*/R - E/RT \quad (4)$$

Our estimate is that the ΔS^* values are accurate to within ±1 e.u. except for isobutylene oxide where the accuracy may be two- or threefold less, since for this oxide rate measurements were recorded at only two temperatures. The values of ΔS^* recorded in both Tables II and III are for liter mole^{-1} sec.$^{-1}$ rate units.

Results and Discussion

In a discussion of the acid-catalyzed hydration of olefins Taft and co-workers[7,8] suggested that reaction by the A-1 mechanism should be characterized by a relatively more positive entropy of activation than reaction by the A-2 mechanism since the latter involves a relative increase of constraint on the reaction system in the transition state due to the orientation and reaction of a specific water molecule from the solvent. The work of Stimson[9] on the rates of acid-catalyzed hydrolysis of *t*-butyl esters is a good example of the application of this entropy criterion. Thus, the hydrolyses of *t*-butyl benzoate and *t*-butyl formate in acidified 60% acetone–water give ΔS^* values of +9.5 and −23.7 e.u., respectively, suggesting that the former hydrolysis proceeds by an A-1 mechanism and the latter by an A-2.

TABLE III

VALUES OF E AND ΔS^* AT 25° FOR ACID-CATALYZED HYDROLYSIS OF OXIDES

Oxide	$10^3 k_H{}^+$ at 25° (l. mole^{-1} sec.$^{-1}$)	E (kcal./mole)	ΔS^* (cal. mole^{-1} °C.$^{-1}$)
Isobutylene	4600	16.1	−4
Propylene	44.7	18.62	−4.3
Ethylene	9.86	18.99	−6.1
Trimethylene	1.57	20.73	−3.9

To find further examples of this ΔS^*-mechanism relationship, we have calculated ΔS^* values from available data for several acid-catalyzed reactions for which the mechanisms are quite well known. Table II shows that these ΔS^* values fall into two distinct groups separated by some 25 to 30 entropy units, corresponding to the two types of mechanism. The criterion that A-1 and A-2 reactions within the same class of compounds should be characterized by a difference in ΔS^* amounting to from 20 to 30 entropy units therefore appears to be quite general.

The results of the ΔS^* measurements for oxides are given in Table III which includes the appropriate rate and Arrhenius energy of activation data. It is evident that the large variations in hydrolysis rates for these oxides are almost entirely due to changes in the energy of activation and that the values of ΔS^* are almost constant. The observed values of E for the epoxides are in the order expected from a consideration of the stability of both the conjugate acids and the carbonium ions derived from the epoxides. Also, the less strained ring of trimethylene oxide would be expected to require a larger activation energy for opening than the epoxides.

The observed close similarity of the ΔS^* values in Table III provides strong evidence that the mechanism of reaction for all of the oxides is the same. By the argument of the previous paragraphs, the ΔS^* values for the primary oxides would be at least 20 entropy units lower than those for the substituted oxides if there were a change of mechanism from A-1 to A-2. This is clearly not the case. Therefore, since the A-1 mechanism is quite well established for the substituted oxides, we conclude that this same mechanism almost certainly holds for ethylene oxide and for trimethylene oxide.

While the ΔS^* values for the epoxides are closer to the absolute values for the A-1 rather than for the A-2 reactions of Table II, the fact that the values for epoxides are intermediate requires some comment. This may be due to a uniquely higher degree of solvation of the conjugate acids or the transition states in the case of the epoxides, or it may be that in A-1 hydrolyses the restriction of rotation about the breaking bond in the transition state for a cyclic structure leads to a more negative entropy change compared to linear structures. However, further study on this is required.

In view of the great instability of the carbonium ion derived from ethylene oxide, it is probable that the union of a water molecule from the solvation shell with a carbon atom of the epoxide ring, forming a covalent bond, occurs almost immediately after the conjugate acid has reached its free energy maximum in the breaking of one of the carbon–oxygen bonds in the ethylene oxide ring. Some realization of the relative stability of carbonium ions derived from the substituted epoxides of Table III may be obtained from the results of previous hydrolysis studies.[2] Thus, the glycol isolated from the A-1 hydrolysis of propylene oxide in water labeled with H_2O^{18} contained $CH_3{\cdot}CHO^{18}H{\cdot}CH_2OH$ and $CH_3{\cdot}CHOH{\cdot}CH_2O^{18}H$ molecules in a ratio close to 2:1. This result strongly suggests that the conjugate acid of propylene oxide yields the unstable ions $CH_3{\cdot}C^+H{\cdot}CH_2OH$ and $CH_3{\cdot}CHOH{\cdot}CH_2^+$ in this same ratio. Also, the A-1 hydrolysis of isobutylene oxide under similar conditions yielded a product labeled only in the tertiary position, $(CH_3)_2{=}CO^{18}H{\cdot}CH_2OH$, showing that the tertiary ion is preferred in this structure to an extent excluding the primary.

Some Buffer Solutions with Low Nucleophilic Activity[1]

BY J. G. PRITCHARD AND F. A. LONG

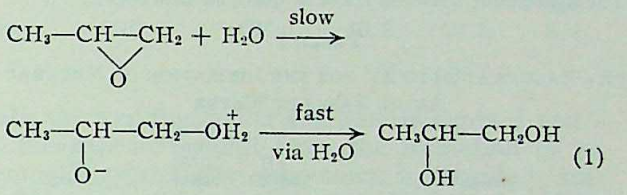
RECEIVED JANUARY 17, 1957

2,6-Dimethylpyridine, 2,4,6-trimethylpyridine, 2-methylquinoline and N-(2-hydroxy-2-methylpropyl)-*cis*-2,6-dimethylpiperidine are shown by kinetic measurements to be unreactive toward propylene oxide in dilute aqueous solution at 50°. These amines may therefore be used, in conjunction with perchloric acid, to form buffer solutions of very low nucleophilic activity for use in the study of reactions sensitive to nucleophilic reagents. In contrast, *cis*-2,6-dimethylpiperidine is found to react readily with propylene oxide and isobutylene oxide. The structure and nucleophilicity of these amines are discussed and details of the preparation and properties of the amine perchlorates are recorded.

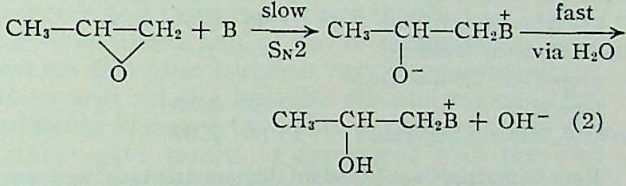
Introduction

In the course of recent investigations on the path of the uncatalyzed hydrolysis of epoxides,[2,3] it was found desirable to control the hydrogen ion concentration of the reaction solutions at values in the range of *p*H 6 to 12. However, for many epoxides, hydrolysis in distilled water is accompanied by a fast drift of the *p*H toward the acid region. Since the reactive epoxides combine readily with nucleophilic reagents of all types[4-8] including the anions of common buffer solution components,[9] the introduction of these into the reaction solution gives rise to both rate and product complications. It was found necessary, therefore, to design buffer solutions which would have a negligible nucleophilic activity. We have examined qualitatively, by a simple dilatometric method, the nucleophilic activity of various hindered amines[10] toward propylene oxide in buffered aqueous solutions, in a manner similar to that used by Eastham and co-workers[5] in their studies with ethylene oxide and various nucleophilic amines. Perchloric acid was used in conjunction with the amines to form the buffer solutions since the low nucleophilic activity of the perchlorate ion is well established.[11]

The hydrolysis of propylene oxide in pure water is known to proceed at a constant rate over the *p*H range 6 to 12, most probably by a scheme similar to that shown in equation 1.[3]



As expected from consideration of the higher densities of glycols compared to the corresponding epoxides, reaction 1 is accompanied by a marked diminution in the volume of the reaction mixture which is proportional to the percentage reaction for dilute solutions of reactants. Tertiary amines such as pyridine should also add to epoxides, to form quaternary ammonium hydroxides as in equation 2.



This reaction should also be accompanied by a diminution in the total volume of the reacting solution. Hence, in our experiments, nucleophilic character in the tertiary amine B should be shown by two criteria. Firstly, if the neutral amine is consumed in reaction with excess of propylene oxide, so producing hydroxide ions, the *p*H of the reaction solution should increase throughout the reaction. Secondly, the apparent dilatometric rate of neutral hydrolysis of the propylene oxide should increase with increasing concentration of the free amine in the buffer solution. In contrast, the hydrolysis of propylene oxide in a solution buffered by a truly anucleophilic amine should show ideally a constant rate for all concentrations of buffer and a constant *p*H throughout the reaction.

In this paper, we report the results of these rate studies together with details of the preparation and properties of the perchlorates of some amines of low nucleophilic activity toward propylene oxide. It is suggested that these and similar compounds may find application as buffer solution components in other fields of research.

Experimental

The Buffer Solutions.—Recrystallization of their salts offered the best means of purifying pyridine and its derivatives. Therefore, it was convenient to make up the buffer solutions from weighed samples of the pure amine perchlorates. These were dissolved, partially neutralized with potassium hydroxide solution and made up to a known volume. The *p*H values of these buffer solutions were recorded, using a standardized Beckman *p*H meter with a glass electrode, at the time of preparation and again at room temperature at the conclusion of the kinetic run with propylene oxide (after *ca.* 36 hours).

Values for the basic ionization constants (K_B) for the amines under study were calculated from the observed *p*H

values of aqueous solutions containing the amine perchlorates (0.0050 *M*) and exactly one-half of an equivalent of potassium hydroxide (0.0025 *M*) in each case. The definitions of K_B and pK_B are shown from the equations

$$B + H_2O \rightleftharpoons BH^+ + OH^- \quad (3)$$

$$K_B = C_{BH^+}C_{OH^-}/C_B, \qquad pK_B = -\log_{10} K_B \quad (4)$$

$$pK_B = 14.0 - pH + \log_{10} C_B/C_{BH^+} \quad (5)$$

For the first four bases in Table I, the equilibrium concentration of OH^- is so small compared to C_B and C_{BH^+} that C_B remains essentially equal to C_{BH^+} and the last term on the right-hand side of equation 5 is zero. For the derivatives of piperidine, which buffer in the *p*H range 10.5–11.0, the value of C_B/C_{BH^+} was calculated from equation 3 and included in the calculation of pK_B by equation 5. Table I records the results of our measurements (at 22 ± 2°) together with some literature values of pK_B where available. The agreement between these is quite satisfactory.

TABLE I

pK_B VALUES AT 20 TO 25° FOR THE IONIZATION OF NEUTRAL AMINE BASES IN WATER

Amine	*p*H 50/50	pK_B from 50/50 buffer	pK_B Lit. values
Pyridine	5.20	8.80	8.85[12]; 8.77[13]
2-Methylquinoline	5.74	8.26	8.6[14]; 8.2[15]
2,6-Dimethylpyridine	6.72	7.28	7.41[12]; 7.38[13]
2,4,6-Trimethylpyridine	7.46	6.54	6.55[13]
N-(2-Hydroxy-2-methylpropyl)-*cis*-2,6-dimethylpiperidine	10.53	3.35	.....
cis-2,6-Dimethylpiperidine	10.86	2.69	.....

Rate Comparisons.—Standard dilatometric technique was used[2,16] with dilatometers of *ca.* 8-ml. capacity. All buffer solutions were thoroughly degassed before addition of propylene oxide The complete hydrolysis of 8 ml. of 0.3 molar propylene oxide gave a meniscus displacement of *ca.* 15 cm. in capillaries of 0.05 cm. internal diameter. The rate equation for the hydrolysis reaction of equation 1 is $-dC_{oxide}/dt = k_1 C_{oxide}$. First-order rate coefficients in sec.$^{-1}$ units were calculated by the Guggenheim method. For those runs with pyridine and 2,6-dimethylpiperidine which involved an abnormally large volume change in the dilatometer due to the nucleophilic activity of these compounds, relative initial rates were calculated by extrapolating the volume diminution data back to the time of mixing the reactants at 50°. Except for these abnormal runs, all rate data gave good straight-line Guggenheim plots. The temperature of the water-bath was controlled at 50 ± 0.01°.

Materials.—Reagent grade inorganic chemicals were used throughout. Reagent grade propylene oxide was distilled before use: b.p. 35°, $n^{25}D$ 1.3638. The perchlorates of the amine bases were prepared and purified as described below, giving good yields except where stated.

Pyridine perchlorate was purified by crystallization from ethyl alcohol giving white crystals of m.p. 289–290°.[17] A solution of 10.5 ml. of 60% perchloric acid and 12 ml. of technical (90%) 2,6-lutidine in 100 ml. of ethyl alcohol was evaporated at 100° and allowed to crystallize. Recrystallization of the product from acetone gave white, crystalline **2,6-dimethylpyridinium perchlorate**, m.p. 110–111°; found C = 40.4%, H = 4.8%, N = 6.7%, as required by $C_7H_{10}O_4NCl$. 11.5 ml. of reagent grade 2,4,6-trimethylpyridine treated as above gave white, crystalline **2,4,6-trimethylpyridinium perchlorate**, m.p. 239–240°; found C = 43.5%, H = 5.4%, N = 6.2%, as required for $C_8H_{12}O_4NCl$ (N = 6.3%). (This substance assumed a faint orange color on exposure to light.) Evaporation of a solution containing 11 ml. of reagent grade quinaldine and 10.5 ml. of 60% perchloric acid in 50 ml. of ethyl alcohol gave a red wine-colored crystalline mass. Repeated recrystallization from alcohol gave straw-colored crystals of **2-methylquinolinium perchlorate**, m.p. 129–130°; found C = 49.1%, H = 4.1%, N = 5.5% ($C_{10}H_{10}O_4NCl$ requires C = 49.2%, H = 4.3%, N = 5.7%).

A solution containing 10 ml. of (*cis*)-2,6-dimethylpiperidine[18] and 9.5 ml. of 60% perchloric acid in 25 ml. of ethyl alcohol was evaporated at 100° and allowed to crystallize. The product was recrystallized from 1,4-dioxane giving fine, white needles of ***cis*-2,6-dimethylpiperidinium perchlorate**, m.p. 186–187°; found C = 39.5%, H = 7.7%, N = 6.4% ($C_7H_{16}O_4NCl$ requires C = 39.4%, H = 7.5%, N = 6.5%).

A solution containing 15 ml. of *cis*-2,6-dimethylpiperidine and 11 ml. of isobutylene oxide in 200 ml. of water was allowed to stand overnight at room temperature. The oily layer which had formed above the aqueous phase was separated and neutralized with alcoholic 20% perchloric acid solution. Evaporation of the alcohol and water present gave a crystalline mass of which only a small part was soluble in ethyl acetate. After washing with boiling ethyl acetate, to remove unreacted 2,6-dimethylpiperidine, the product was recrystallized from a solvent containing equal volumes of ethyl alcohol and ethyl acetate, and gave 2 g. of **N-(2-hydroxy-2-methylpropyl)-*cis*-2,6-dimethylpiperidinium perchlorate**, m.p. 200°; found C = 46.4%, H = 8.4%, N = 4.85%. ($C_{11}H_{24}O_5NCl$ requires C = 46.2%, H = 8.4%, N = 4.9%.)[19] It should be noted that the formation of N-(1,1-dimethyl-2-hydroxyethyl)-*cis*-2,6-dimethylpiperidine in this last reaction may be excluded immediately on steric grounds since the nucleophilic reaction of even the small hydroxide ion with isobutylene oxide occurs almost exclusively at the primary carbon atom of the epoxide ring.[3]

Results

Table II gives the observed first-order rate coefficients for reaction of 0.3 molar propylene oxide at 50° in a series of buffer solutions having two general ranges of concentration. The initial concentrations of free amine in the solutions were calculated using the pK_B values of Table I and the observed initial *p*H values of the reaction solutions.

Since pyridine is known to react readily with propylene oxide[20,21] the results of expts. 1 and 7 exemplify the behavior of a typical nucleophile. In both experiments there is observed a large drift of the *p*H during the reaction, and the rate of volume diminution in the dilatometer is increased about sevenfold on increasing the initial free pyridine concentration from 0.002 to 0.08 molar. A similar behavior is shown by *cis*-2,6-dimethylpiperidine in expts. 2 and 8, and we therefore conclude that this compound exerts a nucleophilic activity similar to that of pyridine.

Completely contrasting behavior is observed for the hindered amines of expts. 4, 5 and 6. For these cases, the *p*H is constant throughout each reaction and the three values of k_1 are identical and somewhat lower than those obtained in expts. 1 and 2. The results of expts. 10, 11 and 12 show that for in-

[a] Initially. [b] Comparative initial rates.

creased concentrations of the same hindered amines, the pH values of the reaction solutions still remain constant and the k_1 values are essentially the same as those obtained in expts. 4, 5 and 6. The small variations in k_1 for these last three expts. of Table II were not outside the *possible* experimental error (± *ca.* 10%) but may actually have been due to small kinetic salt effects. In expts. 9 and 12, the maximum buffer concentrations were limited for solubility reasons. Nevertheless, the free amine concentration of about 0.02 molar was considered adequate to detect dilatometrically any nucleophilic activity. (A comparison of the expts. 1 and 2 with expts. 4, 5 and 6 shows that a concentration of as little as 0.002 molar of a strongly nucleophilic amine gives rise to a detectable increase in the observed value of k_1.) We conclude that the true rate of the uncatalyzed hydrolysis of propylene oxide at 50° is 8.6×10^{-6} sec.$^{-1}$. The good reproducibility of the dilatometric rates leads us to believe that this figure is correct to within ±3%. We conclude also that the hindered amines 2,6-dimethyl- and 2,4,6-trimethylpyridine and N-(2-hydroxy-2-methylpropyl)-*cis*-2,6-dimethylpiperidine have a low nucleophilic activity with respect to propylene oxide.

The case of 2-methylquinoline might appear to be anomalous since it gives k_1 values which are consistently high while the pH during the reaction remains constant at a value of 5.7. The high k_1 values are almost certainly due to the incursion of a small contribution from the acid-catalyzed mode of hydrolysis which would be expected to enter with propylene oxide at pH values below *ca.* 6.0.[3,4] However, the constancy of the pH in both expts. 3 and 9 gives very strong evidence for the very low nucleophilic activity of 2-methylquinoline. In expt. 1 with pyridine, a larger k_1 value might possibly have been expected for the same reason since the reaction was started at pH 5, in the acid-catalyzed region. However, it is highly probable that the pH of the solution drifted into the "neutral" region (pH 6 to 12) during the first few minutes of the reaction, before the first reading of the dilatometer.

Reaction of the Nucleophilic Amines.—The increase of pH for the reaction of propylene oxide with the pyridine buffer solutions in expts. 1 and 7 is the expected result from the formation of an aromatic quaternary ammonium hydroxide.[5] Initially, for such a reaction, the pH drift should be small since the hydroxide ion produced would be almost wholly neutralized by the pyridinium ion. However, this process increases the C_B/C_{BH^+} ratio, and when about half of the total amine has been used up this ratio becomes very large, causing the pH to drift rapidly into the alkaline region. Experiments designed to isolate a product from this reaction gave results in agreement with previous work on similar systems. Namely, the N-(2-hydroxypropyl)-pyridinium hydroxide cannot be isolated as it polymerizes, especially in contact with air, to a dark bro n viscous substance[22]; and whereas the N-(2-hydroxypropyl)-pyridinium halides are reported to be crystallizable,[23,24] the perchlorate salt was found to remain as a viscous oil.[25] The matter was not pursued beyond these qualitative observations.

The pH drift accompanying the nucleophilic reaction of *cis*-2,6-dimethylpiperidine with propylene oxide is directed toward the acid region. Since 2,6-dimethylpiperidine is a secondary amine the product of this reaction by equation 2 should be a tertiary amine and there should be no production of hydroxide ion. Hence, the observed direction of the pH drift in expts. 2 and 8 is consistent with the fact that tertiary amines are generally less basic than the secondary amines from which they are derived. A pertinent example of this is shown by a comparison of the pK_B values in Table I for *cis*-2,6-dimethylpiperidine and its tertiary N-(2-hydroxy-2-methylpropyl) derivative, which was obtained by reaction of isobutylene oxide with the *cis*-2,6-dimethylpiperidine. In this one case, the tertiary amine was prepared in quantity and isolated as its perchlorate since it promised and proved to be a good anucleophilic buffer component for pH *ca.* 10. Experiments are in progress to investigate other members of this class of compounds.

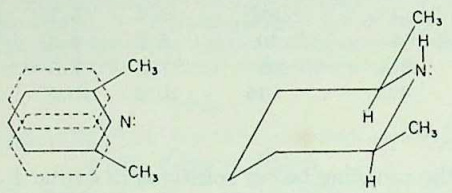
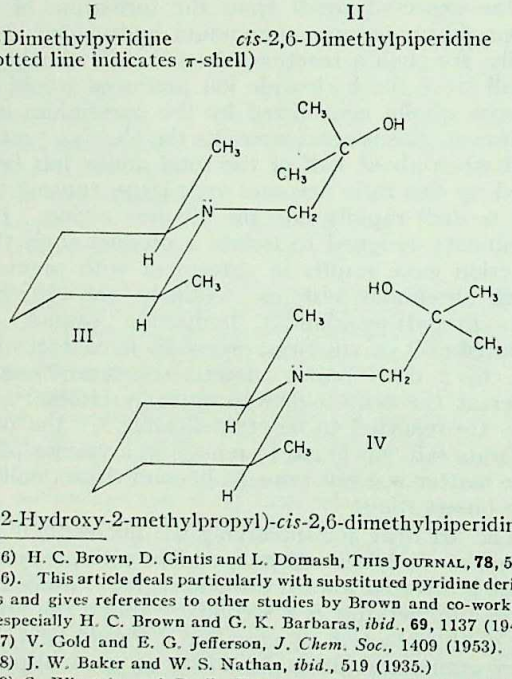
Structural Considerations.—The observed sharp drop in reactivity with propylene oxide on going from pyridine to 2,6-dimethylpyridine (I) is entirely consistent with many other studies of steric effects[26–28] and suggests that the steric requirements for reaction of I with epoxides are quite specific. In an S_N2 reaction involving opening of the epoxide ring in the *trans* sense,[29] the nitrogen atom in I is probably so well shielded by the methyl substituents and the two branches of the π-electron shell of the pyridine ring that this reaction is very slow. The same applies to 2,4,6-trimethylpyridine and to 2-methylquinoline.



I II

2,6-Dimethylpyridine *cis*-2,6-Dimethylpiperidine
(Dotted line indicates π-shell)



III IV

N-(2-Hydroxy-2-methylpropyl)-*cis*-2,6-dimethylpiperidine

The observed high reactivity of *cis*-2,6-dimethylpiperidine (represented by II for one of the four possible configurations) is interesting since from an examination of scale models there appears to be no obvious structural reason why the nucleophilic activities of I and II should be so different toward propylene oxide. However, in I the unshared electrons of the nitrogen atom lie in a plane trigonal sp^2 hybrid orbital directed along the axis of symmetry of I, but in II they lie in a tetrahedral sp^3 orbital which may be directed with respect to the piperidine ring either equatorially as shown in II or axially, depending on inversion of the configuration about the nitrogen atom. Also, owing to their greater "p" character, sp^3 orbitals extend out further from the atomic nucleus than do sp^2 orbitals. The nucleophilic electrons on II should thus be more available than those in I, leading to the much higher basicity and nucleophilic activity of II.[30] From a consideration of models, we consider that the S_N2 reaction of isobutylene oxide with *cis*-2,6-dimethylpiperidine would be most likely to occur through configuration II. Hence, the product from *trans* addition to the epoxide ring would at first be expected to have the structure III. However, the stable modification of this molecule may be the less congested and possibly weakly hydrogen bonded structure IV, since C–C bond rotations in both structures are restricted. The formation of a tertiary ammonium ion by reaction of III or IV with a molecule as large as propylene oxide appears almost impossible on steric grounds, so that the demonstration in this paper of the low or undetectably nucleophilic activity of N-(2-hydroxy-2-methylpropyl)-*cis*-2,6-dimethylpiperidine is easily understood.

As H. C. Brown and co-workers point out,[26] the actual magnitude of a steric effect is dependent on the particular steric requirements of the reaction considered. However, since the epoxide ring is generally considered to be very sensitive to nucleophiles, it is probable that the low nucleophilic activity of the hindered amines discussed in this paper is general toward most types of organic substrate containing two or more carbon atoms.

The Volumetric and Thermodynamic Properties of Fluids. III. Empirical Equation for the Second Virial Coefficient[1]

BY KENNETH S. PITZER AND R. F. CURL, JR.

RECEIVED DECEMBER 22, 1956

An equation has been developed to represent the second virial coefficient of a normal fluid: $BP_c/RT_c = (0.1445 + 0.073\omega) - (0.330 - 0.46\omega)T_r^{-1} - (0.1385 + 0.50\omega)T_r^{-2} - (0.0121 + 0.097\omega)T_r^{-3} - 0.0073\omega T_r^{-8}$ where ω is the acentric factor (defined by $\omega = -\log (P/P_c)_{sat} - 1.000$ at $T_r = 0.7$) which was discussed in an earlier paper. This equation not only fits the volumetric data with considerable accuracy but its second derivative also yields agreement with measured values of the pressure derivative of the gas heat capacity.

In 1907 Berthelot[2] proposed a simple reduced equation for the second virial coefficient which has been of great value in correcting the properties of real gases at low pressures to the ideal gas state. We know, however, that real gases do not follow accurately the principle of corresponding states, hence any such equation is of limited accuracy. In the earlier papers of this series[3] we have shown that the introduction of the acentric factor as an additional parameter increases the accuracy of possible correlation by about one order of magnitude.

In this paper we present an empirical equation for the second virial coefficient in reduced form which includes the acentric factor dependence.

Basic Data.—In addition to the second virial coefficient values based on volumetric measurements,[4] we calculated the volume of the saturated vapor from vapor pressure, heat of vaporization and liquid volume data in several cases.[5]

We also used the information on the change with pressure of the gas heat capacity.[6] If the second virial coefficient is B, thermodynamics yields the equation

$$\lim_{P \to 0} \left(\frac{\partial C_p}{\partial P}\right)_T = -T \frac{\partial^2 B}{\partial T^2} \qquad (1)$$

Consequently, the pressure dependence of the heat capacity offers a very sensitive test of any equation for B.

Selection of the Equation.—Our earlier studies[3] indicated that an equation linear in the acentric factor was usually adequate and we find this to be the case for the second virial coefficient. We have then, in reduced dimensionless form

$$\frac{BP_c}{RT_c} = \frac{B^{(0)}P_c}{RT_c} + \omega \frac{B^{(1)}P_c}{RT_c}$$

where $B^{(0)}$ and $B^{(1)}$ are functions of the reduced temperature, and ω is the acentric factor. Although ω was defined as

$$\omega = -\log P_r - 1.000 \qquad (2)$$

where P_r is the reduced vapor pressure (P/P_c) at $T_r = 0.7$, it may be evaluated readily from any vapor pressure value well removed from the critical point by the use of Table VI of Paper II of this series.[3]

The simple fluids of zero acentric factor are the heavier inert gases A, Kr, Xe. We know their properties are quite well represented by a Lennard-Jones intermolecular potential. Consequently, we took the equation of Stockmayer and Beattie[7] as a point of departure. This was converted from the molecular potential constants to the macroscopic critical constants and then modified slightly to improve the fit at the lowest temperatures by the addition of a small T^{-3} term and other small adjustments. The resulting equation is

$$\frac{B^{(0)}P_c}{RT_c} = 0.1445 - \frac{0.330}{T_r} - \frac{0.1385}{T_r^2} - \frac{0.0121}{T_r^3} \qquad (3)$$

Figure 1 shows the reduced virial coefficient data for a number of substances together with calculated curves. The agreement of the curve for $\omega = 0$ with the points for A, Kr and Xe demonstrates the adequacy of equation 3.

It is impractical to show all of the data considered in the development of the equation for $B^{(1)}$. The resulting fit with the data for benzene and for n-heptane is shown on Fig. 1 for B and on Fig. 2 for the pressure derivative of the heat capacity. Similar agreement is obtained for other substances. The resulting equations are

$$B = B^{(0)} + \omega B^{(1)} \qquad (4)$$

$$\frac{B^{(1)}P_c}{RT_c} = 0.073 + \frac{0.46}{T_r} - \frac{0.50}{T_r^2} - \frac{0.097}{T_r^3} - \frac{0.0073}{T_r^8} \qquad (5)$$

The selection of a term in T_r^{-8} is, of course, somewhat arbitrary, but a very high power is required to fit the data at low temperatures.

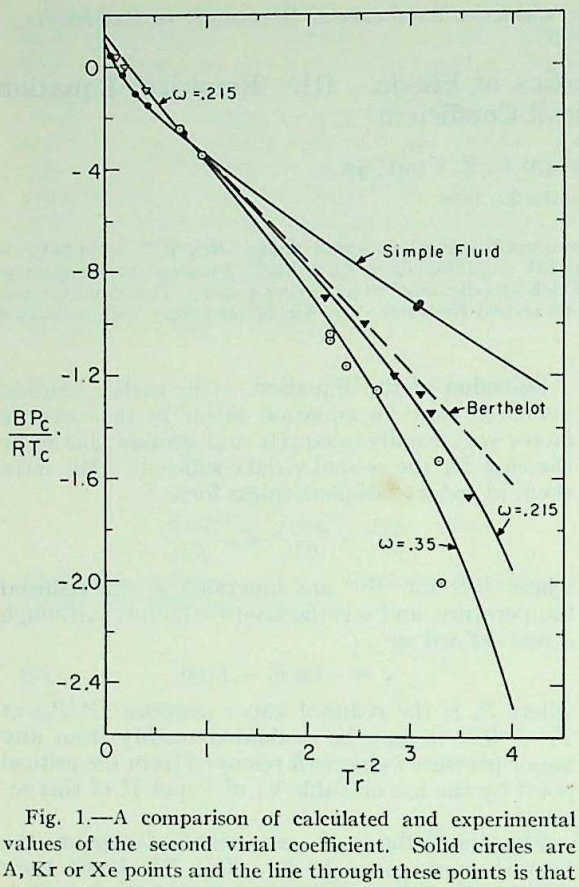

Fig. 1.—A comparison of calculated and experimental values of the second virial coefficient. Solid circles are A, Kr or Xe points and the line through these points is that of equation 3. The open triangles are CO_2 and solid triangles are benzene points. These are to be compared with the line for $\omega = 0.215$. The open circles are points for *n*-heptane ($\omega = 0.35$). It is to be noted that the Berthelot equation yields excellent agreement for ω in the range 0.15 to 0.20.

The work leading to the selection of equation 5 indicated certain small changes in the previously published values of $z^{(1)}$, the term in the compressibility factor expression which is multiplied by ω. The revised values are given in Table I (the upper right-hand portion of each section is unchanged but included for convenience).

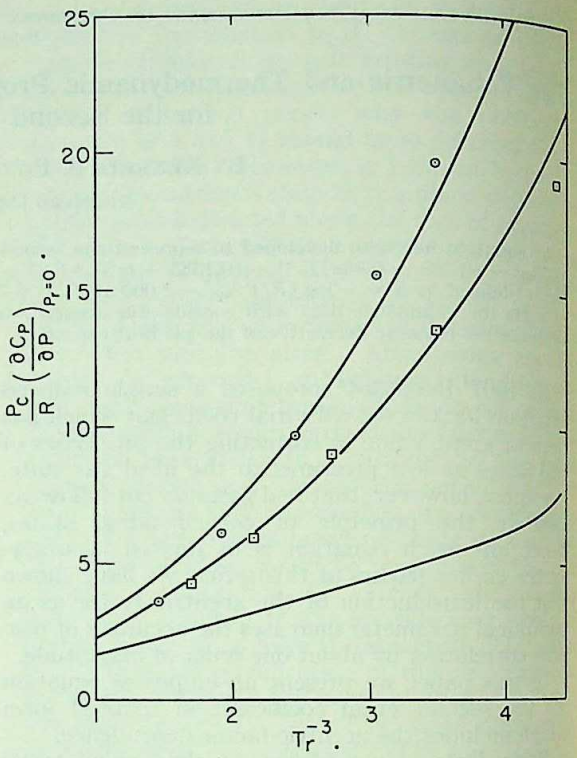

Fig. 2.—A comparison of calculated and experimental values of the pressure derivative of the heat capacity. The circles and upper curve are for *n*-heptane ($\omega = 0.35$); the squares and intermediate curve are for benzene ($\omega = 0.215$). The bottom curve is for $\omega = 0$, but no experimental data are available for comparison.

Discussion.—This equation should be valuable for the estimation of gas imperfection corrections to various data on gases at low pressures. The substances which can be expected to conform are those forming normal liquids. Metals and hydrogen bonding substances must be excluded. The limitations are discussed in greater detail in Papers I and II.[3] The final equations for various properties are readily derived from thermodynamics. In these equations H^*, S^*, C_p^* refer to the properties of the hypothetical ideal gas at the same pressure as the real gas; f is the fugacity.

$$\frac{BP_c}{RT_c} = (0.1445 + 0.073\omega) - (0.330 - 0.46\omega)T_r^{-1} - (0.1385 + 0.50\omega)T_r^{-2} - (0.0121 + 0.097\omega)T_r^{-3} - 0.0073\omega T_r^{-8} \quad (6)$$

$$\log\left(\frac{f}{P}\right) = \left(\frac{P_r}{2.303}\right)[(0.1445 + 0.073\omega)T_r^{-1} - (0.330 - 0.46\omega)T_r^{-2} - (0.1385 + 0.50\omega)T_r^{-3} - (0.0121 + 0.097\omega)T_r^{-4} - 0.0073\omega T_r^{-9}] \quad (7)$$

$$\frac{H - H^*}{RT} = P_r[(0.1445 + 0.073\omega)T_r^{-1} - (0.660 - 0.92\omega)T_r^{-2} - (0.4155 + 1.50\omega)T_r^{-3} - (0.0484 + 0.388\omega)T_r^{-4} - 0.0657\omega T_r^{-9}] \quad (8)$$

$$\frac{S - S^*}{R} = P_r[-(0.330 - 0.46\omega)T_r^{-2} - (0.2770 + 1.00\omega)T_r^{-3} - (0.0363 + 0.29\omega)T_r^{-4} - 0.0584\omega T_r^{-9}] \quad (9)$$

$$\frac{C_p - C_p^*}{R} = P_r[(0.660 - 0.92\omega)T_r^{-2} + (0.831 + 3.0\omega)T_r^{-3} + (0.145 + 1.16\omega)T_r^{-4} + 0.526\omega T_r^{-9}] \quad (10)$$

Application of the Glass Electrode to the Determination of the Thermodynamic Ionization Constants of *p*-Aminobenzoic Acid

BY MARVIN L. DEVINEY, JR.,[1] R. C. ANDERSON AND W. A. FELSING[2]

RECEIVED NOVEMBER 15, 1956

The thermodynamic ionization constants of *p*-aminobenzoic acid have been determined in water at 25° by use of cells without liquid junction using the commercial Beckman "General-Purpose" glass electrode. The values of pK_{A_1} and pK_{A_2} obtained were, respectively, 2.50_1 and 4.87_4.

In this investigation a method was developed for determining the first and second dissociation constants of *p*-aminobenzoic acid by the electromotive force method, using cells without liquid junction. The Beckman "General-Purpose" glass electrode was employed in measuring the hydrogen ion activity because the application of the hydrogen electrode or the quinhydrone electrode was found not to be practicable in this case. This is an extension of previous work in this Laboratory on the dissociation of weak electrolytes, which includes studies on propionic acid,[3,4] *n*-butyric acid[5] and β-alanine.[6]

Experimental

p-Aminobenzoic Acid Buffer Solutions.—The K_{A1} buffer solutions were prepared from *p*-aminobenzoic acid, repurified hydrochloric acid and conductivity water; the K_{A2} buffer solutions were prepared from potassium *p*-aminobenzoate, repurified hydrochloric acid and conductivity water. The *p*-aminobenzoic acid, twice recrystallized Eastman Kodak Company White Label grade, melted sharply at 187° in agreement with the best value from the literature[7]; it was not hygroscopic. The potassium *p*-aminobenzoate, prepared from *p*-aminobenzoic acid and potassium hydroxide, was carefully purified; it was found to be free of carbonate and non-hygroscopic.

A stock solution was prepared in the highest concentration possible (about 0.035 *M* in *p*-aminobenzoic acid); and the various solutions for measurement were prepared by weight dilution, with the same buffer ratio being maintained. All solutions were deaerated immediately after preparation with solvent-saturated, high-purity nitrogen. The repurified hydrochloric acid, 0.1 to 0.3 *N*, was standardized gravimetrically.

Glass Electrode Standardization Solutions.—Three different reference buffer solutions, prepared, respectively, from reagent grade glycine, potassium tetraborate and propionic acid, were used for the standardization of the glass electrodes against hydrogen electrodes. The solutions were deoxygenated and stored under repurified electrolytic hydrogen.

Electromotive Force Measurements.—The measuring circuit consisted of a Leeds and Northrup Type K2 potentiometer (recently calibrated by the manufacturer); a Leeds and Northrup thermionic amplifier, modified internally to make it sensitive to ±0.01 millivolt; and a Leeds and Northrup Type R moving-coil galvanometer. Three standard cells were used, all recently calibrated by the Bureau of Standards. Temperature control was maintained to ±0.01° in a kerosene thermostat.

The preparation of the hydrogen electrodes and the thermal decomposition type silver–silver chloride electrodes has been previously described.[8] Each "General-Purpose" glass electrode selected for use was tested for several days to ensure a minimum drift in asymmetry potential. All glass electrode measurements were made in triplicate.

The electromotive force cells were of special design and contained four side arms. Presaturators with sintered-glass cylinders were used whenever the hydrogen electrode was employed. The cells were filled with the appropriate solutions by employing an oxygen-excluding vacuum technique. A special sweep system (for hydrogen or nitrogen) built into the cell allowed removal of any air which entered during the insertion of the glass electrodes, after the vacuum loading procedure.

The actual procedure of measurement consisted of standardization by measuring the potential of the three glass electrodes against duplicate hydrogen electrodes for at least two hours, followed by transfer of the glass electrodes to the *p*-aminobenzoic acid–buffer cell and measurement of its potential until equilibrium was reached. The glass electrodes were then transferred back to the standardization cell for recheck of their calibration. Agreement was almost always obtained to ±0.10 millivolt for the six glass electrode calibration readings, and similar agreement was obtained between the three glass electrodes in *p*-aminobenzoic acid–buffer solutions.

Calculations

The first and second dissociation reactions of *p*-aminobenzoic acid may be written $HQH^+ \rightleftarrows H^+ + HQ$ and $HQ \rightleftarrows H^+ + Q^-$, where HQ represents the neutral-molecule structure of *p*-aminobenzoic acid. Although aliphatic amino acids are usually 99.99% or more in the zwitterion form, Klotz and Gruen[9] have shown that *p*-aminobenzoic acid exists in solution predominantly (91–97%) in the neutral molecule form. pK_{A1} as determined in this investigation really represents a mixture, in the structural sense, of the predominant neutral-molecule species with a small portion of the dipolar species; the same is true in the case of pK_{A2}. Although the simultaneous presence of both species affects the kinetics of the ionization of *p*-aminobenzoic acid by introducing a second dissociation mechanism, it does not affect the final equilibrium or thermodynamic properties of the solution.[10]

From cells of the type

Glass electrode	*p*-Aminobenzoic acid (m_1), Hydrochloride of *p*-aminobenzoic acid (m_2)	AgCl	Ag

the first thermodynamic ionization constant, K_{A1}, is given by

$$-\log K_{A1} = \frac{E + E^0_{Ag,Cl^-,AgCl} - E_g(1\text{ atm.})}{2.303(RT/F)} + \log \frac{m_{HQH} m_{Cl^-}}{m_{HQ}} + \log \frac{\gamma_{HQH}\gamma_{Cl^-}}{\gamma_{HQ}} \quad (1)$$

where E is the measured voltage of the cell, $E^0_{Ag,Cl^-,AgCl}$ is the molal potential of the silver–silver chloride electrode at 25°,[11] E_g(1 atm) is the glass electrode constant as measured directly against a platinum–black hydrogen electrode (corrected to 1 atmosphere hydrogen pressure) immediately before and after each measurement of E, m is the weight molality and γ is the activity coefficient. The physical constants used in this investigation were the latest and most accurate values available.

The treatment of data used in this Laboratory for the evaluation of the thermodynamic ionization constants of amino acids has been previously described in detail.[6] In the case of *p*-amino-benzoic acid, however, additional calculations were necessary in order to correct for slight concentration changes caused by the overlap of the K_{A1} and K_{A2} ionization reactions. This overlap phenomenon occurs for dibasic-type acids whenever the ratio $K_{A1}/K_{A2} < 10^3$ ($pK_{A2} - pK_{A1} < 3$).[12] Equations were derived to correct for this overlap effect following the principles used by Hamer, Pinching and Acree[13,14] for a dicarboxylic acid (*o*-phthalic acid) and by Smith and Smith[15] for a dicarboxylic amino acid (aspartic acid).

K_{A2} may be determined from cells of the type

Glass electrode	*p*-Aminobenzoic acid (m_3) Potassium *p*-aminobenzoate (m_4) Potassium chloride (m_5)	AgCl	Ag

and the pK_{A2} expression is

$$-\log K_{A2} = \frac{E + E^0_{Ag,Cl^-,AgCl} - E_g(1\text{ atm.})}{2.303(RT/F)} + \log \frac{m_{Cl}m_{HQ}}{m_Q} + \log \frac{\gamma_{Cl}\gamma_{HQ}}{\gamma_Q} \quad (2)$$

The evaluation of K_{A2} was made following the methods referred to in the preceding paragraph.

Results

The data from which the thermodynamic ionization constants of *p*-aminobenzoic acid were calculated were obtained using Beckman "General-Purpose" glass electrodes. It was found in preliminary tests that both the platinized platinum and palladiumized platinum (prepared as recommended by Hamer and Acree[16]) electrodes failed to reach equilibrium in buffer solutions of *p*-aminobenzoic acid and its hydrochloride and in buffer solutions of *p*-aminobenzoic acid and its potassium salt. It was not definitely established in this investigation whether catalytic hydrogenation of *p*-aminobenzoic acid or adsorption on the platinum black and palladium black electrodes was responsible for the instability of the hydrogen electrode. Yoshimura[17] has shown that it is not possible to make accurate electromotive force measurements with the quinhydrone electrode in amino acid solutions because of a condensation reaction between quinone and the amino acid. The mechanism of this reaction has been reported by Posner[18] and Fuson.[19] Although MacInnes and Dole[20] thin-membrane glass electrodes were successfully prepared and tested, it proved to be very difficult to use them because of the extreme fragility of the membrane (on the order of 0.001 mm. thick).

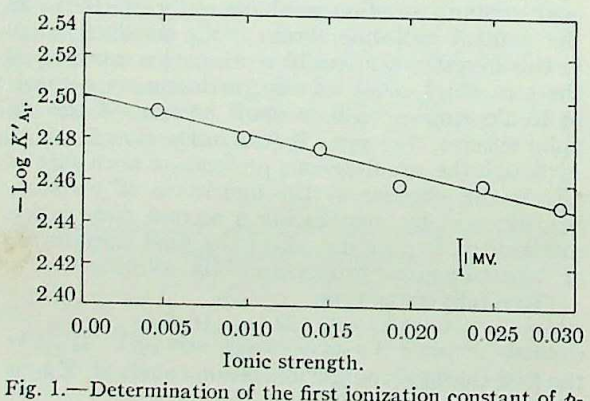

Fig. 1.—Determination of the first ionization constant of *p*-aminobenzoic acid in water at 25°.

In Tables I and II are given the experimental data obtained with the Beckman electrodes for the K_{A1} and K_{A2} determinations, respectively. The E_g (1 atm.) term and the E term represent the average of six and three separate electrode readings, respectively, for the given solution.

drawn with a radius of ± 0.20 millivolt; these are believed to be the respective accuracies in the two determinations. The values of pK_{A1} and pK_{A2} obtained were, respectively, 2.50_1 (corresponding to $K_{A1} = 3.15_7 \times 10^{-3}$) and 4.87_4 (corresponding to $K_{A2} = 1.33_7 \times 10^{-5}$).

The following comparison of the values of the two ionization constants in water at 25°, as determined in this investigation, can be made with values already reported

	pK_{A1}	pK_{A2}	Method
This investigation	2.501	4.874	Galvanic cells without liquid junction
Klotz and Gruen (1945)[9]	2.504	...	Spectrophotometric
Albert and Goldacre (1942)[21]	2.49	4.83	Potentiometric titration

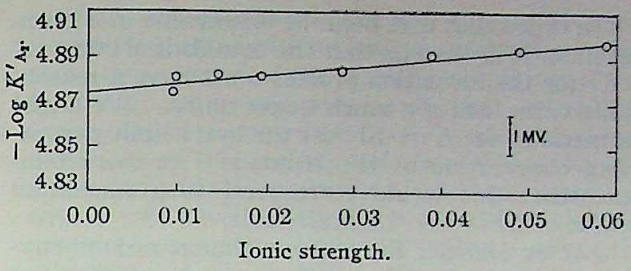

Fig. 2.—Determination of the second ionization constant of *p*-aminobenzoic acid in water at 25°.

The only previous completely thermodynamic method which has been applied to *p*-aminobenzoic acid is the spectrophotometric method, and excellent agreement was obtained between this investigation and the optical method for K_{A1}. The present investigation is apparently the only one in which corrections for the overlap of the dissociation reactions have been applied.

Acknowledgments.—The authors wish to express thanks to the Defense Research Laboratory of The University of Texas, operating under Contract NOrd 9195 with the Bureau of Ordnance, U. S. Navy Dept., for financial assistance during part of this investigation and to the Humble Oil and Refining Company for a fellowship which made possible continuation of this work.

Inter- and Intramolecular Hydrogen Bonds[1]

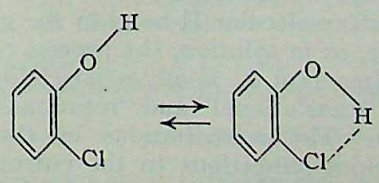
BY H. H. JAFFÉ

RECEIVED SEPTEMBER 24, 1956

The differences in energies of intra- and intermolecular H-bonds are discussed in terms of the entropy changes accompanying H-bond formation.

Since the early work on hydrogen bonds[2] it has generally been accepted that they are usually associated with bond energies in the range of 3 to 7 kcal./mole. These estimates were based almost exclusively on intermolecular hydrogen bonds. In recent years, however, hydrogen bonds have been demonstrated to exist, or at least proposed, for which one would expect appreciably smaller bond energies.[3,4] Most of these cases involve *intra*-molecular hydrogen bonds, many of which could even be demonstrated in solution in polar media,[3] where one might have expected that hydrogen bonding with the solvent might be energetically preferred. It is the purpose of the present paper to call attention to a fundamental thermodynamic difference between *intra*- and *inter*molecular hydrogen bonds which can explain readily why intramolecular H-bonds of much smaller energy than intermolecular ones can be observed.

For the purpose of this discussion, we shall define the process of H-bond formation as the process in which this bond is formed, leaving the molecule (or molecules) otherwise effectively unchanged. For intermolecular H-bonds, this process then is equivalent to association; in case of H-bonds between atoms of the same kind, polymerization or dimerization; in this paper we shall not be concerned with association of more than two molecules, although the arguments presented will hold equally well for more extensive association. For intramolecular H-bonds, the process is represented by reaction 1 (using *o*-chlorophenol as an example) in the forward direction.



(1)

Accordingly, we may consider the process of H-bond formation as an equilibrium reaction, and we wish to examine the thermodynamics of this reaction.

In order that a H-bond be observable in a given system, it is obvious that the equilibrium constant (K) for the formation process must have a reasonable value, not too much below unity. We might arbitrarily set $K = 10^{-1}$ as the lower limit permitting observation of the H-bond.[5] At room temperature, this would correspond to a maximum value of $\Delta F^\circ \sim +1.5$ kcal./mole.

Let us consider the entropy change accompanying this process. The entropy change accompanying the dimerization of gas molecules can be estimated. The loss of three translational degrees of freedom should involve a loss of entropy of around 40 e.u. for a moderately sized molecule. The loss of three rotational degrees of freedom will involve a smaller decrease of entropy, which we will estimate at about 10 to 15 e.u. The rotational and translational degrees of freedom lost upon dimerization give rise to six vibrational modes and even though most of these vibrations will have fairly low force constants (there will be only one bond stretching mode for each H-bond and two bending modes), it is doubtful that these vibrations make a very appreciable (positive) contribution to the entropy change. Hence the total entropy change should be about -50 e.u., corresponding to a $T\Delta S$ term of about 15 kcal./mole at room temp., and 20 kcal./mole at the lowest temperatures where moderately sized hydrogen bonded molecules exist in the vapor state. Accordingly it is not astonishing that H-bonded dimers in the vapor phase are rarely encountered, and then only when more than one bond is responsible.

The estimation of the entropy changes in solution or in the liquid phase is much more difficult. The translational motion is no longer free, but in solution or in a liquid, may be viewed either as translation in a cage (small volume) or as a vibration about a pseudo-lattice-site. In either way, the translational entropy should be greatly reduced. Rotation of large molecules in a liquid phase is not free; rather the degrees of freedom corresponding to rotation in the gas are probably best described as librations. As such, their contribution to the entropy will also be greatly reduced. In solutions, a further positive change in the entropy of the solvent, due to the fact that the dimer molecule is solvated by slightly fewer solvent molecules, is probably negligible. Thus we see that we should expect a much smaller entropy change in liquids and solutions. Since the lower limit of energies of observable H-bonds are of the order of 3 kcal./mole we may infer that this figure is the probable entropy change (in terms of $T\Delta S$) for dimerization. This value is certainly not unreasonable in the light of the above discussion.

For an intramolecular H-bond in the gaseous or liquid phase, or in solution, the process of H-bond formation (reaction 1) involves no change in the number of "translational" and "rotational" degrees of freedom. The contributions of the various bond stretching vibrations to the entropy of the molecule are undoubtedly so small that even moderate changes in the associated force constants cannot give rise to appreciable entropy effects. Accordingly, using again chlorophenol as an example, it seems evident that the in-plane and out-of-plane bending vibrations of Cl and OH, and the torsional vibration of OH are the only vibrations which could affect the entropy. Altogether, these vibrations do not contribute more than a very few e.u. to the total entropy of the molecule, and while their tightening will lead to a slight decrease in entropy, this decrease is quite insignificant, and can be neglected.

In solution, another possible contribution to ΔS° is due to any change in solvation. The degree of solvation is probably limited by steric relations, and it seems hard to visualize that the number of solvent molecules which can sufficiently closely approach the molecule, is appreciably affected by H-bond formation. Hence, we shall also neglect any contribution to ΔS° from solvation.

Assuming, then, that we can neglect ΔS° for reaction 1, ΔH° and ΔF° are equal, and measurement of either would determine both. Neither of these quantities appear particularly amenable to measurement, and few attempts appear to have been made to determine these quantities for intramolecular H-bonds,[6] and the data obtained invariably refer to the vapor state or to inert solvents. Data in some recent papers,[3,4] however, permit some estimates of ΔF° to be made. For example, in connection with the measurement of the pK's of some *ortho*-substituted benzenephosphonic acids, estimates of the effect of H-bonding on the pK were made, and these are, of course, directly the $-\log K$ applying to eq. 1. The values measured were of the order of 0.25–1.5, and hence lead to enthalpies for reaction 1 of 0.2–1 kcal./mole. These figures are probably slight underestimates, firstly, because the $-\log K$ values were lower limits, and secondly, because ΔS° may well contribute a few tenths of a kcal. However, the arguments seem to show that, in solution, even in highly polar media, extremely weak hydrogen bonds may be observed. Other data of similar nature may be found throughout the modern literature.

It frequently has been pointed out that intramolecular H-bonds are particularly readily formed because other bonds in the molecule constrain the atoms into favorable positions. In this form, this statement, of course, implies the small magnitude of the entropy change. This same constraint also explains certain apparent anomalies, such as the fact that the OH—Cl and OH—Br bonds in *o*-chloro- and *o*-bromobenzenephosphonic acids are of approximately equal strengths, although bromine is generally considered to form much weaker H-bonds than chlorine. The geometry of the molecule, due to the relatively large phosphorus atom, is simply such that the OH—Br distance is much more favorable to H-bonding than the OH—Cl distance, thus overcoming the innate lower H-bonding tendency of Br.

We are now ready to inquire why, even in highly polar solvents, we can find such weak intramolec-

(5) Some recent techniques such as measurement of heats of solution permit demonstration of appreciably weaker H-bonds; *cf.* S. Searles, M. Tamres, F. Block and L. A. Quarterman, THIS JOURNAL, **78**, 4917 (1956), and earlier papers by M. Tamres.

ular H-bonds, formed apparently in preference to possible much stronger intermolecular bonds. One answer to this question is, of course, contained in the comparison of the entropy changes associated with the formation of the two types of H-bonds.

There seems to be a further reason, however, in steric effects. Consider the H-bonded form of *o*-chlorophenol. There is no reason to believe that both the O atom and the Cl atom could not serve as electron donors for H-bonds with as many as two solvent molecules each (the H-bond O-H—Cl is probably so weak that, at equilibrium, not many molecules would be that highly solvated). In the non-bonded form, sufficient electron pairs are available so that the molecule could act as donor for five, and as acceptor for one further H-bond. For steric reasons such an extensive solvation of the substituted region of the molecule seems out of the question; it appears quite likely that steric hindrance would prevent solvation beyond four solvent molecules in this region, and thus leave both the H-bonded and the non-bonded forms approximately equally solvated. Hence the intramolecular H-bonding provides additional energy over the solvation.

Acknowledgment.—The author is indebted to Dr. Robert J. Good for several interesting discussions concerned with this work.

Polarized Electronic Absorption Spectrum of Amides with Assignments of Transitions[1]

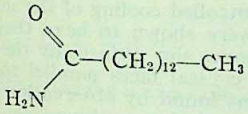
BY DON L. PETERSON[2] AND WILLIAM T. SIMPSON

RECEIVED NOVEMBER 2, 1956

The polarized electronic spectrum of myristamide is obtained to 1600 Å. It is analyzed into n-π; NV_1; Rydberg (2p, 3s) and NV_2 transitions. Emphasis is on obtaining and interpreting the NV_1 transition moment direction.

Introduction

In this investigation the polarized electronic spectrum of myristamide



in the region between 2300 and 1600 Å. was obtained. Starting from the long wave length end there are characterized n-π and NV_1 transitions, a first member of a Rydberg series, and part of the NV_2 transition.

The main result of the paper is considered to be the determination of the direction of polarization of the NV_1 transition, appearing at 1850 Å. In the work on myristamide this direction could not be determined uniquely owing to unfavorable crystal symmetry.[3] Two possible orientations were obtained: one inclined away from the nitrogen–oxygen axis 9.1°, toward the carbon–nitrogen axis; and the other 26.7°, toward the carbon–oxygen axis.[4]

Several methods were employed in an attempt to select the correct direction. The work of Ward on N-acetylglycine was considered first.[5] In addition, an attempt was made to use the results of a π-electron calculation with full configurational interaction in the framework of the ASMO method. During the final stages of this research the crystal structure of N,N′-diacetylhexamethylenediamine was found reported in the literature.[6] This substance has only one molecule per unit cell, a circumstance which made it possible unambiguously to determine the correct polarization direction. The 9.1° value proves to be the correct one, which, gratifyingly was the value selected by the theoretical calculation, and also turns out to be allowed by Ward's experiments.[7]

The theoretical work in this paper is based on calculations described in a collateral paper on the allyl system, particularly allyl anion.[8] Much of the interpretation of the experiments depends on results described in a paper on the nature of resonance force transfer of excitation energy in molecular crystals.[9] Use will also be made of earlier research in which the spectrum of amides in the gas phase down to *ca.* 1300 Å. has been recorded.[10]

I. Experimental

The instrument used in these studies is the same as described elsewhere[11] except for a sliding vane valve situated between the slit compartment and tank.[12]

The calculation of the optical densities of the sample at the various wave lengths was complicated by the fact that there was marked reciprocity failure. Time sensitometry, using numbers of flashes as abscissas, gave characteristic curves which had the usual straight line portion, but with a definite decrease in slope when the intensity was reduced. It was found possible, after a certain amount of trial and error, to assign every density, D, at a given number of flashes, n, an effective gamma determined empirically,

$\gamma(D,n)$;[12] whereupon all optical densities expressing absorptivity were determined from the difference, referring to blank, B, and sample, S

$$\frac{D_B}{\gamma_B(D,n)} - \frac{D_S}{\gamma_S(D,n)}$$

Before using this procedure spectra of thick crystals had apparently different shapes than for thin crystals, though with the correction the expected Beer–Lambert behavior was found. The uncertainty in the empirically determined γ's imposes an estimated 5% error in optical densities.

Measurements on Myristamide.—Purified myristamide was obtained from Dr. J. D. Turner.[3] Single crystals were grown by sublimation in shallow, covered petri dishes. Suitable crystals had well developed 001 faces and displayed uniform interference colors in reflected light. The thinnest crystals were colored steel-grey in crossed polaroids.

In preparing a sample for an exposure a crystal was mounted between optically flat, fused quartz cover slips held under slight pressure. The orientation of the crystal was determined either by observation of edges or by location of extinctions under a polarizing microscope. The *a*- and *b*-axes were distinguished by a cleavage running parallel to *b*, and this was confirmed by a zero level X-ray precession photograph of the mounted crystal.[13]

A mounted crystal was placed in the spectrograph with its *a*- and *b*-axes aligned with the polarization directions of the Wollaston prism. An exposure consisted of between 50 and 200 12-kilovolt discharges through a Lyman tube. Each exposure was accompanied on the same plate (to minimize errors due to irregularities in the fluorescent overlay on the plates) by a blank exposure taken under identical conditions including exposure duration, discharge voltage and capillary diameter.

The *a*- and *b*-polarized myristamide spectra below 2100 Å. (Fig. 1) are the averages of separate spectra taken with three crystals of varying thickness. The thicknesses were estimated by converting to an expected vapor spectrum and comparing with that observed for dimethylformamide. They were found to range from 0.3 to 0.5 micron. Above 2100 Å. each spectrum is a composite of spectra for four crystals with estimated thicknesses ranging from 2 to 50 μ. The curves as obtained directly from the spectrograms appeared similar to the wavy curve of Fig. 4 and with this exception have all been smoothed.

The absorption curves for light polarized along the *a*- and *b*-axes are given in Fig. 1. The broken portions signify uncertainty: in the region of the maximum of the D_a curve

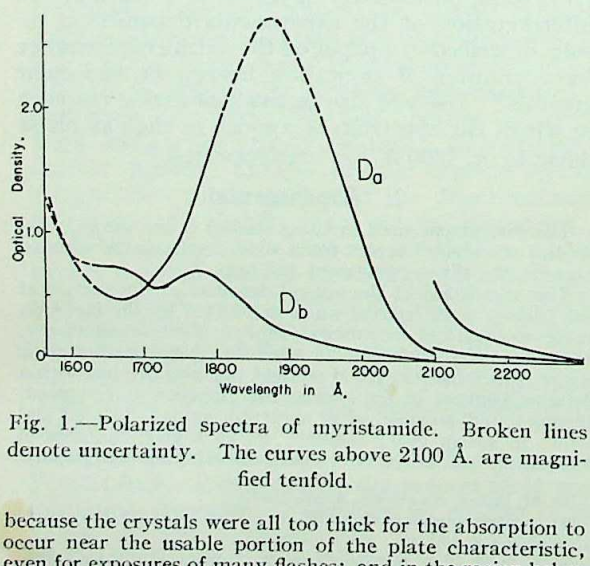

Fig. 1.—Polarized spectra of myristamide. Broken lines denote uncertainty. The curves above 2100 Å. are magnified tenfold.

because the crystals were all too thick for the absorption to occur near the usable portion of the plate characteristic, even for exposures of many flashes; and in the region below 1630 Å. mainly because of anticipated trouble from reflection from the interfaces in the holder assembly. The curves above 2100 Å. are magnified tenfold.

In Fig. 2 the function $\log D_a/D_b$ is plotted against the same abscissa as in Fig. 1 (heavy curve). The expected vapor absorption is also included. It was obtained by introducing artificial random orientation trigonometrically.

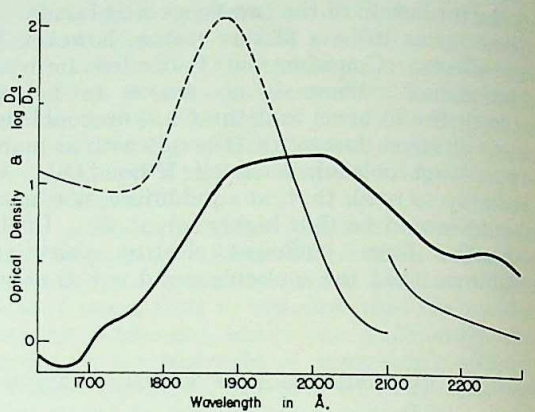

Fig. 2.—Variation of $\log D_a/D_b$ with wave length (heavy curve) and predicted vapor spectrum with region of greatest uncertainty distinguished by a broken curve. The spectrum is magnified tenfold above 2100 Å.

Measurements on N,N′-Diacetylhexamethylenediamine.—The compound was prepared by acetylation[14] of Distillation Products Inc. commercial grade (72%) hexamethylenediamine which was first purified by fractional crystallization. The product was recrystallized from 95% ethanol. In preparing specimens a thin layer of pulverized crystals was enclosed between fused quartz cover slips previously conditioned by immersion in 12 *N* NaOH. Crystallization occurred through controlled cooling of the melt.[15] The crystals so obtained were shown to have their (100) faces in contact with the cover slip surfaces by the identification of the angle "a" in crystal faces parallel to these surfaces.[4] The orientation was found by observation of extinction directions under the polarizing microscope. The extinction direction, *X*, corresponding to the larger refractive index for visible light, was found to be at an angle of 19 ± 2° with the *c*-axis (see Fig. 3). All the molecules are oriented the same way in this material, so that the principal directions are determined by the amide transition moment directly, in the 1900 Å. region.

Only seldom were sufficiently large monocrystalline sections found. The absorption measurements were made on two such sections, the area and thickness of which were estimated to be about 1 mm.^{2} and 0.1 μ. Spectra were recorded for various orientations of the crystals in light polarized in each of the two fixed perpendicular directions of the Wollaston prism. When the orientation was such that the polarization direction of one component of the light was approximately aligned with the projected transition moment direction in the 100 plane, $\vec{m'}$, complete absorption set in below 2100 Å. The crystal may then be regarded as a piece of Polaroid. The angle which $\vec{m'}$ makes with the polarization direction of the other of the two beams could then be obtained easily. Measured from the *X* direction the resulting angle is 5 ± 3° (Fig. 3).

Effect of Varying Polarization of Incident Light.—Crystal spectra must be understood as involving absorption of energy out of two independent beams along the principal directions, or, equivalently, as requiring that the light be represented as a statistical ensemble having parts polarized along the two principal directions. The weights of the two streams of photons, oppositely polarized, are given by the cosine squared law. It is believed that this phenomenon is an example of a disturbance due to the possibility of there having been a "measurement" (absorption of a photon by a crystal oscillator) thus leading to the reduction of the wave function of the light. This point has been considered in

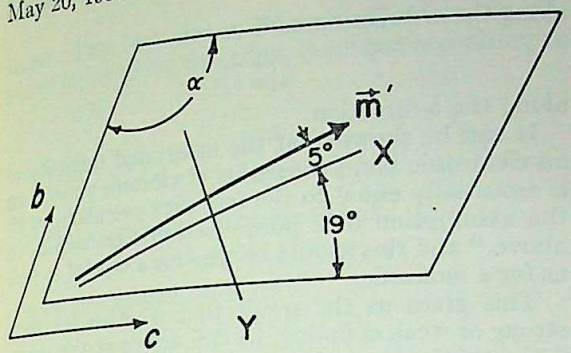

Fig. 3.—The 100 face of the N,N′-diacetylhexamethylenediamine unit cell showing the orientation of the extinction direction, X, and transition moment, m'.

previous work[11,16] and receives a practical verification from the curves in Fig. 4. The dashed curve is obtained by concluding that since the light is polarized in incidence with an angle of 45° to one of the principal directions, it exists with the same polarization inside the crystal. For this situation we project the crystal absorbers onto the electric vector of the light. The D_a and D_b curves from Fig. 1 are thus projected onto this polarization direction, giving for log I/I_0 the average

$$\cos^2 45°\ D_a + \sin^2 45°\ D_b$$

The solid curve is obtained by assuming the polarization of half the beam to be along the a-axis and, in this connection, by using the D_a data from Fig. 1. This gives an intensity I_a' emerging with polarization along the a direction according to

$$\log \frac{I_a'}{I_0/2} = D_a$$

or

$$I_a' = \frac{I_0}{2}\, 10^{D_a}$$

Similarly the intensity emerging in the b direction is given by

$$I_b' = \frac{I_0}{2}\, 10^{D_b}$$

whence the total intensity emerging is the sum

$$I = \frac{I_0}{2}\,(10^{D_a} + 10^{D_b})$$

from which the solid curve is calculated as log I/I_0. The spectrum actually obtained with the light polarized at 45° to the principal directions is the wavy curve, in agreement with the solid curve.

II. The NV_1 Transition

Looking at Figs. 1 and 2 we can see a region from 2050 to 1700 Å. where the absorption is strong, though not with a constant D_a/D_b ratio. This region is interpreted as the crystal absorption associated with the NV_1 electronic band of an isolated myristamide molecule, *e.g.*, as found in the gas phase at low pressures.

It is believed that the long wave length shoulder consists of *vibronic* transitions only weakly split by the resonance force interaction in the myristamide crystal (a situation described as weak coupling). In this region the D_a and D_b curves should be proportional, at low resolution. The ordinates would not be equal because the projection of the transition moment of a typical molecule is unequal on the two principal directions.

When the electronic band half-width, $2V$, for an ideal non-vibrating crystal much exceeds the half-width of the absorption band for isolated

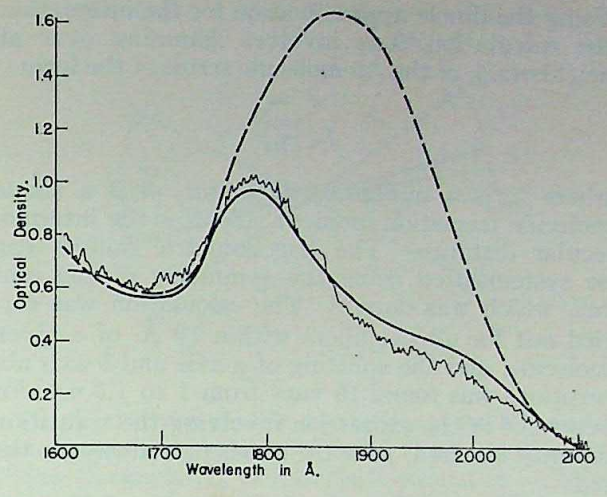

Fig. 4.—Erroneously (broken curve) and properly (heavy curve) calculated myristamide crystal spectrum for light polarized at 45° with the a-axis. The wavy curve is observed.

molecules, Δ, a situation called strong coupling is expected.[9] In this case the D_a and D_b curves would lose their resemblance to one another and to the gas phase spectrum. The separation of the peaks of the two curves would give the crystal splitting of the entire *electronic* transition, just as if vibrations could be disregarded. The separation in Fig. 1 is considered to be an example of this effect though the ratio $2V/\Delta$ is a little less than unity (0.6, see below). It is thought that the middle of the band must be treated as involving strong coupling, even though the wings of the band show weak coupling.

Crystal Spectrum with Strong Coupling.—For strong coupling we assume that the nuclei are fixed and calculate the allowed resonance force spectrum[17] based on the absorption for a single molecule. This requires a knowledge of the strength and direction of the total electronic transition moment. Before the ambiguity about the direction of the NV_1 transition moment was resolved, it was considered that the calculation might aid in the determination, so calculations for all plausible directions were carried out.

Looking at the 001 face of myristamide there will be allowed crystal transitions along the a and b crystallographic axes. Thus only two excited state crystal wave functions need be considered, where the phases for single molecule transitions are picked to reinforce along the respective directions. The upper state functions for a crystal of n molecules are of the form

$$\frac{1}{\sqrt{n}} \sum_{i=1}^{n} \psi_1\psi_1 \ldots \psi_i\dagger \ldots \psi_n$$

where the dagger signifies that the ith molecule is in the V_1 state and the coefficients are approximated as all equal in absolute value (infinite wave length of the light). The expectation value of the interaction operator for an infinite crystal reduces to

$$\int (\psi_1\psi_2 \ldots \psi_i\dagger \ldots \psi_n)^*\, H_{int} \sum_{j=1}^{n} \psi_1\psi_2 \ldots \psi_j\dagger \ldots \psi_n d\tau$$

Using the dipole approximation for the interaction, the calculation thus involves summing over all neighbors, j, of the ith molecule terms of the form

$$f_{ij}\frac{|\vec{m}|^2}{R^3}$$

where f_{ij} is a trigonometric factor, $\vec{m}$ is a single molecule transition moment, and R is the intermolecular distance. The trigonometric factors can be systematized using the symmetry of the unit cell, which was done.[12] The calculation was carried out for all neighbors within 10 Å. of a given molecule, and the splitting of a-axis and b-axis absorptions was found to vary from 1 to 1.5 e.v. for every Å.^{2} in the expression involving the transition moment squared, with the a-axis part always to the red.

With the transition moment direction 9.1° away from the oxygen–nitrogen line (the value finally found experimentally) and assuming that the transition moment squared is given by[10]

$$|\vec{m}|^2/e^2 = 0.44 \text{ Å.}^2$$

the a-axis absorption is calculated to lie toward the red of the single molecule absorption at 0.11 e.v., while the b-axis absorption should lie to the blue a distance of 0.53 e.v. The calculated splitting is thus 0.64 e.v. or 5.2×10^3 cm.$^{-1}$, with the a-axis part to the red. It is believed that the calculated value is in reasonable agreement with the experimental value (estimated as 0.4 e.v.) when it is considered that the position of the peak of the a-axis absorption is uncertain, and that not all of the single-molecule intensity contributes to the observed crystal splitting, owing to the intervention of the single-molecule vibrations spoiling the resonance.[9]

It has been suggested[9] that the electronic band width parameter for a crystal should be calculated as for a dimer with its molecules disposed according to the strongest interaction in the actual crystal. With the 9.1° angle for the transition moment this calculation leads to

$$2V = 0.4 \text{ e.v.}$$

The single-molecule band width, which is also needed to give the fraction $2V/\Delta$ which determines the nature of the coupling, was taken to be 0.7 e.v.[10] It is the ratio 0.4/0.7 which was used above in this connection.

Direction of the Transition Moment.—Let us consider once again that all the nuclei in the crystal are fixed. The transition moment along either principal direction (provisionally, the a and b crystallographic axes) is then calculated to be a sum of individual molecular moments projected on that direction

$$\frac{1}{\sqrt{n}}\sum_{i=1}^{n}\vec{m_i}\cdot\vec{a}$$

($\vec{a}$ and $\vec{b}$ are unit vectors along the principal directions). Owing to the molecular arrangement in the unit cell, all the terms are the same for an allowed transition in myristamide, so the intensity for strong coupling is given by

$$n|\vec{m}\cdot\vec{a}|^2$$

along the a-direction, and

$$n|\vec{m}\cdot\vec{b}|^2$$

along the b-direction.

It can be shown that the integrated intensity of an electronic band consisting of vibronic transitions is essentially equal to the intensity calculated with the assumption of a pure electronic transition, as above,[18] and this should be true for a crystal as well as for a molecule.

This gives us the result that whether we have strong or weak coupling, we can arrive at the orientation of the transition moment through the ratio of areas of the curves. If there is borrowing, or if the region where one band stops and another starts is ill-defined, this ratio of areas is very likely not going to give an accurate value for the direction. The situation is improved, however, by the fact that with weak coupling the D_a and D_b curves should be proportional in low resolution, so that we have the result

$$\frac{\int D_a d\lambda}{\int D_b d\lambda} = \frac{D_a}{D_b}$$

where the "dichroic ratio" D_a/D_b is independent of wave length. The situation encountered in the case of myristamide is intermediate, but it can be seen that there is a wide region on the long wave length side of the absorption where D_a/D_b is constant, at *ca.* 14.6 (see Figs. 1 and 2, particularly from 2020 to 1890). This region is considered to be the weak coupling part of the NV_1 band (see Fig. 2d of ref. 9). The dichroic ratio for the region gives two possible directions for the orientation of the moment with respect to the amide group: 9.1 and 26.7° with the N–O line, toward the C–N and C–O lines, respectively.[19]

The ambiguity in the work on myristamide has been resolved using the measurements on N,N′-diacetylhexamethylenediamine, and with a new interpretation of the work on N-acetylglycine.[5] In the former compound the direction of $\vec{m'}$ (Fig. 3) is equivalent to a transition moment direction $18 \pm 5°$ away from the N–O line toward the C–N line. This selects the 9.1° value for myristamide.

Unexpectedly, confirmation is provided by working up the results on N-acetylglycine paying attention to the fact that, as with myristamide, there are two values for the polarization, one extraneous. The dichroic ratio was found by Ward to be $D_c/D_b = 20$ to 60 at 2100 Å. for the 100 face,[5] which gives as the correct one of the two possibilities the angle 15° from the N–O line toward the N–C line.

The various angles are all given in Fig. 5, together with arcs indicating estimated experimental uncertainties. It will be noted that the angle for myristamide is more nearly along the N–O line, perhaps outside of experimental uncertainty. (The directions for amides in different environments might well be somewhat different.)

Theoretical Significance of the Polarization.—We take as a starting point a representation of the NV_1 transition for the formate ion, using struc-

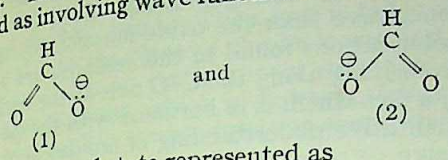
tures. The two states, N and V_1, may be depicted as involving wave functions corresponding to



(1) and (2)

with the normal state represented as

$$\psi_N = 2^{-1/2}(\psi^1 + \psi^2)$$

and the first excited state as[8]

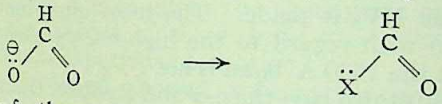
$$\psi_{V_1} = 2^{-1/2}(\psi^1 - \psi^2)$$

(Superscripts refer to structures.) The transition moment is

$$e\int \psi_N \vec{q} \psi_{V_1} d\tau = \frac{e}{2}\left[\int \psi^1 \vec{q} \psi^1 d\tau - \int \psi^2 \vec{q} \psi^2 d\tau\right]$$

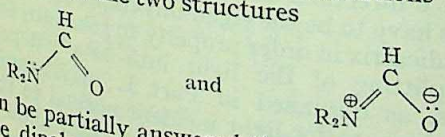
which is just one-half the difference in moments of the structures. This difference is a vector along the O–O line with the length (factor) predicted to be equal to the O–O distance.[20] The transition moment length thus is estimated to be of the order of 1.1 Å., while the value found is *ca.* 0.7 Å.[10]

If the electronegativity of one of the oxygen atoms could be successively increased we should have a *series* of compounds going through the acid all the way, say, to the acid halide, and beyond.



At the furthest extreme the NV_1 transition would be the same as the NV_1 transition for a carbonyl group and so would be polarized along the C–O line. Amides are in or just outside the series, the nitrogen having comparable electronegativity to that of an oxygen with a formal negative charge. It might be expected that the transition moment direction would change monotonically from the O–O to C–O lines in such a series, so that the direction of the moment could be used very simply to characterize the various members.

It is certainly a matter of interest to locate amides in the series. In fact this may be taken as the central question concerning the electronic structure of amides. The question is very closely related to the one regarding the relative contributions to the ground state of the two structures



It can be partially answered through consideration of the dipole moment,[21] infrared intensity,[22] carbonyl force constant,[23] and even the position of the n-π band.[24] It is felt that one of the best approaches is through the Brooker deviation. Brooker in his work on the merocyanine dyes has been able to show convincingly that for vinylogous amides the energy of the charged and uncharged structures

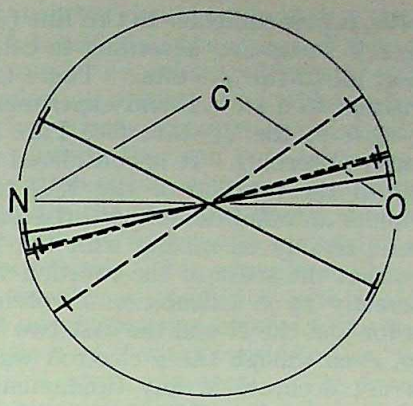

Fig. 5.—The two possible orientations of the NV_1 transition moment for myristamide (solid lines) and N-acetylglycine (broken lines), and the single orientation for N,N′-diacetylhexamethylenediamine (dashed line) as referred to the plane of the amide group. Uncertainties are indicated by the lengths of arcs through the lines.

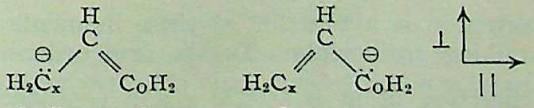
must be nearly equal; for some dyes he has found conditions under which true equality of energy may be demonstrated.[25] The Brooker deviation of a very simple vinylogous amide

$$Me_2\ddot{N}—CH=CH—CH=CH—CH=CH—CH=O$$

has been found to be zero in water, and the color shifts monotonically toward the blue as methanol is added. In pure methanol the deviation is 40 mμ.[26] This positive or normal deviation means that the uncharged structure is the more stable, even in the relatively polar water–methanol environment. That the same conclusion may apply to the amides themselves is easy to imagine, and is borne out by considering the question in detail.

If we now look at the experimental values of the polarizations (Fig. 5) we see that the direction is toward the N–C line, which is surprising considering our expectation for the series. Thus either the amides in their crystalline environment are outside the series, or else the theoretical polarization direction for the series does not vary monotonically between the O–O and the C–O lines. The second alternative is favored by much evidence, including the following calculation.

Theoretical Calculation of the Polarization.—In view of the discussion in the last section, short of having the wave functions for amides themselves, it would be desirable to have good functions for formate ion and apply perturbation theory. We had obtained, in another connection, a set of state wave functions after configurational for allyl anion[8]



We shall use these wave functions as a substitute for the formate functions to represent the start of the series. (The subscripts x and o will be used below to distinguish positions affected differently by a particular perturbation.) The first singlet-singlet transition, NV_1, for the allyl anion is polarized along a line joining the terminal carbons (||) and the

Digitized by Arya Samaj Foundation Chennai and eGangotri

second, NV_2, is perpendicular to this line ($\perp$). The next higher V states are, according to calculation, not close at all to the V_2 state.[8] There is a Rydberg transition to a state found experimentally to be fairly close to the V_2 state (see Part III) but quite weakly absorbing. It is considered that the magnitude of the rotation of the NV_1 transition moment under an infinitesimal perturbation should thus depend mainly on mixing with the V_2 state. It follows that the sense of the rotation would be given correctly by a calculation involving wave functions for just the N and the first two V states. Moreover, even though the π-electron wave functions are not accurate in any fundamental way, they are known empirically to represent positions and intensities of π-electron transitions quite well provided that configurational interaction has been introduced. Perhaps it is not being unrealistic, therefore, to expect the calculation here to provide the correct sense of the rotation. Probably the greatest uncertainty stems from using allyl anion functions for formate ion functions.

What was done was to obtain the abbreviated first-order perturbed wave functions

$$\psi_N = \psi_N^0 - \frac{H'_{NV_1}}{W_{V_1} - W_N}\psi_{V_1}^0 - \frac{H'_{NV_2}}{W_{V_2} - W_N}\psi_{V_2}^0$$

$$\psi_{V_1} = \psi_{V_1}^0 - \frac{H'_{V_2V_1}}{W_{V_2} - W_{V_1}}\psi_{V_2}^0 - \frac{H'_{NV_1}}{W_N - W_{V_1}}\psi_N^0$$

under a perturbation at one of the terminal carbons (labeled C_x, referring to the allyl anion structures above) such that the Coulomb integral for that carbon decreases infinitesimally. This change represents the first increase in electronegativity of x as the series develops, away from formate ion. The functions are found to be

$$\psi_N = \psi_N^0 - 0.0903\epsilon\psi_{V_1}^0 - 0.0318\epsilon\psi_{V_2}^0$$

$$\psi_{V_1} = \psi_{V_1}^0 + 0.0903\epsilon\psi_N^0 - 0.1303\epsilon\psi_{V_2}^0$$

where for atom C_x

$$\int(2p)H'(2p)d\tau = \epsilon < 0$$

The various state moments and transition moments for the unperturbed state functions have to be evaluated paying careful attention to consistency in the selection of phases. They are given in Table I. The NV_1 transition moment after the

TABLE I

THEORETICAL ELECTRIC MOMENT LENGTHS FOR ALLYL ANION IN Å.

	N	V_1	V_2	NV_1	NV_2	V_1V_2
$\parallel$	0	0	0	−1.2994	0	−0.4562
$\perp$	0.8161	0.7418	1.0439	0	−0.4127	0

perturbation is a function of these moments and the mixing coefficients. To the first order in ϵ, the direction of $\vec{m}$ is $0.0605\ \epsilon\ \vec{j} + (-1.2994 + 0\ 0145\ \epsilon)\ \vec{i}$. The $\vec{i}$ vector is parallel ($\parallel$) and the $\vec{j}$ vector perpendicular ($\perp$), with senses as given above in connection with the structures for allyl anion. With $\epsilon < 0$ this gives a twisting away from the parallel direction toward the bond connecting C_x with the center carbon, as found experimentally. Similarly, the NV_2 transition moment is found to twist from $\perp$ toward the $C-C_o$ line.

We may conclude that notwithstanding the observed NV_1 polarizations, amides can still be in the series, with the nitrogen being effectively more electronegative than the oxide ion of formate ion. The polarizations found in this research are a long way from lying along the C–O axis of the carbonyl group, a fact which is in harmony with the customary qualitative understanding of amides in organic chemistry.

III. Absorptions at 2200 and 1660 Å.

Returning again to the consideration of Figs. 1 and 2 we find from the behavior of the polarization that the long wave length tail of the NV_1 absorption may be interpreted as containing a separate electronic transition, which is assigned as n-π[10,27] and called the 2200 Å. band. The region around 1660 Å. is qualitatively different from the NV_1 part and is believed to be the first member of the Rydberg series previously found.[10] It is tentatively assigned as involving a jump of a non-bonding 2p electron on the oxygen to an orbital which is an in-phase linear combination of 3s atomic orbitals. There is a polarization change below 1600, which, however, is in a region where the experimental error is likely to be great. There is an NV_2 transition expected on quite general theoretical grounds in this region, so the tentative assignment of the absorption below 1600 as NV_2 is made. The most important conclusion with regard to the high energy absorption is that the 1660 Å. band is not NV_2.

In this third part the n-π and Rydberg transitions will each be discussed, though first it is convenient to introduce a somewhat formal trigonometric theory connecting the crystal-fixed and molecule-fixed polarization directions.

Trigonometric Analysis of the Dichroic Ratio.—With the assumption of weak coupling one has the following relationships connecting absorption densities along molecule-fixed (x,y,z) and crystal-fixed (a,b,c) axes.[16]

$$\begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix} = \mathbf{M}\begin{pmatrix} D_a \\ D_b \\ D_c \end{pmatrix} \text{ or } \begin{pmatrix} D_a \\ D_b \\ D_c \end{pmatrix} = \mathbf{M}^{-1}\begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix}$$

In practice the matrix **M** is derived from its inverse, a matrix with elements equal to the squared projections of molecule-fixed unit vectors on the a, b and c directions in the crystal. The a-, b- and c-axes have to be the eigen-directions of a section of the indicatrix in order properly to take into account the splitting of the light into two independent beams, as discussed in Part I. Myristamide is monoclinic, so for light incident normal to the 001 face the principal directions are parallel to the a and b crystallographic axes. For light polarized along the a-axis the E vector inside the crystal is not required by symmetry to lie in a plane containing the 001 face. However considering the orientations of the NV_1 transition moments it is believed that to assume this particular orientation is a good approximation—so that the c-axis is defined here as effectively normal to the 001 plane, and the a- and b-axes as coinciding with the crystallographic a- and b-axes.[28]

(27) J. S. Ham and J. R. Platt, *J. Chem. Phys.*, **20**, 335 (1952).

(28) Detailed consideration of the error introduced by this assumption gives the result that if the correct c-axis were inclined by the unlikely amount of 30° away from the 001 plane the final deter-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

As a simple example of the formal use of the above relationships consider the weak coupling region of the NV_1 band. The z-axis is taken as perpendicular to the plane of the molecule and the x direction is the as yet unknown direction of the transition moment, which is, however, assumed to be in-plane. The inverse equation simplifies to

$$\begin{pmatrix} D_a \\ D_b \\ D_c \end{pmatrix} = \mathbf{M}^{-1} \begin{pmatrix} D_x \\ 0 \\ 0 \end{pmatrix}$$

resulting in an equation for the polarization direction

$$D_a/D_b = M_{11}^{-1}/M_{21}^{-1}$$

It was the observed dichroic ratio combined with this ratio of $\mathbf{M}^{-1}$ elements which led to the angles given in Fig. 5. The fact that the matrix elements are projections squared is to be connected with the fact that the dichroic ratio is always positive, and is of course responsible for the ambiguity.

The n-π Transition.—What is known with certainty about the n-π transition is that a simple orbital approach to the system of 4 π electrons in 3 π orbitals makes the highest filled level non-bonding, so the n-π transition should have approximately the same frequency as the first π-π transition. The 2200 Å. band may then be provisionally assigned as n-π because it is in about the right place and because the analysis of the dichroic ratio is consistent with the expected polarization.

The predicted allowed polarization is out-of-plane, or z, but with a strength depending on the extent to which the lobes of the non-bonding 2p orbital on the oxygen are put out of balance by interaction with the nitrogen, which is long-range. It would therefore be anticipated that except for the zero-zero region there would be a comparatively strong formally forbidden part, polarized like the neighboring NV_1 transition.[5] The z molecular axis does not have an appreciable projection on the a crystal axis in myristamide so the test of the degree of forbiddenness is the deviation of D_a/D_b from zero. Actually D_a/D_b is around 3.6 at 2200, becoming understandably smaller at the long wave length edge.

The expression for the crystal fixed densities with x the NV_1 polarization direction, becomes

$$\begin{pmatrix} D_a \\ D_b \\ D_c \end{pmatrix} = \mathbf{M}^{-1} \begin{pmatrix} D_x \\ 0 \\ D_z \end{pmatrix}$$

giving

$$D_a = M_{11}^{-1}D_x + M_{13}^{-1}D_z$$
$$D_b = M_{21}^{-1}D_x + M_{23}^{-1}D_z$$

The required $\mathbf{M}^{-1}$ elements are known from the work on the NV_1 transition and from the orientation of the molecular plane, so that the ratio of "allowed" to "forbidden" absorption can be computed. It turns out to be

$$D_z/D_x \approx 1/2$$

The Rydberg Transition.—There is a Rydberg series in formamide corresponding to the formula[10]

$$\nu = 82{,}566 - \frac{R}{(n - 0.639)^2} \qquad n = 3, 4, 5, \ldots$$

The first member should be at 1610 Å. and is identified with the 1660 Å. absorption of myristamide.

The formula is written differently than originally[10] following a scheme by which it is expected that the low energy termination point may be predicted.[11] Briefly the plan is to write the formula with an appreciable negative quantum defect. Only then are the quantum numbers presumed to give a correct description of the nodal characteristics of the orbitals. For example, having $n = 3$ as the first member is connected with the fact that there are no unfilled molecular orbitals for amides which have $n = 2$ when considered as "fused," as for a united atom approach. (The fused atomic orbital description of the π orbitals is illustrated in Fig. 6.) We go on now to make a tentative assignment of the Rydberg transition guided by the above considerations.

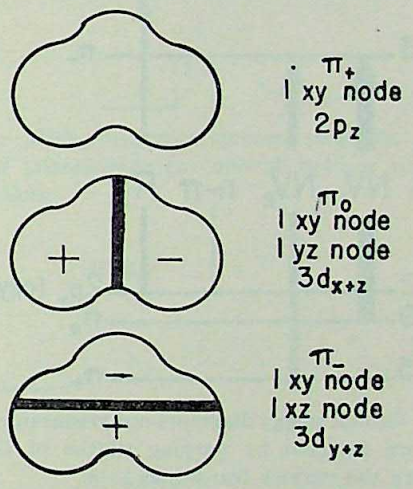

Fig. 6.—Illustration of the fused atomic orbital description for allylic π orbitals.

There are two $n = 3$ empty orbitals, either one of which might be reached in the first transition. One is the anti-bonding $2p_\pi$ orbital, π_-, which is 3d with respect to nodal behavior and the other is a bonding linear combination of 3s AO's which is 3s. These orbitals could well have comparable energies, the anti-bonding character of the π orbital balancing the promotion involved in going to the molecular orbital made up of 3s AO's.

This leaves the question of the originating orbital. It could not be the highest filled or non-bonding π orbital, $\pi\sigma$, because this would lead to the possibilities (fused AO description in parentheses)

$$\pi_0(3d) \longrightarrow \pi_-(3d)$$
$$\pi_0(3d) \longrightarrow 3s(3s)$$

The former is the NV_1 transition and the latter is forbidden provided that amides are considered as having allylic symmetry. The two most plausible possibilities for the originating orbital are considered to be the bonding π orbital, π_+, and the nonbonding oxygen 2p orbital, $2p_y$. The first member of the Rydberg series would then be

$$\left.\begin{matrix} \pi_+(2p) \\ 2p_y(2p) \end{matrix}\right\} \longrightarrow \left.\begin{matrix} \pi_-(3d) \\ 3s(3s) \end{matrix}\right\}$$

Of the four possibilities the one

$$2p_y(2p) \longrightarrow 3s(3s)$$

mination of the angle of the NV_1 polarization direction would be only 5° in error.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

seems to be the most plausible. The $2p_y \rightarrow \pi_-$ transition is the n-π transition assigned to the 2200 Å. region. (It would appear that the experimental results for the 1660 band, polarization and nearness to the NV_1 transition, make it possible to assign the band as n-π; however the allowed intensity is too high. The formally allowed intensity for the n-π transition must, it should be remembered, be quite small.) The $\pi_+ \rightarrow \pi_-$ transition is also the NV_2 transition and on the most general theoretical grounds would not be expected to lie so close to the NV_1 transition. (This closeness is most acutely demonstrated in the spectrum of formamide itself[10] where the absorption around 1600 A. is not even resolved, but shows up as a broadening of the NV_1 band relative to the band

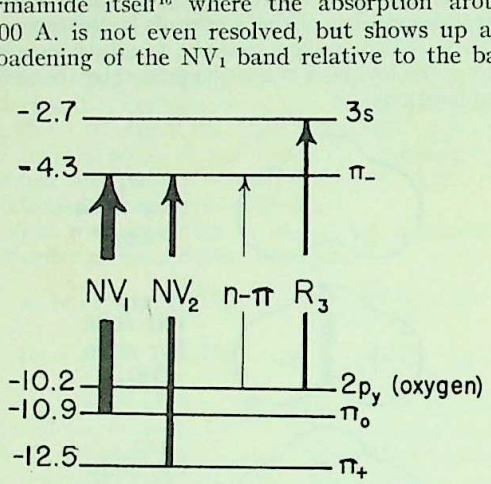

Fig. 7.—Orbital energy diagram for myristamide: (e.v.) intensities are depicted by varying widths of the arrows representing the various transitions.

in dimethylformamide.) The $\pi_+ \rightarrow 3s$ transition would be at shorter wave lengths than the $2p_y \rightarrow 3s$ transition, so unless there is yet another Rydberg band at longer wave lengths the $2p_y \rightarrow 3s$ assignment is to be preferred.

The picture of the orbital reached in the transition is a linear combination of 3s orbitals, all in phase, with perhaps the greatest amplitude on the oxygen, though the higher Rydberg members gradually become more and more like atomic orbitals. The structure in the 1600 Å. region of formamide,[10] with a spacing of 1600 cm.$^{-1}$, may then be interpreted as vibrational intervals corresponding to a carbonyl stretching motion in the upper state (the ground state stretching frequency is 1740 cm.$^{-1}$).[29]

Examination of Fig. 1 shows that the absorption in the 1660 Å. region is likely to be partly from the b-axis component of the NV_1 transition (considered from the strong coupling point of view) and partly from the long wave length part of the band below 1600 Å. Nevertheless the qualitative result

$$D_b > D_a$$

is believed to be a characteristic of the Rydberg member itself. It is found using the trigonometric methods illustrated in the foregoing that this result is consistent with the polarizations expected for all four possibilities considered above, in particular for the possibility which is considered the most likely

$$2p_y \longrightarrow 3s$$

If we adopt this latter process we can, by considering various combinations, represent all the transitions found in this research for myristamide by means of an orbital energy diagram. This is done in Fig. 7. The effective orbital energy of the π_+ orbital is obtained by adopting for the NV_2 absorption a value of 1520 Å. This is estimated by assuming for myristamide an NV_1/NV_2 energy ratio intermediate between the ratio for formamide and dimethylformamide.[10] The zero of energy is taken as the ionization limit for the observed Rydberg series.

Nuclear Magnetic Resonance Study of the B_2D_6–B_5H_9 Exchange Reaction[1]

BY WALTER S. KOSKI, JOYCE J. KAUFMAN AND PAUL C. LAUTERBUR

RECEIVED NOVEMBER 15, 1956

The exchange of deuterium between diborane and pentaborane was investigated by nuclear magnetic resonance. It was found that the exchange proceeded preferentially in the terminal hydrogen positions in pentaborane. The rate of exchange of the apex hydrogen appeared to be within ±10% the same as the exchange rate of the base terminal hydrogen. Under the experimental conditions the bridge hydrogens in pentaborane did not participate in the exchange.

Introduction

Recently we have had occasion to investigate the exchange of deuterium between diborane and pentaborane and we have found that the reaction proceeds through borane, derived from the dissociation of diborane, as an intermediate. By means of a mass spectroscopic study[2] we were able to disentangle the exchange from a complicating reaction due to the pyrolysis of diborane to form pentaborane, and by an infrared study[3] to show that only the five terminal hydrogens participated in the exchange reaction. The bridge hydrogens

of pentaborane did not participate in the exchange reaction and neither did the boron atoms under the conditions of the experiments.

The pentaborane molecule has a tetragonal pyramidal arrangement of borons with a hydrogen attached to each boron by a normal boron to hydrogen bond (terminal hydrogens). Four other hydrogens are attached to the base borons by bridge bonds. It was of interest to our program to confirm by an independent technique our previous observations on the difference in the exchangeability of bridge and terminal hydrogens in pentaborane and to determine whether the rate of exchange of the hydrogen attached to the apical boron in pentaborane differed from the exchange rate of a terminal hydrogen attached to the base of the molecule. This report summarizes our study of this exchange using nuclear magnetic resonance as a tool.

Experimental

All of the spectra used in this study were obtained with a Varian Model 4300A high resolution nuclear magnetic resonance spectrometer at a frequency of 40 Mc./sec. and a magnetic field of about 9400 gauss. They were recorded with a Sanborn recorder at a speed of 25 mm./sec. In most cases, the sweep width was 700 milligauss and the sweep rate 70 milligauss/sec. Calibration was made by a water signal modulated at 400 cycles/sec.

The radiofrequency power was kept low enough so that the spectra appeared to be about the same when swept through in either direction. This precaution ensured that saturation effects were largely eliminated.

All of the samples were sealed in Pyrex glass tubes, 5 mm. outside diameter and 3 mm. inside diameter, except for the 55.6% deuterated pentaborane samples which were in tubes 3 mm. outside diameter and 1 mm. inside diameter, because only small quantities were available. The lengths of the samples ranged from 5 to 25 mm. All spectra were taken at room temperature.

Pentaborane of normal isotopic content was prepared by pyrolysis of diborane at 180°. The procedure and purification method has been published previously.[3] The 5% deuterated pentaborane sample was prepared by treating 53.2 cm. of B_2D_6 and 12.55 cm. of B_5H_9 in a 325-cc. bulb at 80° for 2 hours and 50 minutes. The sample, after separation and purification, was sealed in the standard 5 mm. outside diameter tube. The length of this liquid sample was 25 mm. The pentaborane samples containing 26.5 and 55.6% deuterium were prepared in a similar manner except that the reaction times were 11.5 and 48 hours. The latter time actually consisted of two 24-hour contact times with the diborane being replaced with a fresh sample of B_2D_6 at the end of the first 24-hour period. The procedure for separation of the diborane and pentaborane and the purification methods were similar to that previously used.[2] The analysis for total deuterium content was made by decomposing the boron hydride and subjecting the resulting hydrogen–deuterium mixture to a thermal conductivity method.[4] The deuterium content of the B_2D_6 used for deuteration of the pentaborane ranged from 96–98%.

Results and Discussion

The structure of pentaborane has been established by X-ray diffraction of the crystal,[5,6] electron diffraction[7,8] and microwave spectroscopy[9,10] work on the gas. The nuclear magnetic resonance spectra of H and B^{11} in pentaborane have been reported and analyzed by Shoolery[11] and Kelly, Ray and Ogg.[12] The H spectrum of pentaborane of normal isotopic content shown in Figs. 1a and 2a is identical with the ones reported by the earlier observers. Three main sets of peaks are found and

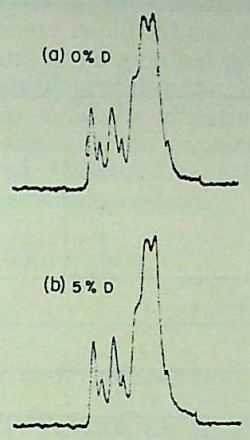

Fig. 1.—High resolution proton magnetic resonance spectra of pentaborane (a) normal isotopic content, (b) 5% deuterium.

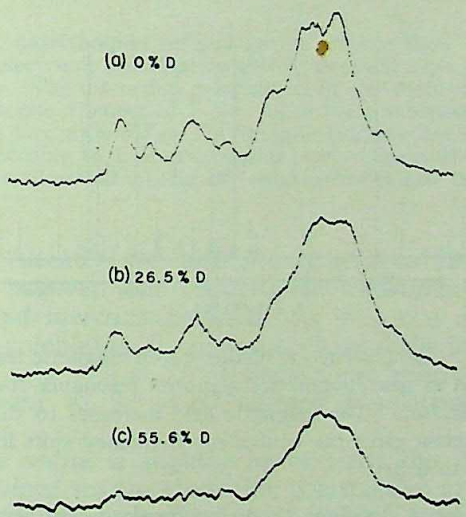

Fig. 2.—High resolution proton magnetic resonance spectra of pentaborane containing (a) normal isotopic abundance, (b) 26.5% deuterium and (c) 55.6% deuterium.

are assigned to hydrogen attached to B^{11} atoms. Other smaller peaks, usually unresolved, arise from those hydrogens bonded to B^{10}. Figure 3 shows a step by step reconstruction of the theoretical spectrum, using the experimentally determined relative chemical shifts and spin couplings estimated on the assumption that there are four large peaks from base terminal hydrogens attached to B^{11}, four small peaks from the apex hydrogen attached to B^{11}, and a broad unresolved peak from the bridge hydrogens. The synthesized spectrum in Fig. 3 has the following contributions: (a) four lines arising from the coupling of the four base terminal protons with B^{11}; (b) four equal lines, one-fourth the intensity of those in (a) representing the apex protons attached to B^{11}; (c) seven lines

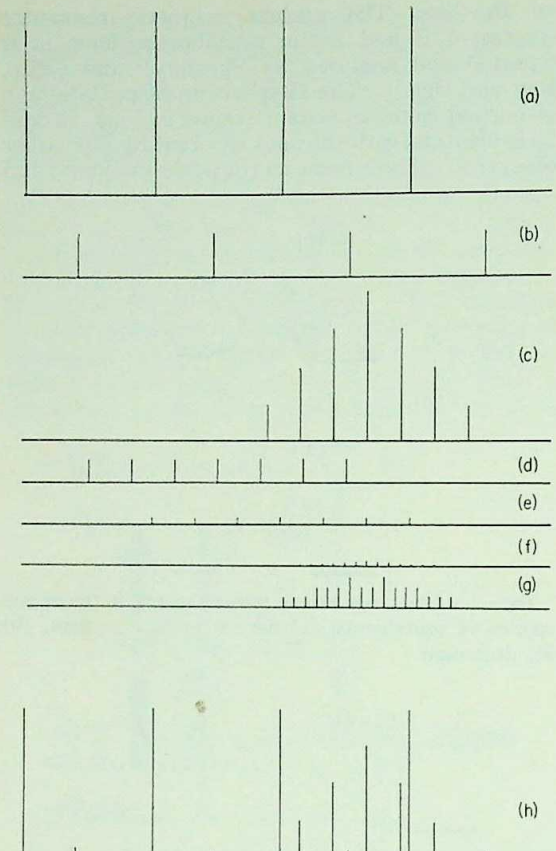

FIG. 3

Fig. 3.—Reconstruction of the proton magnetic resonance spectrum in pentaborane for a proton resonance frequency of 40 Mc./sec. The magnetic field increases to the right. The abscissa gives the equivalent frequency shift in cycles relative to water.

from those bridge protons flanked by two B^{11} atoms; (d) seven lines from the base hydrogens bonded to B^{10}; (e) seven more lines, all equal, from apex protons on B^{10}; (f) a set of small lines arising from the fact that 3.5% of the bridge hydrogens are situated between two B^{10} atoms; (g) this contribution arises from bridge protons joining one B^{10} and one B^{11}; (h) the addition of all these contributions results in a spectrum that compares very well with the experimental results when instrumental resolution is taken into account. In assembling Fig. 3, it was assumed that B^{11} has an isotopic abundance of 81.17%, a nuclear magnetic moment of 2.6880, and a spin of 3/2. B^{10} has an abundance of 18.83%, a magnetic moment of 1.8006, and a spin of 3.

The peaks designated as x and y in Fig. 3h were used in this study to follow the progress of deuteration in the base and apex terminal hydrogen positions, respectively. Our first analysis of the *n-m-r* spectra of partially deuterated pentaborane prepared by exchange was made to obtain a measure of the relative rates of exchange of the terminal and bridge hydrogens in the molecule. It was found that the best place to divide the spectrum in order to separate the two types of hydrogens was between peaks x and y mentioned above, and the rest of the spectrum. A number of spectra of both the undeuterated and deuterated samples were taken and only those which showed no evidence of a field shift or other irregularity were used. Both forward (from low to high field) and backward sweeps were used and the results were calculated separately.

The areas under the peaks were determined by cutting out the entire spectrum, snipping it in two at the minimum after the first two peaks, and weighing for both the forward and backward sweep directions. The ratio of the large area to the smaller one was 7.79 and 7.31 for the forward and backward directions, respectively. The error is estimated as being ± 0.03. The corresponding theoretical ratio as obtained from Fig. 3 was 7.02. The experimental ratios obtained with the 26.5% deuterium sample for the forward and backward sweeps were 10.5 ± 0.1 and 10.0 ± 0.1, respectively. We assume in treating these data that the differences between calculated and observed ratios for the undeuterated pentaborane are possibly caused by the arbitrary process of selecting the point at which to cut the spectrum apart, or more likely the discrepancy probably arises because of a difference in the spin-lattice relaxation times of the different types of protons. We have attempted to minimize this effect by keeping the power level low so as to avoid saturation. The patterns obtained for the forward and backward sweeps indicated an absence of such saturation effects. At any rate the point at which the spectrum was cut was quite far away from any bridge hydrogen lines, so we have further assumed that the ratio of the observed to theoretical values will remain constant in going from one sample to the other. Applying this correction, we get the corrected ratio for the 26.5% deuterium sample as 9.47. Applying simple stoichiometric calculations to these ratios, we find that in the 26.5% sample more than 90% of the deuterium has gone into the terminal hydrogen positions and somewhat less than 10% has gone into the bridge positions. In view of the fact that all of the deuterium in the bridge positions can be accounted for by the pyrolysis of diborane,[1] we conclude that to within experimental error none of the bridge positions in pentaborane participate in the exchange reaction under the conditions of our experiments.

Further qualitative evidence for the difference in rates is provided by the 55.6% deuterium sample, the spectrum of which is shown in Fig. 2c. It is clear that only a trace of the terminal hydrogen remains, whereas the bridge hydrogen peak is still strong.

In view of the fact that the n-m-r technique can, at least partially, resolve the apex and base terminal hydrogens, it is possible to make some deductions on the relative rates of exchange in these positions. Examination of Fig. 3 shows that the small peak y is made up of two lines, one from apex protons on a second smaller contribution from base

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

protons on B^{10}. Admittedly this is not a completely satisfactory situation; however, it is the best place in the spectrum to check on progress of deuteration at the apex position.

The procedure chosen was to run somewhat compressed spectra, similar to those shown in Fig. 1. The heights of the two peaks were measured from the base line and the ratio of the second to the first was calculated. Pentaborane samples containing 0, 5 and 26.5% deuterium gave 0.660, 0.675 and 0.681, respectively, as peak ratios. At least five measurements were made for each deuterium content. If we make a rough calculation of the peak height ratio to be expected, taking into account the composite nature of peak y, the differences between the ratios listed above can be accounted for by a 10% difference in the extents of deuteration in the base terminal and apex hydrogen positions. We therefore conclude that as far as terminal hydrogens in pentaborane are concerned the rates of exchange in the base and apex positions are the same to within ±10%.

It should be pointed out that these studies do not permit us to eliminate mechanisms in which only base or apex terminal protons exchange with BD_3 followed by a more rapid intramolecular exchange between base and apex terminal protons. In view of the properties of pentaborane, however, we feel that this is an unlikely situation and a more probable mechanism is the exchange of deuterium between deuterated borane and each of the terminal hydrogen positions independently.

Interpretation of Abnormalities in Atom Polarization in Terms of Electric Moment

BY C. C. MEREDITH, L. WESTLAND AND GEORGE F WRIGHT

RECEIVED DECEMBER 14, 1956

Dielectric constant determinations of pelletted solid benzoquinone, naphthoquinone and anthraquinone show that the atom polarizations are not abnormally high. Assignment of the non-electronic polarization chiefly as orientation polarization has been confirmed by demonstration of temperature dependence. The distortion polarization of 4,4′-dinitrobiphenyl has also been shown to be normal, so this substance must have an electric moment of 1 *D*. All of these substances must have non-planar and non-linear structures. The so-called abnormal polarization (57 cc.) of ferric acetylacetonate seems to be partly (21 cc.) atomic and partly due to orientation polarization according to dielectric constant determinations of solids and solutions. Since some of these studies contradict earlier evidence the reliability of the measurements and the interpretation is discussed.

A discrepancy has been observed between the total electrostatic polarization and the electronic polarization in certain substances. This discrepancy has been assigned as atom polarization.[1] Typical compounds to which these molecular deformations are attributed are quinones, *p*-substituted biphenyls and metal acetylacetonates, none of which are presumed to contribute to orientation polarization. These types have been considered in the present study.

The Quinones

The difference, $P_T - P_E = 8$–10 cc., for a series of 1,4-benzoquinones would indicate moments of 0.6–0.7 *D* but the orthodox expectation that quinones are planar, as well as the temperature-independent constancy of $P_T - P_E$ among these quinones, has brought forth the theory[2] of an atom polarization due to lateral deformation of "balanced carbonyl dipoles." The apparent dipole moment for 2,5-di-*t*-butylbenzoquinone (= 0.81 ± 0.03 *D* in benzene at 25°)[3] seems to be the only, and minor, exception to this generalization.

In view of this conclusion we sought by use of benzoquinone to test our method[4] for determination of atomic plus electronic polarization by use of solid organic compounds pelletted to maximum density. Already we had found reasonable agreement between our capacitance measurements of pelletted mercuric chloride (P_A = 5 cc.) and the value calculated from vapor phase dielectric constants (P_A = 6 cc.).[5] However our pelletted benzoquinone at 22 ± 2° showed a polarization of 30.1 cc.

This value is slightly lower than the 30.9 cc. determined for the electronic polarization at 5892.6 Å. in benzene solution but is slightly higher than the 28.4 cc. value accepted by many workers[1] and derived from group polarizations (26.8 cc.) plus 1.58 cc. of "exaltation."[6] In any event the derived value deviates from the observed pellet polarization only by the amount expected[7] for normal atom polarization. But this pellet polarization is 7–9 cc. less than the total polarization reported from benzoquinone in solution or in the gaseous state. Therefore the difference cannot be attributed to atom polarization.

In view of this discrepancy we have determined at several temperatures the dielectric constants and specific volumes of a series of solutions of benzoquinone. The precision of these determinations may be judged from Fig. 1 (solutions in benzene) and Fig. 2 (solutions in dioxane) from which the

derivatives of dielectric constant ϵ, and specific volume V, with respect to weight fraction (α and β, respectively) may be evaluated. Calculation by the method of Halverstadt and Kumler[8] for total polarization of the solute

$$P_{20} = \left[\frac{3\alpha V_1}{(\epsilon_1 + 2)^2} + \frac{\epsilon - 1}{\epsilon + 2}(V_1 + \beta)\right] M$$

leads to the polarization values in Table I. This method of calculation seems to be reliable since the dielectric constants for the pure solvents are in close numerical agreement (Table I) with ϵ obtained by extrapolation (Fig. 1 and 2) of $\delta\epsilon/\delta\omega$ to zero weight fraction ω. The maximum deviation shown in Table I (detd. − extrap./$\Delta\epsilon$) is 1%. This would lead to an error (largely from the slope of β) not exceeding 0.5 cc. in P_{20} for benzoquinone where M is 108. Thus there is no necessity for application of the corrections suggested by Smith[1] and the polarizations in Table I have been calculated by use of V, and ϵ of pure solvent. It

[a] This value is reduced to 0.55 D when the polarization (36.1 cc.) is determined at 2600 kc.

is apparent that the polarization is not temperature independent, either in benzene or dioxane. Unfortunately a plot of these polarizations against reciprocal absolute temperature cannot be used to find, by extrapolation to $1/T = 0$, the intercept corresponding to distortion polarization because the Debye relationship is inadequate in this respect for solutions. Nevertheless an orientation polarization rather than an abnormal distortion (atom) polarization seems to be indicated by the temperature dependence.

In order to test this observation further we have determined the dielectric constant of anthraquinone. Previously a moment of 0.6 D was reported without detail[9] but subsequently it was stated that the moment of this substance in the same solvent (benzene) was zero.[10] Actually the solubility in benzene is too low for precise measurement of dielectric constant. According to our study in dioxane at 30° the total solute polarization is 71.5 cc. There is some doubt about the electronic polarization. Fischer and Rogowski give the value 64 ± 2 cc. without stating their source or method. The refraction measured in a 0.3% solution in pyridine gives an electronic polarization for anthraquinone of 61.7 cc.[11] Our extrapolation of apparent dielectric constant *versus* pellet thickness gives a value of P_{E+A} of 61.1 cc. and from this value (and a density at 20° by flotation of 1.44) we calculate the electric moment to be 0.71 D.

We have found that 1,4-naphthoquinone behaves similarly with benzo- and anthraquinone. The combined electron and atom polarization deduced from pellet studies is close (45.9 cc.) to that expected (46.1 cc.) by group moment subtractive calculation from the observed P_E for anthraquinone. When this polarization of the solid is subtracted from the total solute polarization (77.0 cc.) of 1,4-naphthoquinone in benzene at 20° the corresponding moment is found to be 1.21 D. This value differs from that of benzoquinone by about the same amount (0.46 D) as was found in benzene at 25° for 1,2-benzoquinone (5.1 D) and 1,2-naphthaquinone (5.67 D).[12]

It is of interest to consider the source of the apparent moments of these quinones since temperature dependence seems to exclude an abnormal atom polarization. Orientation polarization has been considered previously in terms of molecular distortion due to thermal agitation.[13] Hampson, Hammick and Jenkins have observed that a deviation from planarity of 8° in benzoquinone due to thermal agitation would not be energetically absurd despite the resonance stabilization (13 kcal./mole) reported for benzoquinone.[14] However they aban-

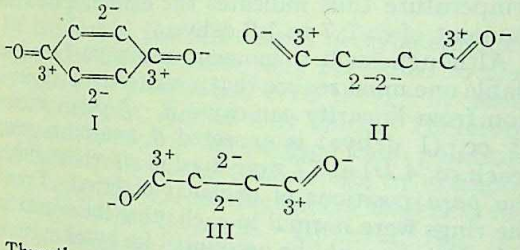
don this explanation because the period of carbonyl bending calculated from the infrared absorption at 120 cm.$^{-1}$ is too small (10^{-13} sec.) to contribute to the orientation polarization.

Of course there is implied in this reservation the common-sense expectation that benzoquinone will be planar in its unactivated, and especially in the orbitally degenerate, state expected for such substances. However, the present experimental evidence requires a factual rather than a common-sense attitude, and some explanation of a permanent moment must be devised. If the group moment for each carbonyl is taken as 2.5 D then the moment for benzoquinone in the vapor phase[2] (0.67 D) may be accounted for by a 6° deviation of these groups from planarity.

In this circumstance a "boat" type of structure may be postulated in which the atom cores may be disposed in an electronic field such as is described as structure I, in Fajans' sense.[15] The 3$^+$C atom cores may then be considered to be disposed symmetrically within the field, forming a constellation such as II (boat) rather than the chair form III, in which a lesser symmetry obtains, especially with respect to the 3$^+$C atoms.



I II III

Thus the non-planar structure II has been defined, like that of water or ammonia, as the lowest energy state of free benzoquinone. This structure might also be considered as a distortion caused by interaction with the solvent, and therefore might resemble iodine in polarizable solvents.[16,17] This latter relationship is doubtful. The excess of polarization over that accountable as electronic, which we have found for benzoquinone to be temperature dependent, has previously been observed in carbon tetrachloride, hexane and in the vapor state.[1,2] Under these conditions iodine does not exhibit orientation polarization. Furthermore the behavior of benzoquinone in solvents like benzene and dioxane (in which iodine has a moment) is unique with respect to the type of temperature dependence that has been observed.

Although it is recognized that the extrapolation of total polarization *versus* reciprocal temperature to $1/T = 0$ is applicable only in vapor-phase studies we have plotted the polarizations of Table I against $1/T$ in Fig. 3. It may be seen that the benzoquinone polarizations in benzene (A, slope 31×10^3) intersect the line (B, slope 15×10^3) joining the polarizations determined in dioxane at a point corresponding to a polarization of 39.3 cc. By reference to Fig. 4 in which these data (after subtraction of $P_{E+A} = 30.1$ cc.) are expressed in terms of electric moments *versus* temperature,

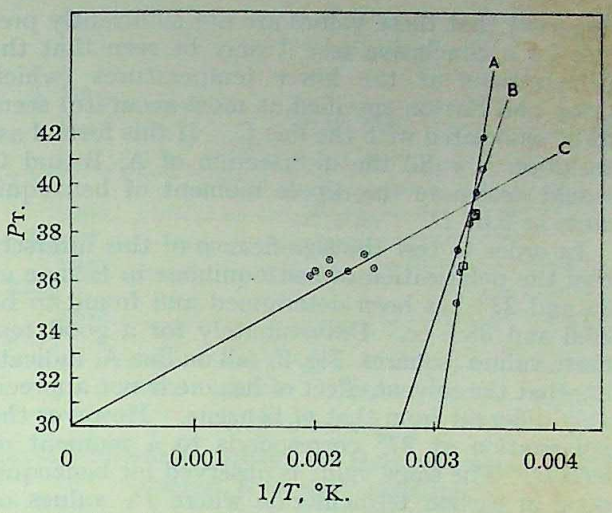


Fig. 3.—Total polarization *vs.* reciprocal temperature, benzoquinone.

it may be seen that the deviations from the moment (0.67 D) calculated from vapor phase studies indicate both positive and negative solvent effect. It is of interest that the model, II, suggested for benzoquinone is of a type (where the axis normal to the dipolar axis is relatively long) for which such deviations are expected.[18]

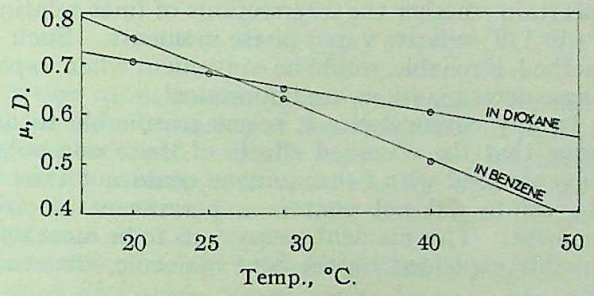

Fig. 4.—Dipole moments *vs.* temperature, benzoquinone.

One should not infer that benzoquinone is abnormal because of these moment variations with respect to temperature and solvent. Such variations are characteristic of most polarization studies but they seem insignificant except when the moment is the square root of a small number. Nevertheless efforts have been made to find theoretical justification for solvent effects (ref. 1, p. 127). However, no useful quantitative generalizations have been found because the electrostatic fields surrounding the molecules cannot be defined precisely.

In view of the difficulty of discovering molecular geometry which might rationalize the solvent effect (ref. 1, p. 145) we have utilized an empirical relationship shown in Fig. 3. We suggest that the intersection of the polarization lines A (benzene solutions) and B (dioxane solutions) may specify the point where solvent effects are minimal or absent. A line, C, has been drawn between the intersection and the point at $1/T = 0$ which represents the distortion polarization (30.1 cc.) determined from the dielectric constants of benzoquinone pellets. The points along this line, C, record the polarization data determined by Coop and Sutton for benzoquinone in the vapor phase. Although it is

apparent that these values are not sufficiently precise for a conclusive test it may be seen that the polarizations at the lower temperatures (which Coop and Sutton specified as most accurate) seem to be associated with the line C. If this formal association is valid the intersection of A, B and C would designate the dipole moment of benzoquinone as 0.67 *D*.

In order to test the significance of this intersection the polarization of benzoquinone in hexane at 35 and 27° has been determined and found to be 36.6 and 38.7 cc. Unfortunately for a good test these values (squares, Fig. 3) fall on line A, indicating that the solvent effect of hexane is not appreciably different from that of benzene. However the polarization at 27° corresponds to a moment of 0.65 *D*. The same value is observed for benzoquinone in carbon tetrachloride where P_T values of 41.0, 38.8 and 36.0 cc. are obtained at 20, 27 and 40°, respectively. Therefore our results designate the benzoquinone moment as 0.65–0.67 *D*.

Of course some rational alternative to the Debye relationship must eventually be found to equate $\delta P/\delta T$ (11.146) for benzoquinone in benzene and $\delta P/\delta T$ (5.409) in dioxane with the slope of line C in Fig. 3. Meanwhile it seems worthwhile in future to examine the polarizations of candidate substances in several solvents at different temperatures in order to ascertain whether the intersections of lines relating P_T to $1/T$ indicate vapor phase moments. Such a method, if reliable, would be convenient when vapor phase determinations are impractical.

In any circumstance it seems reasonable to assume that the observed effects of these non-polar solvents used with benzoquinone could not exist if the solute did not contain a permanent electric moment. This moment seems to us to be most reasonably explained by the bent molecule, structure II.

The evidence from dielectric constant evaluation of pelletted benzoquinone, which has led us eventually to an assignment of electric moment in this compound, was not entirely unexpected. Previously a small discrepancy between total and electronic polarization of diphenylmercury[19] was shown by measurement of pellets not to be due to abnormal atom polarization.[20] The $P_T - P_E$ difference was interpreted as an electric moment due to angularity in the C–Hg–C bond. Although this condition might seem to be unusual it may reasonably be attributed to the distortion of the "O" shell of the bulky mercury atom.

4,4′-Dinitrobiphenyl

The foregoing examples seem to show that planarity and linearity are not always necessary for electronic orbital degeneracy. It has seemed worthwhile to re-investigate other substances to which abnormal atom polarization has been assigned largely on the reasonable belief that they were geometrically planar or linear. We have chosen 4,4′-dinitrobiphenyl for which the difference between the total polarization and that part attributable to electron polarization (87.5 cc. minus 66 cc.) was designated as a high atom polarization of 21.5 cc. The alternative dipole moment (1.0 *D*) was considered only as an apparent one, because of the expectation that the substance would have axial symmetry.[21]

We have prepared pellets from 4,4′-dinitrobiphenyl and have extrapolated the ratios of apparent dielectric constant with respect to thickness to obtain the dielectric constant, free from edge-effect error. This extrapolation (A), together with those of benzoquinone (B), naphthoquinone (C), anthraquinone (E), mercuric chloride (F) and ferric acetylacetonate (G), are shown in Fig. 5. Calculation gives P_{E+A} for 4,4′-dinitrobiphenyl as 66.8 cc., or only 0.8 cc. higher than that ascribed to electronic polarization. Therefore the atom polarization is not abnormal.

In order to confirm that the polarization in excess of P_{E+A} is due to an electric dipole in 4,4′-dinitrobiphenyl we have determined the dielectric constants of benzene and dioxane solutions at 40°. The total polarizations at this temperature are 77.7 and 80.3 cc., the former being about 10 cc. lower than was observed by LeFèvre and Vine at 25° in benzene.[21] The dependence of polarization upon temperature thus indicates the existence of a real moment of *ca* 0.7 to 1.0 debye.

Although such a moment seems to be appreciable one must realize that a relatively small deviation from linearity can cause it. A polarization of 21 cc. (1 debye) is expected if two nitro groups (each *ca*. 4 *D*) at 7° were fixed in *cis* relationship at the *para* positions of coplanar biphenyl. Even if the rings were normal to each other the orientation polarization could be accounted for by nitro groups at an angle of 14.5° from the planes of the rings.

Actually this non-linearity is predicted in a sense by X-ray crystallographic studies. The space group assigned to crystalline 4,4′-dinitrobiphenyl[22] is the non-centrosymmetric "Pc." As Bunn has pointed out[23] centrosymmetrical molecules do not in fact assume non-centrosymmetrical space group arrangements. Furthermore the nitro groups in *meta*-dinitrobenzene are thought to be inclined from the plane of the benzene ring.[24]

Metal Acetonylacetates

Perhaps the most important examples of high atom polarization have been those of the metal acetylacetonates. A difference between total and electronic polarization at one temperature was first observed by Smith and Angus[25] for beryllium acetylacetonate. Later a careful study in a series of solvents at one temperature showed the total polarization to be reasonably constant,[26] thus excluding solvent effect as a cause of the difference between total and electronic polarization. Furthermore the same authors found that in decalin over a temperature range of 298–415° only a small down-

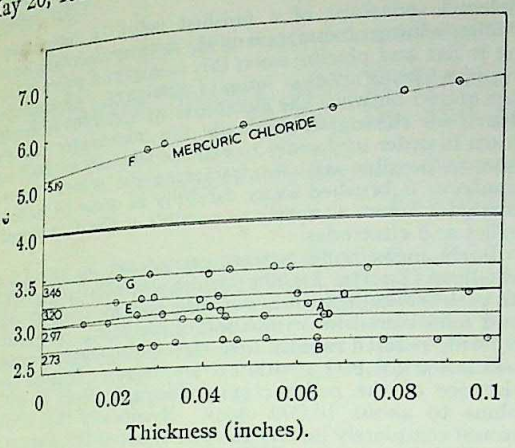

Fig. 5.—Dielectric constant *vs.* thickness of pellets.

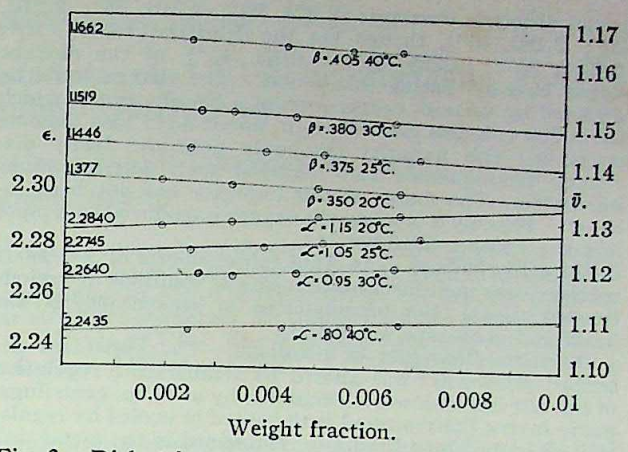

Fig. 6.—Dielectric constants and molar volumes *vs.* weight fraction, ferric acetylacetonate.

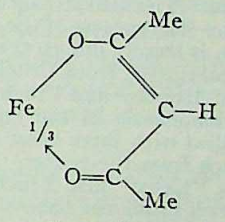
ward drift (86.91 to 85.10 cc.) in total polarization occurred. This temperature independence was confirmed[2] by vapor phase measurements from which the drift in total polarization was found to be even less (86.6 to 86.0 cc. from 185 to 255°) than was found for the solution measurements. Upon this evidence the difference between total and electric polarization (25–28 cc.) was designated as atom polarization.

By implication the other eight acetylacetonates examined by these workers were presumed to display high atom polarization even though no temperature coefficient studies were made. Therefore we expected to confirm the assigned atom polarization of 57 cc. for ferric acetylacetonate by extrapolation of our dielectric constant-pellet thickness ratios to zero pellet thickness. However, Fig. 5G shows a dielectric constant of 3.46. Since the density of ferric acetylacetonate is found to be 1.41 the P_{E+A} value by this measurement is only 112.7 cc. If the electronic polarization value (91.5 cc.) of Finn, Hampson and Sutton is subtracted from this number an atom polarization value of 21.2 cc. remains, by contrast to 57 cc.

In view of this large discrepancy we have determined the total polarization of benzene solutions of ferric acetylacetonate at 20, 25, 30 and 40° and have indeed found a temperature dependence corresponding to total polarization (calculated from α and β of Fig. 6) of 158.8, 150.6, 144.5 and 133.6 cc., respectively. These polarizations correspond to permanent moments of 1.48, 1.35, 1.25 and 1.05 D. With reference to the vapor phase study[2] these moments include solvent effects, both positive and negative, depending on the temperature. Therefore according to these experiments ferric acetylacetonate contributes both atomic and orientation polarization in the electric field. Perhaps it is fortuitous that the atomic polarization 21.2 cc. is approximate to that of beryllium acetylacetonate which has been shown not to have (and on the basis of the tetrahedral symmetry of beryllium would not be expected to have) a permanent moment.

The structural feature of ferric acetylacetonate which gives rise to an electric moment cannot be specified with assurance. In absence of orientation polarization one is tempted to attribute complete bonding degeneracy to the system, as was proposed by Finn, Hampson and Sutton. In the face of an observed orientation polarization one can in resonance theory easily rescind this attitude. Furthermore as Smith (p. 279) has pointed out[1] the constellar oscillation of the non-planar six-membered rings in this coördinate structure may give rise



to either atom or orientation polarization depending on the relationship of this frequency to that of the applied field. Finally there is no compelling reason to assume that the electronic and nuclear fields are centrosymmetrically coincident in this substance.

The authors wish to thank the National Research Council of Canada for generous financial support and Mr. Henry Sawatzky for experimental aid.

Experimental

Reagents.—Mercuric chloride was Mallinckrodt reagent, used as received. Benzoquinone was purified by repeated crystallization from 95% ethanol, m.p. 113.5°, d^{20}_4 1.313. Naphthoquinone, obtained as a by-product in naphthalene oxidation to phthalic acid, was five times crystallized from 95% ethanol using Darco decolorization, m.p. 148.4°, d^{20}_4 1.385. Anthraquinone (Kahlbaum) was twice crystallized from chloroform (38 ml. per g.), m.p. 281°, d^{20}_4 1.440. The 4,4′-dinitrobiphenyl was crystallized from ethanol (with Darco) and benzene, m.p. 240.9–241.8°, d^{20}_4 1.445. The ferric acetylacetonate was prepared by Claisen's method[27] in 82% yield, m.p. 179–180°, and was thrice purified by solution in benzene (3.5 ml. per g.) and then addition of petroleum ether (b.p. 60–70°, 4 ml. per g.), m.p. 181.5°, d^{20}_4. All melting points are corrected against reliable standards. The melting points were found to be identical when these substances were recovered after determinations of dielectric constant except for benzoquinone where the melting point was decreased to 112.5°. All recoveries from solution were effected by vacuum evaporation at room temperature.

Solvents.—Benzene and dioxane were purified as described previously but were maintained and delivered under positive pressure of nitrogen freed from oxygen, water and carbon dioxide. No metallic sodium was used in the storage containers. The initial dielectric constant (2.284, 20°; 2.262, 30°; 2.245, 40°) and densities (0.8788, 20°; 0.8681, 30°; 0.8628, 35°; 0.8575, 40°) of the benzene were unchanged after six months of such storage. However the

Digitized by Arya Samaj Foundation Chennai and eGangotri

initial dielectric constants (2.224, 20°; 2.216, 25°; 2.210, 30°; 2.189, 40°), though not the densities (1.0336, 20°; 1.0278, 25°; 1.0225, 30°; 1.0109, 40°), of the dioxane slowly changed during this period. The change could be detected by vacuum evaporation of a 50-ml. aliquot which left a few colorless crystals, m.p. about 45°; also dioxane containing this impurity (probably peroxide) badly discolored benzoquinone and rendered such determinations unreliable. The source of this impurity has not been located. Possibly it involves the oxygen introduced by a pipet into the nitrogen-filled bottle.

Refractive Indices.—An Abbé refractometer of ±0.00002 precision was used for measurements of solutions of various concentrations. For benzoquinone in benzene $\delta n/\delta\omega$ was 0.042 and in dioxane was 0.120.

Dielectric Constants of Solutions.—The apparatus described previously[4] was altered by temperature regulation of the test cell with water circulated by a 3/4 hp. centrifugal pump from a thermostated bath heated or cooled by regulation prescribed by a thermistor embedded in the metal wall of the test cell. This thermistor was balanced in a Wheatstone bridge against a second, matched, thermistor immersed in the master bath (±0.01°) in which the density determinations were made. The stray inductance errors in the measuring system were evaluated by the substitution method and were found to cause a positive capacitance error at the standard condenser of 16–22% (non-linear) at 5 mc., 3.6–5% (non-linear) at 2.6 mc., but only 0.1% at 500 kc. and 0.002% at 220 kc. All measurements but one have been carried out at 500 kc. The field strength is about 1 e.s.u.

The Pellet Press.—The success of the solid dielectric constant determination is largely due to the quality of this device. This die is fabricated from Crucible Steel Co. "Ketos" bar 2 inches in diameter and 1 inch long axially drilled centrally for accommodation of the finely powdered substance and also drilled with three holes spaced equally at a distance of 0.75 inch from the center. These holes match threaded holes in a "Ketos" disc 2 inches in diameter and 0.75 inch thick which forms the base of the die. The two pieces are held tightly together by means of three 0.125 × 1.7 inch cap screws. Both pieces are hardened to Rockwell C of 60 and the flat surfaces are finely surface-ground. The axially central hole also is ground to size after hardening.

The surface-ground surfaces between which the powder is compressed to a pellet are presented by two pieces of hardened drill rod finely turned to the exact (+0.000–0.0001 inches internal) diameter of the centrally axial hole in the top member of the die assembly. The bottom piece of drill rod is 0.125–0.375 inch long depending on the life of the die, which gradually expands after long usage where the powder is compressed. This short piece of drill rod is expelled in front of the finished pellet after removal of the bottom plate. Pressure both for compression of the powder and extrusion of the pellet is provided by the other piece of drill rod which is 1.25 inch long; its upper surface obviously need not be surface ground since it receives the ram of the hydraulic press.

All metal parts should be washed with an efficient solvent (usually acetone) after each pellet extrusion, then liberally oiled. The oil is thoroughly wiped away before preparation of the next pellet.

Pellets.—The consolidation of pellets either 0.2500 inch or 0.2675 inch in diameter and of various thicknesses is accomplished as has been described previously[4] under a hydraulic pressure of 10,000 p.s.i. but not *in vacuo*. It is important that the finely powdered substance be distributed uniformly in the die, by twisting the pressing pin without appreciable load, before the hydraulic ram is applied. The dielectric constant of a finished pellet is determined by placing a lump of amalgam on the bottom electrode, smoothing it flat and placing upon this amalgam a pellet upon the top of which is another lump of amalgam. After the pellet is centered between the electrodes by means of a chamfered sleeve on the upper electrode the micrometer is screwed down in order uniformly to extrude laterally as much amalgam as possible without fracturing the pellet. Excess of amalgam is brushed away carefully in order to leave both amalgam layers as nearly as possible at the diameter of the pellet and electrodes.

Early measurements were carried out by use of a zinc amalgam (Zn:Hg, 1 g.:6 g.) which was sufficiently inert that all pellets except those of mercuric chloride could be cleaned and remeasured for evaluation of precision. The mercuric chloride reacted rapidly with the zinc amalgam, preventing oscillation (V.F.O.) within a few minutes because the resistance of the pellet rapidly decreased from 80–100,000 ohms to about 10,000 ohms. Eventually this amalgam would completely liquefy the pellet, but at the moment that the V.F.O. ceased to function because of conductivity the pellet face was apparently unaffected when the amalgam was completely brushed from it. However the cleaned pellet was still a conductor when an inert (tin) amalgam replaced that of zinc. This phenomenon has not been explained. Successful measurements of new mercuric chloride pellets can be made either directly with tin amalgam or with zinc amalgam if the surfaces of the pellets are first coated with an invisible layer of Vaseline.

Amalgams.—The zinc amalgams deteriorate after a few days in contact with air so amalgams with other metals have been examined. Indium and iron amalgams are gritty while silver amalgam is too resilient. Copper amalgam is satisfactory but best is a tin amalgam (1 g. Sn:3 g. Hg) which is always briefly ground, before each application, in the mortar in which it has been prepared by grinding together the two metals. This amalgam is stable for weeks.

Dielectric Constants of Solids.—Determinations have been carried out with the apparatus described previously and also with a duplicate circuit in which the precision was increased fivefold by reducing the variable capacitance in the V.F.O. to 110 pf. The determinations were made in a room at 20 ± 1° with 45 R.H. In order to avoid stray capacitance–inductance errors the dielectric constant determination[4] was altered. The thickness of the pellet was first determined with the pellet test condenser. Then the pellet and amalgam were installed and the V.F.O. was balanced to zero beat with respect to the 500 kc. crystal-controlled oscillator. The pellet and amalgam were then removed quickly and thoroughly and the pellet condenser readjusted to zero beat. In a convenient variation of this technique both adjustments rapidly could be made 50 cycles off zero beat by inclusion of a Hewlett–Packard frequency meter into the circuit. In either circumstance the dielectric constant was evaluated as: thickness of pellet *versus* equivalent thickness of air.

Dipole Moments of 4,4′-Dinitrobiphenyl.—Dioxane solutions at 40° gave a value of $d\epsilon/d\omega = 1.00$ extrapolating smoothly to $\epsilon_1 = 2.1914$ and of $dV/d\omega = 0.425$ extrapolating to $V_1 = 0.9895$. Total polarization (80.3 cc.) thus may be expressed after deduction of $P_{E+A} = 66.9$ cc. as $\mu = 0.83\ D$. Benzene solutions at 40° behaved erratically but a least squares evaluation of 12 analyses gave $d\epsilon/d\omega = 0.55$ extrapolating to $\epsilon_1 = 2.2419$ and $dV/d\omega = 0.445$ extrapolating to $V_1 = 1.1667$. The calculated total polarization (77.7 cc.) thus leads to a moment of 0.74 D.

The Microwave Spectra and Molecular Structure of 1,1,1-Trifluoroethane and its Mono-, Di- and Trideutero Derivatives[1]

BY WALTER F. EDGELL, GEORGE B. MILLER[2] AND JONATHAN W. AMY

RECEIVED OCTOBER 22, 1956

The microwave spectra of CF_3CH_3, CF_3CH_2D, CF_2CD_2H and CF_3CD_3 have been observed in a Stark modulated sweep spectrometer of the Hughes and Wilson type. The frequencies of R-branch transitions in all four molecules are given and an extensive number of Q-branch transition band-heads corresponding to $J \geq 9$ are reported for the asymmetric molecules. Moments of inertia have been evaluated and a molecular structure consistent with these data has been calculated assuming a rigid rotor model and also that C–H = C–D and ∠CCH = ∠CCD. The following structure was obtained: C-C = 1.530 ± 0.005 Å., C–F = 1.335 ± 0.005 Å., C–H = C–D = 1.085 ± 0.008 Å., ∠CCF = 111°02′ ± 17′ and ∠CCH = CCD = 108°19′ ± 35′.

Introduction

The molecular structure of methylfluoroform has been investigated by use of electron diffraction[3–5] and microwave spectroscopy.[6] The results of the electron diffraction work are summarized in Table I, together with a set of parameters which is compatible with, but not proved by the microwave data of reference 6.

TABLE I

PREVIOUS RESULTS ON CF_3CH_3

	Ref. 3	Ref. 4	Ref. 5	Ref. 6
C-C, Å.	1.45 ± 0.04	1.53 ± 0.04	1.52 ± 0.04	1.54
C-F, Å.	1.35 ± 0.03	1.36 ± 0.02	1.33 ± 0.02	1.33
C-H, Å.	.....	.....	.....	1.093
∠FCF	108.5 ± 2°	107 ± 3°	.....	109°
∠HCH	.....	.....	.....	109°28′
∠CCF	112 ± 2°	.....	111.5 ± 1.5°	.....

Because of the inconsistencies in the results listed above, it seemed desirable to investigate the microwave spectra of methylfluoroform and its deuterated derivatives in order to establish a definitive set of structural parameters. This effort is part of a larger program dealing with the study of the structure of simple fluorinated molecules and it is hoped that the results herein described will be helpful in extending present day knowledge and understanding of the nature of chemical bonding in such molecular species.

Experimental

The spectrometer used in this investigation has been described elsewhere.[7] Comparison with previous measurements made on the ammonia inversion spectrum[8] indicates that the spectrometer has a precision of ±0.2 mc. or better and is sensitive enough to detect lines having an absorption coefficient of 10^{-7} cm.$^{-1}$. All measurements in this work were made in a K-band wave guide cell. Quantitative intensity measurements were not made.

The samples used by us were prepared in this Laboratory[9] for a study of the Raman and infrared spectra of these molecules. Mass spectral analysis showed that the deuterated samples contained not more than 12% of the other molecular isotopes as impurities. Although the compounds were not further purified, no lines were found to be common to more than one spectrum.

Interpretation of the Spectra

In order to predict the main features of the spectra of these four molecules, the structural parameters of reference 5 were assumed to be correct. It was found that the K-band spectrum (*ca.* 17,000–37,000 mc.) of each symmetric top should consist of only two R-branch transitions, corresponding to $J:1 \rightarrow 2$ and $J:2 \rightarrow 3$, and, perhaps, some satellites involving the expected low frequency torsional modes.[10,11]

The two asymmetric rotors should deviate only slightly from a prolate symmetric top ($\kappa = -0.90$ for CF_3CH_2D and $\kappa = -0.82$ for CF_3CD_2H). Accordingly, each of the R-branch lines of the symmetric rotors is replaced by a pattern consisting of three closely spaced lines for the $J:1 \rightarrow 2$ transition and five for $J:2 \rightarrow 3$. These lines should still be accompanied by some torsional satellites. In addition, a rather extensive, although not necessarily complicated, Q-branch structure should occur. These transitions were predicted to form bands having very close line spacing. Bands associated with transitions involving $J \geq 9$ were expected to appear throughout the K-band.

The only lines from which definite assignments were made were in the R-branches of all four molecules. The extreme simplicity of the R-branch structure made identification very straightforward. Torsional satellites were identified by comparing their relative intensities at room and Dry Ice temperatures. Table II gives the observed frequencies and their assignments. Rotational constants evaluated from these assigned frequencies are presented in Table III. The calculated frequencies listed in Table II are based on these constants.

As indicated in Table III, there is a rather large uncertainty in the constants, A. This is due to the fact that, as mentioned previously, CF_3CH_2D and CF_3CD_2H are only very slightly asymmetric rotors. For such small asymmetries the frequencies of the $^aR_{0,1}$ transitions depend on the rotational constants in such a way that an error of the order of 0.01 mc. in frequency is sufficient to cause an error of the order of 1 mc. in the rotational constant, A.

	$A = (5409 \pm 240)$
	$B = (4804.83 \pm 0.04)$
	$C = (4743.29 \pm 0.04)$

The use of the Q-branch spectra to eliminate the uncertainty in these constants, A, was found to be unsatisfactory due to the difficulty of making proper assignment to each individual line within the various series. In order to make specific assignments of these lines it would be necessary to be sure that the observed band-heads were the true ones. The distribution of intensities within each series, however, is such that it is by no means certain that the true band-head was observed. An alternative method of assignment would involve making precise assumptions as to the effect of centrifugal distortion but, in view of the lack of relevant experimental data, such assumptions did not appear to be justified.

In order to obtain frequencies leading to a precise evaluation of A, one would have to observe transitions associated with the component of the dipole moment along the axis perpendicular to the a-axis and lying in the molecular plane of symmetry. These would be ${}^bR_{1,1}$ transitions for CF_3CH_2D and ${}^cR_{1,0}$ transitions for CF_3CD_2H. Calculations based on the assumed structure and on the measured dipole moment of methylfluoroform[12,13] showed that the dipole components in question could be expected to be about one hundredth the value of the dipole components along the a-axes. Hence, one would expect these transitions to be very weak and, indeed, no such transitions were observed in spite of a careful search of the regions in which they would be expected.

Table IV lists the apparent band-heads and the number of transitions observed in each of the Q-branch series of the asymmetric tops.[14]

The structure and location of each Q-branch series is in good agreement with predictions based on a rigid, slightly asymmetric rotor model. In particular, one expects and finds that the lines will be closely spaced, with separations of a few megacycles, for the lower J-values in each series, and spacing increasing steadily toward higher J's (lower frequencies). From the apparent beginning of each series, the intensities rapidly approach a maximum with increasing J and then drop off gradually as J is further increased.

Determination of the Structure

Methylfluoroform and its deuterated derivatives can be described structurally by the general molecular formula CF_3CX_2Y. Assuming that each molecule is a rigid rotor and that isotopic substitution at any one atom affects only the coördinates of that atom, one finds that seven parameters completely describe the structure above.

From the four isotopic species, microwave data yield a total of eight moments of inertia which are related to the structure of CF_3CX_2Y by eight nonlinear equations containing the seven parameters as unknowns. The exact form of these equations is determined when the parameters are explicitly defined. However, of the eight moments available,

only six are known with sufficient accuracy to permit their use in determining the structure. Taking into account also the fact that the moments of inertia are not very sensitive to the locations of the relatively light hydrogen and deuterium atoms, it seemed best to assume that the geometry of the molecule, CF_3CX_2Y, was completely unaffected by isotopic substitution. The configuration then depends on only five parameters which must be evaluated using a method of successive approximations.

The results of these considerations are presented in Table V in the form of a set of bond distances and angles giving the best agreement with the observed moments of inertia. Table VI compares the results of this set with the observed moments. It

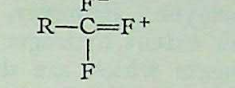
[a] The uncertainty in these moments is ±6.8 whereas the uncertainty in all other moments is ±0.007.

can be seen that the calculated values are in good agreement with the observed ones. The structural parameters determined in this work are in excellent agreement with the values obtained by Brandt and Livingston[5] (Table I).

The C–F bond distance and the CCF angle are consistent with those values found in other molecules containing the CF_3 group.[15] In particular, comparison with the fluoromethane series[16] shows that the C–F bond distance determined for CF_3CH_3 has about the expected value for a singly bonded CF_3 group (C–F = 1.385 Å. in CH_3F, 1.358 Å. in CH_2F_2 and 1.326 Å. in CHF_3). It has been postulated[16] that the slight shortening of the C–F bond and slight closing of the FCF angle in CHF_3 can be associated with the occurrence of resonance structures[17] of the type



(I)

It is certainly conceivable that structures of this type can also contribute to the slight closing of the tetrahedral umbrella of the CF_3 group in CF_3CH_3.

Since the C–H distance in Table V is based upon the assumption that C–H = C–D, it probably represents an average value lying somewhere between the true values of the C–H and C–D bond distances. By analogy with the results obtained by Miller, *et al.*,[18] for the methyl halides, the C–D bond could be expected to be shorter than the C–H bond by perhaps 0.009 Å.

Heats of Adsorption of Hydrogen and Helium on Prepared Surfaces*

BY WILLIAM A. STEELE AND J. G. ASTON

RECEIVED OCTOBER 31, 1956

Measurements have been made of the heats of adsorption of helium on titanium dioxide powder which had varying amounts of argon preadsorbed on it. Some measurements of the heats of adsorption of hydrogen were also made on similar systems. It is assumed that high energy sites for physical adsorption occur at surface roughnesses and faults. The experimental data are discussed in terms of this model, and it is seen that this work provides an excellent confirmation of this hypothesis.

Introduction

In a recent publication by the authors and Tykodi,[1] an analysis was made of the isotherms and heats of adsorption of a number of rare gases on titanium dioxide. The data were fitted to a model in which lateral interaction in the adsorbate was neglected, but in which the surface heterogeneity of the adsorbent was taken into account. A single site distribution function was taken to characterize the titanium dioxide surface in all cases. The physical considerations underlying the choice of distribution function were as follows: the major portion of the adsorption sites (about 60%) were considered to be those formed by the flat surface of the adsorbent, having energies which could be estimated by calculating the energy due to dis-

persion forces between a gas atom and a planar titanium dioxide surface[2]; the remainder of the adsorption sites were then assumed to be due to imperfections in the surface structure (so-called topographical heterogeneity) such as cracks, holes, grain boundaries, etc. On such a site, an adsorbed atom would have a larger interaction with the solid than on a planar site, due to adjacent surfaces making angles (other than zero) with the planar surface.

This model for adsorption could not be expected to work too well for neon or argon, since these adsorbates exhibit appreciable lateral interaction near the monolayer. However, adsorbed helium, and to a lesser extent hydrogen, should give isotherms and heats which are determined almost exclusively by the site distribution of the adsorbent. The actual site distribution chosen was admittedly a rough approximation to reality, but agreement between experiment and theory was sufficient to inspire further investigation.

The present paper is concerned with an attempt to verify the assumptions made concerning the source of surface heterogeneity of the titanium dioxide used previously. To this end, the heats of adsorption of helium and hydrogen were measured on titanium dioxide powder which had had varying amounts of argon preadsorbed upon it. If the heterogeneity was actually due to imperfections in the surface, a sufficient amount of preadsorbed argon would be expected to fill in the high energy sites, effectively removing them and replacing them by a planar surface composed partly of argon atoms and partly of titanium dioxide molecules. The application of the Kirkwood–Müller formula[3] shows that the energy of interaction of a helium atom with an argon crystal is about the same as that of a helium atom with a titanium dioxide crystal. Thus, the preadsorption of argon on a titanium dioxide surface should produce a roughly uniform surface for helium adsorption. In a preliminary communication[4] it was shown that about one-half layer of argon is sufficient to remove almost all signs of heterogeneity in the heats of adsorption of helium. The results of an extensive investigation of this effect will be presented here, and also the experimental techniques used will be discussed in some detail.

Results and Discussion

Measurements were made of the heat of adsorption of helium on a bare titanium dioxide surface, on titanium dioxide plus 0.36 layer of argon, 0.60 layer and 1.05 layers. The temperatures of measurement were from 10–17°K., and the adsorption pressures of the helium were less than 100 cm. at all times. Under these conditions, no multilayer adsorption can occur, and the correlation of the measured heats with the site distribution in the surface is very nearly complete. The results of these experiments are shown in Fig. 1, where isosteric heats of adsorption of helium in cal./mole are plotted against the amount adsorbed in units of cc.-S.T.P. per gram of adsorbent. Some heats measured by Aston, Mastrangelo and Tykodi[5] on another sample of the same titanium dioxide as that used in this work are included for comparison. The precision of the data is within the estimated 5% (see Experimental), and the corrected calorimetric heats agree well with those calculated from the isotherms. Even the preadsorption of 0.36 layer of argon markedly reduces the heterogeneity of the surface and removes all sites with heat of 400 cal./mole or greater. The heat curves are such that in terms of the topographical model only a small number of sites of energy 250–400 cal./mole are left, and this residue of high energy sites is filled in by 0.25 additional layers of argon.

No significant change can be detected in the shape of the curve of heat of adsorption *versus* coverage when one adds 0.45 layer of argon to a surface which already holds 0.60 layer, although the curve is not quite flat. If the energy of interaction of a helium atom with a titanium dioxide surface was not essentially identical with the energy of interaction with a titanium dioxide substrate covered with a monomolecular layer of argon, one would expect that the heat of adsorption curve would change significantly upon the addition of argon to uncovered titanium dioxide surface. Thus, one may conclude, in agreement with the result calculated from the Kirkwood–Müller formula, that the energy of interaction of an adsorbed atom with titanium dioxide is identical to the interaction energy with titanium dioxide coated with argon, within the accuracy of these experiments.

There is, however, a small decrease in the heat of adsorption with coverage even in the system where a full layer of argon has been preadsorbed. It is suggested that this residual heterogeneity is due to the fact that preferred sites will occur on a perfectly planar surface, due to the periodic nature of the surface potential energy. For instance, the maximum calculated energy due to dispersion forces is roughly 100% greater for a helium atom over the center of a lattice cell in the surface of a simple cubic argon-like crystal than the energy of interaction when the helium atom is over a corner of the lattice cell.[6] Since the energy of interaction of helium with a solid such as titanium dioxide is due mainly to the dispersion energy of the adsorbed atom with the atoms in the solid, one would certainly expect some decrease in the differential molar heats of adsorption of helium on such a solid, independent of any topographic effects.

In Fig. 2 are displayed the heats of adsorption of hydrogen *versus* coverage for two surfaces: bare titanium dioxide and titanium dioxide plus 0.60 layer of preadsorbed argon.

The heats of adsorption of hydrogen on the titanium dioxide plus 0.6 layer of argon show no signs of topographical heterogeneity. The effect of the residual heterogeneity mentioned in the previous paragraph seems to be of the same order of magnitude for hydrogen as for helium. How-

ever, the higher energy sites fill in more rapidly in the case of hydrogen adsorption.

When the heat curves for helium and hydrogen adsorbed on bare titanium dioxide are compared, it is apparent that a large fraction of the high energy sites seems to be absent when the hydrogen is used as an adsorbate. For instance, the number of sites of energy two or more times the energy of adsorption on the flat surface is quite large when helium is adsorbed. However, almost no such states are available for hydrogen adsorption. At first glance, it would seem that such an effect is in contradiction to the hypothesis that the high energy sites are found in cracks or holes in the titanium dioxide crystals. It is unlikely that this unavailability of high energy sites for hydrogen could be due to any great extent to the difference in molecular dimensions, since the two molecules are very similar in size (the collision diameters of hydrogen and helium are 2.9 and 2.6 Å., respectively[7]).

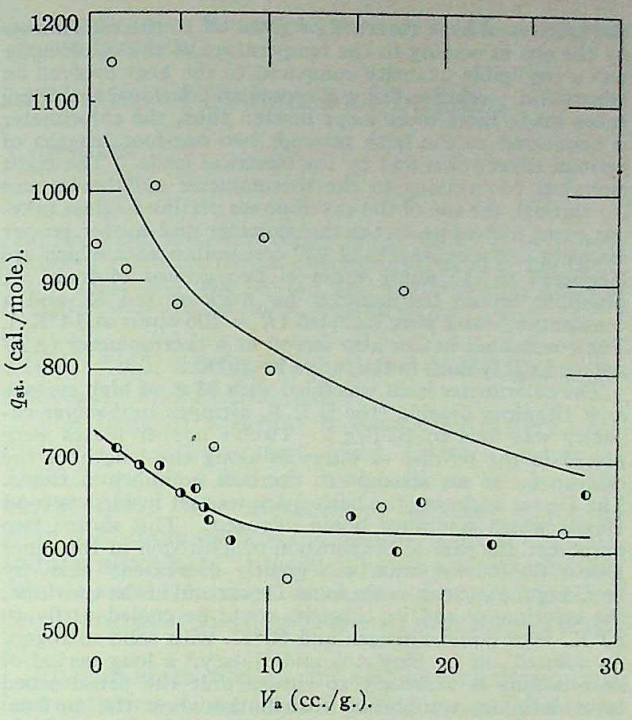

Fig. 2.—Isosteric heat of adsorption of hydrogen on various surfaces: O, parahydrogen on bare titanium dioxide; ◑, parahydrogen on titanium dioxide plus 0.60 layer of preadsorbed argon; ◐, normal (room temperature equilibrium) hydrogen on titanium dioxide plus 0.60 layer of preadsorbed argon.

The most probable explanation has its basis in the fact that the thermal energy of hydrogen molecules at the temperatures of these experiments is quite small compared to the energy of binding to the surface. Thus, the hydrogen will be almost completely immobilized upon adsorption. In particular, the rate of diffusion into the surface faults which give rise to the high energy sites may be negligibly small. Indeed, the adsorbed phase is most probably in a metastable state during the time span of an experiment. This line of reasoning is further supported by the extremely long "equilibrium times" (see Experimental) and by the fact that the scatter of the data for the bare surface is considerably larger than the estimated precision of the method. (For these reasons, it did not seem worthwhile to make any more extensive measurements at low coverages of adsorbed hydrogen than those presented here.)

Experimental

The calorimeter used in this work was a modified version of the one used by Frederikse.[8] This system is designed to operate with the surroundings kept at a constant temperature close to that of the calorimeter by regulating the vapor pressure of the bath. The temperature rise during any process was then found by extrapolation of the equilibrium drift rates. Adequate thermal isolation of the calorimeter from the surroundings could be obtained by maintaining a good vacuum in the envelope which separated the calorimeter from the bath. Two german silver filling tubes were led through the bath space to the top of the vacuum envelope. These tubes make two loops in the bath just above the vacuum envelope to ensure that the incoming gas passes through at least one foot of tubing at the temperature of the bath. In this way, it is believed that the gas was brought sufficiently close to the temperature of the adsorbent that

(8) H. P. R. Frederikse, Thesis, Leiden, 1950.

the amount of heat absorbed or given off to the calorimeter by the gas in coming to the temperature of the calorimeter was a negligible quantity compared to the heat evolved on adsorption. After entering the vacuum envelope, the filling tubes made three more loops inside: thus, the calorimeter is connected to the bath through two one-foot lengths of german silver tube, and by the electrical leads. The eight electrical connections to the thermometer and heater are led through the top of the envelope *via* platinum–glass take-out caps, and come to the thermometer and heater proper *via* eight one-foot lengths of #29 constantan wire which are lacquered to the filling tubes in two groups of four. A phosphor bronze thermometer for work at 1–4°K. and a constantan heater were included (R = 106 ohms at 14°K.). The constantan heater also served as a thermometer ($\Delta T/\Delta R$ = 6.071°/ohm) in the range 10–20°K.

The calorimeter itself was filled with 83 g. of high surface area titanium dioxide (the B.E.T. nitrogen monolayer capacity was 52.4 cc. STP/g.). Twelve copper plates were placed in the powder at intervals along the length of the calorimeter in an attempt to decrease equilibrium times. The Dewar enclosing the bath space was set inside a second Dewar which contained liquid nitrogen. This served two purposes: the rate of evaporation of hydrogen in the inner Dewar due to radiation was greatly decreased; also, by breaking the vacuum in the inner Dewar and in the envelope, the calorimeter and its contents could be cooled easily to 80°K. with liquid nitrogen and 60°K. with solid nitrogen. As pointed out by Singleton and Halsey,[9] a long period of slow cooling is necessary to ensure that the preadsorbed layer is in an equilibrium distribution over the surface. Since these experiments were made with comparatively small amounts of preadsorbed gas, the gas was more firmly bound to the surface, and the equilibrium process was not quite as sensitive to variations in method as in the experiments of Singleton and Halsey. Allowing small variations in the time and technique of precooling, three runs were made on the system with one-half layer of preadsorbed argon, and two runs on the system with one layer. No significant difference could be detected in isotherms or isosteric heats. In general, the desired quantity of gas was admitted to the calorimeter at 80°K.; the system then was cooled slowly to 60°K. and held at that temperature for at least eight hours. The bath space subsequently was filled with liquid hydrogen and the remainder of the cooling done in 30 minutes or less.

The techniques used in the measurement of the helium heats differed in some respects from those used in the hydrogen work. In the helium experiments, the calorimeter was first cooled to 10°K. The heat capacity of the system was measured; following this, a measured amount of gas was admitted to the calorimeter. After the system had reached thermal equilibrium, a second heat capacity measurement was made. Since these determinations were made without cooling the calorimeter during the sequence, the final temperature was then about 17°. The system was then cooled to 10°K. and the cycle repeated. After applying the usual corrections,[10,11] curves of heat capacity *versus* coverage at two temperatures were constructed; a further correction was necessary to correct the measured heat capacities to two common temperatures. In order to determine partial molal heats of adsorption (often called "differential" heats or isosteric heats[10,11]), the heat capacity at the average temperature of measurement was obtained by interpolation. The partial molal heat of adsorption was then calculated in the customary manner. The conventional corrections for heat of compression were, of course, applied.[10,11] The largest source of error lay in the interpolation procedure, since the heat capacity changed by roughly a factor of two over the temperature range of the experiments. The estimated precision of the partial molal heats of adsorption of helium is 5%. The corrections for heat of compression become excessively great at coverages where the pressure is large (over 100 mm.). In this region, more accurate results were obtained by calculating the heats from the measured isotherms.

The procedure followed in the hydrogen experiments could be simplified somewhat due to two factors: the time required to pump out exchange gas is considerably less at 18°K. than at 10°K., and the heat capacity of the system is not so sensitive to temperature changes in this region. Thus the calorimeter was cooled to 18° and a heat capacity measurement was made. The calorimeter was then cooled to 18° again and the desired quantity of gas admitted. The corrections for heat of compression were negligible, since the adsorbed hydrogen had no appreciable vapor pressure at the temperatures and coverages of these experiments. The major source of error in these measurements was in the determination of the equilibrium drift rates after gas was admitted to the system and also, to a lesser extent, after a heat capacity. In these experiments, the time required for equilibrium was extremely long (of the order of 1.5 to 2 hours in some determinations). Thus, errors in the calculated temperature rise were quite appreciable if the equilibrium drift rate was in error by a small amount. The estimated precision of these heats is also about 5%.

In order to ensure that no spurious heat effects were present due to the conversion of the room temperature mixture to parahydrogen, the hydrogen used in all but one of these experiments was first converted to the 20°K. equilibrium mixture. The method followed was that of Squires and Stewart,[12] who used a catalyst of charcoal plus preadsorbed oxygen at 20°K. They estimated the half-time of the reaction to be 10–20 minutes. In the present work, the hydrogen was left in contact with the catalyst for a minimum of 60 minutes before it was used.

Room temperature equilibrium hydrogen was used in one of the runs on the titanium dioxide plus 0.60 layer of preadsorbed argon to ascertain whether the rotational state of the adsorbed hydrogen had an appreciable effect on the heat of adsorption. It is clear from the data shown in Fig. 2 that the difference in the heats is negligible insofar as these experiments are concerned.

Heats of Formation of Crystalline Aluminates of Sodium and Lithium

BY JAMES P. COUGHLIN

RECEIVED JANUARY 11, 1957

Heat of solution measurements of crystalline $NaAlO_2$, $LiAlO_2$, Al, NaCl and LiCl were conducted at 303.15°K. in 4.360 *m* hydrochloric acid solution. Based upon these data the following heats of formation from the component oxides at 298.15°K. are derived: −20,890 ± 780 cal./mole for $NaAlO_2$ and −12,880 ± 1,030 cal./mole for $LiAlO_2$. Corresponding heats of formation from the elements are −270,840 ± 170 cal./mole and −284,330 ± 210 cal./mole, respectively.

A recent article dealt with the heats of formation of three calcium aluminates.[1] In continuation of this activity, the present paper reports the heats of formation of crystalline sodium aluminate ($NaAlO_2$) and lithium aluminate ($LiAlO_2$). Sodium aluminate is of interest as an important intermediary in the extraction of pure alumina from bauxite. Low temperature heat capacities and entropies at 298.15°K. of these substances were reported by King.[2]

Materials

The sodium and lithium aluminates were prepared by prolonged, repeated sintering of stoichiometric mixtures of appropriate pure ingredients. These compounds were portions of the samples used by King[2] who reported the results of chemical analyses and X-ray diffractions. The samples used in this work contained, in addition, small amounts of moisture (0.11% for $NaAlO_2$ and 0.08% for $LiAlO_2$) for which appropriate corrections have been applied to the thermal measurements.

The lithium aluminate sample was very difficultly soluble and required special treatment to obtain material that would dissolve completely within 90 minutes. The sample was repeatedly ground and elutriated in a stream of oxygen traveling vertically at a rate of 1.2 cm./sec. The maximum particle size, calculated from Stoke's law, was equivalent to a sphere 14 μ in diameter.

Analytical data and heat of solution measurements for aluminum metal already have been reported by the author.[1] Also outlined in that paper are the method of standardizing the hydrochloric acid solution and methods of applying minor corrections to the heat of solution measurements.

The sodium chloride sample was analytical reagent grade, containing less than 0.03% total impurities originally, plus 0.01% moisture picked up in handling.

The lithium chloride sample was also an analytical reagent with original impurities totaling less than 0.55%; the sample picked up 0.08% water in handling for which a correction has been applied. To check the possibility of sample hydrolysis during drying a ten-gram portion which had been dried at 550–600° was titrated with 0.1 *N* acid and the indicated alkalinity, as lithium hydroxide, was found to be only 0.014%. As the total heat of solution was quite small, and the principal impurities are other alkali chlorides, the correction for impurities is considered negligibly small and therefore omitted.

Method and Results

The calorimetric apparatus is essentially the same as described by Southard,[3] with minor improvements by the author.[4] The results are expressed in defined calories (1 cal. = 4.1840 abs. joules), and all molecular weights are based on the 1953 International Atomic Weights.[5] Sample weights were corrected to vacuum using the following densities: Al, 2.70; H_2O, 0.997; 4.360 *m* HCl, 1.062; LiCl, 2.068; NaCl, 2.49; $NaAlO_2$, 2.6 (estimated); and $LiAlO_2$, 2.554.

The heat of solution measurements were conducted in a two-quart glass Dewar containing 1,936.2 g. of 4.360 *m* hydrochloric acid ($HCl \cdot 12.731H_2O$). The amounts of samples employed were 0.02 mole each of aluminum, sodium chloride, sodium aluminate, lithium chloride and lithium aluminate, and requisite amounts of water and hydrochloric acid solution as shown in reactions 6 and 14.

The amounts of water impurities and the equivalent net corrections applied to the various measurements are as follows: sodium aluminate, 0.11% impurity and −64 cal./mole; sodium chloride, 0.01% and −0.3 cal./mole; lithium aluminate, 0.08% and −41 cal./mole; and lithium chloride, 0.08% and −14 cal./mole. A small correction was applied to adjust the electrical calibration measurements to the mean temperatures of the corresponding heat of solution measurements. This correction amounted to −12 cal./mole for sodium aluminate, −10 cal./mole for lithium aluminate, −1 cal./mole for lithium chloride, and was negligible for the other measurements.

All measurements, except one, were made within 0.04° of 30.00° and required no correction to 30.00°. The first measurement of sodium aluminate was made at approximately 29.74°[6] and required a correction of −8 cal./mole.

$NaAlO_2$(c).—Table I gives the skeleton equations for the reactions measured to obtain the heat of formation of sodium aluminate. Reactions 1, 2 and 3 were measured consecutively in the same acid solution; reactions 4 and 5 were measured consecutively in a second portion of acid. Thus the final solution from reactions 1, 2 and 3 and the final solution from reactions 4 and 5 are identical, so that $\Delta H_6 = \Delta H_1 + \Delta H_2 + \Delta H_3 - \Delta H_4 - \Delta H_5$.

Reaction 1 has been discussed in an earlier paper.[1] The molal heat of solution of aluminum in 4.360 *m* hydrochloric acid, including all corrections, is −127,050 ± 120 cal./mole at 303.15°K.

Six measurements were made of the heat of solution of sodium chloride in the final solutions from reaction 1, resulting in +1,924 ± 4 cal./mole as the mean of +1,920, +1,917, +1,920, +1,930, +1,928 and +1,926.

The heat of reaction 3, −1,196 ± 12 cal. for 14.731 moles of water, is the resultant of five meas-

(4)	$NaAlO_2(c) + 4H^+(sol) = Na^+(sol) + Al^{+++}(sol) + 2H_2O(sol)$	− 51,220	± 20
(5)	$HCl{\cdot}12.731\ H_2O(sol) = H^+(sol) + Cl^-(sol) + 12.731\ H_2O(sol)$	− 10	± 10
(6)	$Al(c) + NaCl(c) + 14.731\ H_2O(l) = NaAlO_2(c) + HCl{\cdot}12.731\ H_2O(sol) + 3/2\ H_2(g)$	− 75,100	±130

At 298.15°K., $\Delta H_6 = -74,880 \pm 130$ cal./mole

urements conducted in solutions containing 0.02 mole of aluminum and 0.02 mole of either sodium chloride or lithium chloride (see Table II).

TABLE II

HEAT OF SOLUTION OF H_2O(l) IN SOLUTIONS CONTAINING SODIUM CHLORIDE OR LITHIUM CHLORIDE

H_2O sample size (g.)	NaCl or LiCl	$\Delta H_{303.15}$ (cal./mole)
0.9306	NaCl	−81.0
1.0191	NaCl	−82.0
4.8205	NaCl	−81.9
5.5531	LiCl	−81.3
5.2210	LiCl	−80.0

Mean $\Delta H_{303.15} = -81.2 \pm 0.8$ cal./mole

The heat of reaction appears to be independent of the water sample size and also of whether sodium ion or lithium ion is present in solution. These results agree substantially with similar measurements made in connection with the calcium aluminates.[1]

The heat of reaction 4, −51,220 ± 11 cal./mole, resulted from five measurements, −51,230, −51,230, −51,220, −51,200 and −51,220.

Reaction 5 (the heat of mixing of approximately 5 ml. of the original acid solution with the final solution from reaction 4) required only two measurements to verify that its heat was nearly zero. The first measurement, −7.4 cal./mole, was conducted in the final solution from reaction 4; the second measurement, −5.7 cal./mole, was conducted in the final solution from reaction 12 of Table III. Thus, the rounded value for reaction 5 (and also reaction 13 of Table III) is −10 ± 10 cal./mole.

Reaction 6 represents the heat of formation of sodium aluminate plus aqueous hydrochloric acid from aluminum metal, sodium chloride and water. The heat of reaction was corrected to 298.15°K. using heat capacity data of King,[2] Kelley[7] and Rossini.[8] The heats of formation from the oxides (reaction 7) and from the elements (reaction 8) were obtained by substitution of literature values for sodium chloride and hydrochloric acid,[9] water and sodium oxide[10] and aluminum oxide.[11]

$$^1/_2Na_2O(c) + {}^1/_2Al_2O_3(\alpha) = NaAlO_2(c),$$
$$\Delta H_{298.15} = -20,890 \pm 780 \text{ cal./mole} \quad (7)$$

$$Na(c) + Al(c) + O_2(g) = NaAlO_2(c),$$
$$\Delta H_{298.15} = -270,840 \pm 170 \text{ cal./mole} \quad (8)$$

The free energy changes of these reactions, shown in Table IV, were evaluated using entropy data of Kerr, Johnston and Hallett,[12] King[2] and Kelley.[7]

$LiAlO_2$(c).—Table III shows skeleton equations of the reactions measured to obtain the heat of formation of lithium aluminate.

TABLE III

HEAT OF FORMATION OF $LiAlO_2$(c) (CAL./MOLE)

Mol. wt. = 65.92

	Reaction	$\Delta H_{303.15}$	Uncertainty
(9)	$Al(c) + 3H^+(sol) = Al^{+++}(sol) + 3/2\ H_2(g)$	−127,050	±120
(10)	$LiCl(c) = Li^+(sol) + Cl^-(sol)$	− 6,880	± 10
(11)	$14.731\ H_2O(l) = 14.731\ H_2O(sol)$	− 1,200	± 20
(12)	$LiAlO_2(c) + 4H^+(sol) = Li^+(sol) + Al^{+++}(sol) + 2H_2O(sol)$	− 46,000	± 50
(13)	$HCl{\cdot}12.731\ H_2O(sol) = H^+(sol) + Cl^-(sol) + 12.731\ H_2O(sol)$	− 10	± 10
(14)	$Al(c) + LiCl(c) + 14.731\ H_2O(l) = LiAlO_2(c) + HCl{\cdot}12.731\ H_2O(sol) + 3/2\ H_2(g)$	− 89,120	±140

At 298.15°K., $\Delta H_{14} = -88,900 \pm 140$ cal./mole

Reactions 9, 11 and 13 have been discussed as reactions 1, 3 and 5, respectively. The heat of reaction 10, −6,878 ± 3 cal./mole, is the mean of five measurements, −6,878, −6,876, −6,875, −6,879 and −6,882.

Five measurements of the heat of solution of lithium aluminate, −46,060, −45,960, −45,970, −45,970 and −46,060, yield a mean of −46,000 ± 46 cal./mole. Because of difficulty in preparing large amounts of the finely divided sample, two of the measurements (the second and fourth) were made with samples of one-half the theoretical size, measured consecutively in the same acid solution. Comparison with the other three measurements shows that the heat of solution is independent of sample size, within the limit of experimental error.

Reaction 14 was corrected to 298.15°K., using previously mentioned heat capacity data.[2,7,8] Heat of formation values from other sources[9-11] are used to evaluate reactions 15 and 16, the heats of

$NaAlO_2$(c)	−20.89 ± 0.78	−21.58 ± 0.80	−270.84 ± 0.17	−255.60 ± 0.19
$LiAlO_2$(c)	−12.88 ± 1.03	−13.50 ± 1.03	−284.33 ± 0.21	−269.49 ± 0.22

formation of lithium aluminate from the component oxides and from the elements, respectively.

$$\tfrac{1}{2}Li_2O(c) + \tfrac{1}{2}Al_2O_3(\alpha) = LiAlO_2(c), \quad \Delta H_{298.15} = -12{,}880 \pm 1030 \text{ cal./mole} \quad (15)$$

$$Li(c) + Al(c) + O_2(g) = LiAlO_2(c), \quad \Delta H_{298.15} = -284{,}330 \pm 210 \text{ cal./mole} \quad (16)$$

Johnston and Bauer's[13] entropy value for lithium oxide is used, together with entropy data from sources,[2,7,12] to calculate the free energy data in Table IV.

Although no high temperature heat content and entropy increment data are available for these aluminates, the entropies of formation at 298.15°K. indicate that both substances should become increasingly stable with respect to their component oxides with increasing temperature.

Heat Capacities at Low Temperatures and Entropies at 298.15° K. of Nickelous Oxide, Cobaltous Oxide and Cobalt Spinel

BY E. G. KING

RECEIVED DECEMBER 26, 1956

Heat capacities of nickelous oxide (NiO), cobaltous oxide (CoO) and cobalt spinel (Co_3O_4) were measured throughout the temperature range 51 to 298°K. The heat capacity of cobaltous oxide has a pronounced maximum at 287.3°K. The entropies at 298.15°K. are 9.08 ± 0.04, 12.66 ± 0.08 and 24.5 ± 0.2 cal./deg. mole, respectively.

This paper presents heat capacity measurements in the temperature range 50 to 298°K. and entropy values at 298.15°K. for crystalline nickelous oxide (NiO), cobaltous oxide (CoO) and cobalt spinel (Co_3O_4). No previous similar data exist for the cobalt compounds. Seltz, DeWitt and McDonald[1] have reported low temperature heat capacity data for nickelous oxide.

Materials.—Nickelous oxide[2] was prepared from reagent grade nickelous nitrate hexahydrate and nickelous sulfate hexahydrate. These materials were dissolved in water and precipitated as basic carbonate with ammonium hydroxide and carbon dioxide. The precipitate was heated slowly to 1000° where it was kept for nine days. Analysis showed 99.96% nickelous oxide, 0.05% cobaltous oxide, 0.01% sodium oxide, and 0.02% acid insoluble. Tests showed no calcium or sulfate. The X-ray diffraction pattern agreed with the ASTM catalog.

Cobaltous oxide was obtained from recrystallized, reagent grade cobaltous sulfate heptahydrate as the starting material. After heating slowly to 1000°, it was maintained at this temperature for nine days. Additional treatment involved heating for 16 hours at 1000° and cooling in nitrogen, followed by an additional six hours *in vacuo* at 1000° with cooling in nitrogen. Analysis showed 78.61% cobalt (theoretical, 78.65%). The X-ray pattern was identical with that in the ASTM catalog.

Recrystallized reagent grade cobalt sulfate heptahydrate was the starting material for preparing cobalt spinel. It was heated in air for 15 days at 850° and 16 hours at 900°, after which it was quenched to room temperature. At this point the product contained too much cobalt (73.71%). It was next heated for 16 hours at 720° and finally for 16 hours at 780°, followed by quenching to room temperature. Analysis of the final product gave 73.40% cobalt, as compared with the theoretical 73.42%. The X-ray diffraction pattern agreed with the ASTM catalog.

Heat Capacity Measurements and Results.—The heat capacity calorimeter has been described.[3] Results are given in defined calories (1 cal. = 4.1840 abs. joules). Weighings were reduced to vacuum and molecular weights were obtained using the 1954–55 Report on Atomic Weights.[4] Sample masses were 275.83 g. of nickelous oxide, 396.86 g. of cobaltous oxide and 161.23 g. of cobalt spinel.

The measurements are tabulated in Table I and plotted in Fig. 1. The heat capacity curves of nickelous oxide and cobalt spinel show a regular behavior over the measured range of temperature. A comparison of the heat capacities of nickel oxide with those of Seltz and co-workers[1] shows the present values to be lower. The difference is 2.0% at 75°K., becomes zero at 125°K., then increases again to 1.5% at 258°K., and finally decreases to 0.1% at 298°K.

Cobaltous oxide possesses a peak with the maximum at 287.3°K., at which point the heat capacity is greater than 17.6 cal./deg. mole. As may be seen in Fig. 1, abnormal heat capacities persist for a wide temperature range both above and below the maximum. At the highest measured temperature (307.6°K.) the heat capacity continues to decrease with increasing temperature. Results labeled (a) in Table I were obtained without temperature gaps. In the immediate neighborhood of the peak, runs with temperature rises of only about one degree

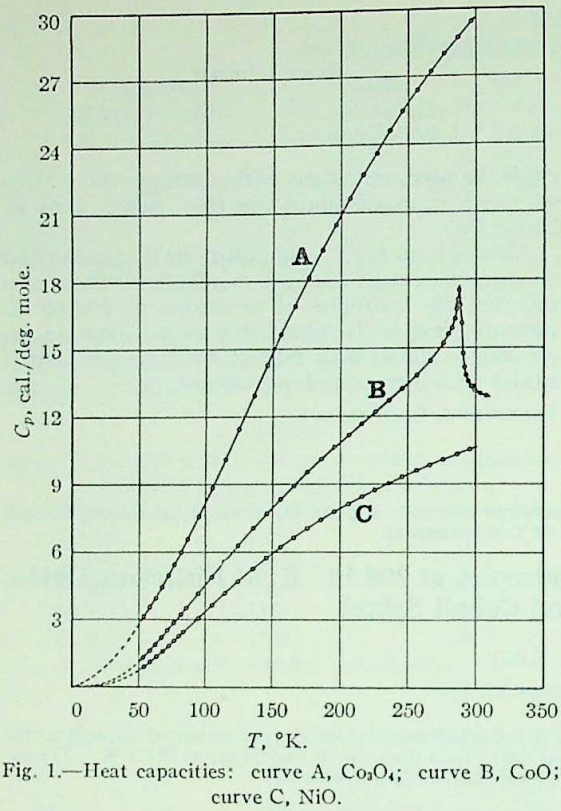

Fig. 1.—Heat capacities: curve A, Co_3O_4; curve B, CoO; curve C, NiO.

were made to better portray the heat capacity curve. This heat capacity maximum is similar to the one found by Todd[5] at 188.5°K. for the compound $Fe_{0.947}O$.

Two separate total heat measurements were made for cobaltous oxide between 280.00 and 294.00°K., enclosing the sharpest part of the peak. The measurements gave identical heat absorptions of 217.9 cal./deg. mole. The runs labeled (a) in Table I also were used (in summation) to obtain this total heat. The latter method gave 219.9 cal./deg. mole, in fair agreement with the total heat runs.

Entropies at 298.15°K.—The entropy of cobaltous oxide between 0 and 51°K. (the extrapolated portion) was calculated from the Debye–Einstein function sum $D(359/T) + E(484/T)$, which fits the measured data within 1.0% between 51 and 100°K. The entropy for the intervals 51–280°K. and 294–298°K. were obtained by graphical integration of a C_p *vs.* log T plots of the data. These increments totaled 11.48 cal./deg. mole. The entropy between 280.00° and 294.00°K. was calculated from the equation

$$\Delta S = \Delta H \frac{\Sigma C_p \Delta T/T}{\Sigma C_p \Delta T}$$

where ΔH is the total heat over the temperature interval and the other two terms were obtained from the consecutive run data marked (a) in Table I. This portion of the entropy was evaluated as 0.76 cal./deg. mole.

The entropy for nickelous oxide below 51°K. was calculated from the function sum $D(422/T) + E(585/T)$, which fits the experimental data below 200°K. within 2.0%. Likewise, the entropy of cobalt spinel below 51°K. was obtained from the function sum $D(219/T) + 3E(485/T) + 3E(926/T)$ which fits the measured data below 200°K. within 1.0%. The entropies between 51 and 298.15°K. for nickelous oxide and cobalt spinel were obtained from C_p *vs.* log T plots.

Table II summarizes the entropy calculations. The present entropy value at 298.15°K. for nickelous oxide is considered more reliable than the value of 9.24 cal./deg. mole calculated by Kelley[6] from the data of Seltz and co-workers.[7]

The Vibrational Spectra and Structure of Cyclobutene and Cyclobutene-d_6[1]

BY R. C. LORD AND D. G. REA[2]

RECEIVED DECEMBER 5, 1956

Cyclobutene and cyclobutene-d_6 have been prepared by the method of Cope, Haven, Ramp and Trumbull.[5] The infrared absorption spectra of both vapor and liquid have been obtained in the range 250–3800 cm.$^{-1}$ and Raman spectra (including semi-quantitative depolarization factors) have been determined for the liquids. Many vibrational frequencies permitted to occur in the Raman effect by selection rules were not observed. The spectra have been interpreted in terms of a C_{2v} structure, for which the chief spectroscopic support is the number and position of infrared bands of type C. In cyclobutene the carbon–carbon double bond frequency is observed at the unusually low value of 1566 cm.$^{-1}$. The Raman line at this frequency is intense but the infrared band is so weak that it could have been ascribed to an overtone.

The cyclobutene molecule contains a C–C double bond in a four-membered ring, and offers the molecular spectroscopist an unusual example of the effect of ring strain on the double bond frequency and the carbon–hydrogen frequencies associated with a double bond. It is also useful in assisting the evaluation of vibrational frequencies of the CH_2 group in small ring compounds as a member of the series cyclopropane-ethylene oxide–cyclobutene-cyclobutane whose spectra have recently been reported together with those of the deuterium analogs.[3] Its structure apparently has not been investigated by X-ray diffraction or by microwave spectroscopy, but a recent study by electron diffraction has been carried out by Goldish, Hedberg and Schomaker.[4]

Experimental

Cyclobutene and cyclobutene-d_6 were obtained as intermediates in the synthesis of cyclobutane and cyclobutane-d_8, respectively. The synthesis was that of Cope, Haven, Ramp and Trumbull,[5] modified to adapt it to the preparation of the deuterium compound.[6] The general method having already been reported, only the purification procedure and the characteristics of the compounds obtained will be given.[7]

The crude cyclobutene (and cyclobutene-d_6 also) was purified by the addition of bromine and fractional distillation of the resultant dibromocyclobutane. Cyclobutene was then regenerated by reduction with zinc in ethanol[8] with a 97% recovery. Unfortunately the infrared spectrum of the regenerated material indicated the presence of an appreciable amount of butadiene, whose boiling point differs by only 5° from that of cyclobutene. The butadiene was removed by bubbling the impure gas four or five times through molten maleic anhydride, the extent of the removal being followed by means of the butadiene infrared bands at 997–1012 cm.$^{-1}$. It was estimated that the final concentration of butadiene was less than 0.1%. The cyclobutene was then distilled once again (at 200°K., condensed at 77°K.) and stored in the vapor phase for spectroscopic study.

Both the cyclobutene prepared in this way and the cyclobutane obtained from it by subsequent hydrogenation were subjected to careful infrared and mass spectrometric analysis.[9] The observed purity of the latter compound confirmed that the original cyclobutene was in excess of 99.9% pure chemically. The isotopic purity of cyclobutene-d_6 by both methods was 99.7 atom-% D.

Spectroscopic Procedures.—Infrared spectra were measured in the range 250–3800 cm.$^{-1}$ on the gaseous compounds and from 400 to 3800 cm.$^{-1}$ for the liquids. The spectrometer was a Perkin–Elmer 12B single-beam instrument, in which prisms of LiF, CaF_2, NaCl, KBr and KRS-5 were employed in their respective regions of optimum dispersion. The low temperature liquid cell was that designed by Lord, McDonald and Miller[10] who also have described the modified optics of the spectrometer used in this work. The liquid was cooled by Dry Ice–acetone slush, and its temperature was probably slightly above −75°.

The spectra are shown in Figs. 1 and 2 and the wave numbers (vac) of the transmission minima in cm.$^{-1}$ in Tables I and II. The precision of wave number measurement is 2 cm.$^{-1}$ or better below 2500 and 5 cm.$^{-1}$ or better above.

Raman spectra of liquid samples were photographed by standard techniques[3] with a Zeiss three-prism spectrograph. Semiquantitative depolarization factors were determined by a single-exposure method.[11] An attempt was made to photograph the Raman spectrum of cyclobutene excited by the mercury resonance line Hg-2537, but decomposition of the sample under intense ultraviolet radiation was sufficiently rapid that inferior spectra were obtained. The results of the Raman work are listed in Table III. The Raman spectrum of cyclobutene has not been reported previously, but there were available to us the results of an earlier study by Slowinski[12] on a cyclobutene sample prepared by a different method.[13] Slowinski's results agree closely with those of Table III both as to frequency and intensity, except that he reported fewer lines and the intensity of the butadiene line at 1635 cm.$^{-1}$ indicated about 5–10% of this substance in his sample. A very weak line found in spectra of some samples during the present work at about 515 cm.$^{-1}$ has been rejected as probably belonging to butadiene since it was not found in spectra from which the 1635 butadiene line was absent.

The infrared spectrum of cyclobutene obtained with the instrument used in the present work has been reported earlier by Roberts and Sauer.[13]

Discussion of Spectroscopic Results

The selection rules for the highest possible symmetry (C_{2v}) for cyclobutene permit all 24 fundamental frequencies to be Raman-active and all but five in the infrared. Thus the assignment of fundamentals has to be carried out with little help from selection-rule arguments. Fortunately the infra-

[a] Abbreviations: P, Q, Q′, Q″, R refer to the rotational branches of a single band and A, B, C to the band type (see text and Fig. 3). sh = shoulder, v = very, s = strong, m = medium, w = weak for cell thicknesses and pressures shown in Figs. 1 and 2. Overtones which cannot be explained as binary combinations are labeled "?." Between 1800 and 2800 cm.$^{-1}$ there are about 25 weak or very weak overtone bands in the vapor and a similar number (though not always at similar frequencies) in the liquid. For brevity these are not included in Table I. They are recorded in the thesis of D. G. Rea.

red band contours indicate the assignments for a number of frequencies and comparison with the spectra of cyclopropane and ethylene oxide and their deuterium derivatives[3] is also helpful.

The expected modes of vibration for each species are given in column 3 of Table IV. Approximate moments of inertia required for calculation of band contours and product rule values may be obtained from the geometrical parameters of the molecule as determined by Schomaker, *et al.*[4] If one takes the twofold axis (C_{2v} symmetry) as the z-axis with the x-axis perpendicular to the ring plane at the center of gravity, and adopts the values C=C, 1.34 Å.; C–C (perpendicular to C_2^z), 1.57 Å.; C–C ("parallel" to C_2^z), 1.54 Å.; C–H (CH_2), 1.08 Å.; C–H (C=C), 1.07 Å.; ∠HCH, 110°; ∠HC=C, 120°; ∠C–C–C bisected by CH_2 plane, one obtains I_x = 123.8, I_y = 71.5, I_z = 63.0 for cyclobutene and I_x = 158.1, I_y = 95.8, I_z = 83.6 for cyclobutene-d_6, all in units of 10^{-40} g.-cm.^{2}. The band contours and theoretical product-rule ratios are not sensitive to the precise values of the geometrical parameters.[14]

From these values it follows that vibrations of species A_1 (Table IV) should produce bands of type A,[15] species B_1, type B, and species B_2, type C. The shapes of the band contours for room temperature observation have been calculated by the procedure of Badger and Zumwalt[16] and it is found that in cyclobutene, type A bands should have a Q branch of medium intensity and a P–R separation of about 29 cm.$^{-1}$. Type B bands should exhibit a split Q branch (spacing about 7 cm.$^{-1}$) and P–R separation of some 30 cm.$^{-1}$. Type C bands should have a sharp, strong Q branch and P–R spacing of about 40 cm.$^{-1}$. These contours are shown for T = 300°K. in Fig. 3.

Assignment of Frequencies

Although in principle all twenty-four fundamentals are Raman-active, it is apparent from Ta-

(14) The values adopted for the geometrical parameters are not exactly the same as those given by Goldish, Hedberg and Schomaker,[4] though they do lie within or close to the latters' estimates of error. It appears to us that the decreased double bond frequency implies a lower C=C force constant than usual and hence a slightly larger C=C distance. The value given by Goldish, *et al.* (1.325) is slightly smaller than their "standard" value (1.330), but their limits of error (±0.046) are wide enough to include our value of 1.34. The large value appears more reasonable to us in light of the unusually low C=C frequency (1566 cm.$^{-1}$). Quite possibly the C=C distance is even larger than 1.34.

[a] ρ = depolarization ratio of Raman lines; r_{calcd} = theoretical value of product-rule ratio; r_{obsd} = product-rule ratio of observed frequencies; CX refers to olefinic CX bonds, CX_2 to aliphatic CX_2 group, X = H or D; ( ) means "estimated frequencies," [ ] means "observed frequency assigned to two fundamentals."

observed. Most of the fundamentals must therefore be evaluated from the infrared.

Species A_1.—There are six polarized Raman lines in cyclobutene and five in cyclobutene-d_6 which can be assigned readily as indicated in Table IV. The remaining two A_1 frequencies in cyclobutene are placed at 1276 and 986 on the basis of their expected locations. The former is questionably depolarized and the latter, though observed as depolarized, coincides with a source line which could have influenced the depolarization ratio under the conditions of measurement. In the deuterium compound the lines at 1031 and 1054, though so weak that their depolarization factors could not be measured, are placed in species A_1 because they lie approximately at the plates to which the CH_2 deformation and CH in-plane bending frequencies should shift in cyclobutene-d_6. The remaining frequency—723—is selected from the pair 723–735 because this region is the expected location of CD_2 wagging and the lower of the pair is more intense and gives slightly better agreement with the product rule. The pair 723–735 also occurs in the infrared of liquid cyclobutene with an intensity ratio similar to that in the Raman effect. This fact suggests Fermi resonance, and after attempts to assign 735 as fundamental encountered difficulties, it was attributed to the combination tone $\nu_{12} + \nu_{13}$, in resonance with ν_8.

Species B_1.—If the foregoing assignments are correct, most of the B_1 vibrations must be either unobserved in the Raman effect or in coincidence with A_1 frequencies. However, some of this species can be assigned from the infrared band type (B) and others can be located by elimination, *i.e.*, because their band types are not A or C. In the spectrum of cyclobutene vapor, the bands at 3134, 1294 and 1214 are rather definitely of type B and those at 1434 and 885 are probably of type B, though overlapping of other bands interferes with the identification. In cyclobutene-d_6 the distinction between band types A and B is much less clear-cut and only the band at 706 is sufficiently free from overlapping to be identified as type B. However, the locations of the B_1 fundamentals in cyclobutene and the product rule assist considerably in the assignments. The ones shown in Table IV show good correlation with analogous frequencies in cyclopropane, ethylene oxide and their deuterium analogs.[3] It is interesting that the B_1 vibrations show greater intensity than the A_1 vibrations in the infrared.

Species B_2.—The infrared (type C) bands of this species in both compounds are the most intense of all. This fact together with the distinctive band shape and freedom from overlapping enables all B_2 vibrations to be identified readily. The assignment given in Table IV fits the product rule satisfactorily and correlates well with related molecules.[3]

Species A_2.—This species is inactive in the infrared. Although the A_2 vibrations are formally allowed in the Raman effect, the only observed line which cannot easily be assigned to other species is the extremely weak one at 325 in cyclobutene. This is so low that it can correspond only to the ring-puckering vibration. The analogous frequency in cyclobutene-d_6 is expected at about 275 cm.$^{-1}$, but was not detected in the Raman effect. Certain overtones in the infrared are best explained with the help of an A_2 fundamental of this frequency, and it is therefore entered in Table IV as an observed value.

All the other A_2 modes are similar to the B_2 modes and frequencies are estimated for them by analogy.

Overtones.—In various regions of the infrared spectrum many overlapping overtones are observed. The selection rules are so lax (only species A_2 is forbidden), the overlapping so extensive and the effect of anharmonicity so uncertain that the information obtainable from overtones is limited. Many of the weaker overtone frequencies have been omitted from Tables I and II. Plausible explanations are given for most of those listed in the tables.

Discussion

Since the highest reasonable symmetry for the cyclobutene molecule is C_{2v}, the structural problem from a symmetry standpoint is the rather empty one of distinguishing between C_{2v}, C_2, C_s and C_1

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(no symmetry). In any of these structures, all vibrations would be both infrared- and Raman-active except for the infrared-silent vibrations of species A_2 of C_{2v}. Therefore the vibrational selection rules are unfavorable *a priori* for a structural decision, and in addition the failure of numerous vibrations to appear in the Raman effect renders firm decision impossible.

The most significant structural evidence is furnished by the type-C infrared bands. The number of these found is just that predicted for C_{2v} symmetry for both cyclobutene and cyclobutene-d_6. The frequencies and band shapes (see Fig. 3) are those expected and the frequency product ratio for species B_2 agrees with the theoretical value. To be sure, these things might happen by accident for a structure of lesser symmetry, particularly if the deviation from C_{2v} geometry were rather small. The best one can say is that there is some rather definite evidence in favor of a C_{2v} structure and nothing compelling against it. High-resolution study of the rotation–vibration spectra for bands of all three types in both molecules should furnish sufficient information to evaluate the most important geometrical parameters.

An interesting result of this study is the unusual location and intensity of the double bond frequency. Presumably the low frequency is the result of a decrease in the C=C force constant due to strain in the four-membered ring,[17] as was pointed out above. The high intensity of the double bond vibration in the Raman effect is remarkable, as is the unusually low intensity of the infrared band. The latter, which is weaker than the overtone bands at 1540 and 1760, cannot be used with assurance to indicate the presence of HC=CH in a four-membered ring, and particularly its absence from an infrared spectrum is not an indication of the absence of this group from a molecule. The Raman spectrum is a more reliable guide for this purpose.[18] Substitution of one of the hydrogens by methyl, halogen, or other group will of course affect both the frequency and intensity of the C=C infrared absorption band.

Thermodynamic Functions of Cyclobutene

So far as the authors are aware, no investigation has been made of the heat capacity and heats of transition of cyclobutene. It is therefore not possible to check the assignment given in Table IV by comparison of calculated with measured entropy, free energy or heat capacity. Calculation of these quantities has been carried out by Mr. Alfred Danti of this Laboratory and these results will be published separately.

(17) J. O. Halford (*J. Chem. Phys.*, **24**, 830 (1956)) has shown that a considerable variation in the carbonyl frequency of ketones could result without changing the force constants simply by a change of the bond angles of the carbonyl group. Possibly a similar effect is partially responsible for the low C=C frequency in cyclobutene.

(18) D. E. Applequist and J. D. Roberts (THIS JOURNAL, **78**, 4012 (1956)) have recently published infrared spectra of methylenecyclobutene and certain related compounds. Although the exocyclic double bond of methylenecyclobutene gives a strong infrared absorption band at about 1670 cm.$^{-1}$, no band is reported near 1550 cm.$^{-1}$ for the internal double bond. In the Raman spectrum of this compound, on the other hand (M. V. Evans and R. C. Lord, unpublished results), both double bond frequencies are present, at 1673 and 1530 cm.$^{-1}$, respectively, the latter being considerably stronger.

The Surface Catalysis of the Ortho- to Para- Conversion in Hydrogen under Pressure at Low Temperatures

BY DOUGLAS S. CHAPIN[1] AND HERRICK L. JOHNSTON

RECEIVED OCTOBER 5, 1956

The surface catalysis of the ortho- to para- conversion in hydrogen was investigated on a series of catalysts consisting of 0.05 to 2.47% chromia–alumina under pressures in the range 5 to 100 atmospheres at 77°K. and on a 0.05% chromia–alumina catalyst at approximately 29 atm. in the region 55–195°K. For catalysts of lower chromia concentrations the half-life varied linearly with pressure and linearly with the reciprocal of the number of gram-atoms of chromium in the catalyst chamber. The rate data, which were first order with respect to composition, support the theory of Harrison and McDowell[2] who adapted the Wigner[3] theory to the case of conversion in a physically adsorbed hydrogen layer on a paramagnetic surface. The rate constant temperature dependency, in agreement with this theory, was positive for the case of high hydrogen surface coverage investigated in this research. This is in contrast to the negative temperature dependency of the rate constant usually observed for the case of low surface coverage. Absolute rate calculations were made for the case of high surface coverage using Harrison and McDowell's choice of reasonable values for certain constants in the rate expression. Good agreement with experiment was obtained.

Introduction

Though considerable experimental work has been done concerning the surface catalysis of the ortho–para- conversion in hydrogen at pressures of 1 atm. or less, the catalysis at higher pressures and low temperatures has been little studied since the initial experiments of Bonhoeffer and Harteck[4] and Farkas and Bonhoeffer[5] to prove the existence of the heterogeneous catalysis.

Harrison and McDowell,[2] in their study of the para–orthohydrogen conversion on the free radical α,α-diphenyl-β-picrylhydrazyl at low temperatures and pressures, concluded that the conversion takes place by interaction between hydrogen mole-

cules in a mobile physically adsorbed layer and paramagnetic sites. By using the transition probabilities given by Wigner[3] and by calculating the fraction of the time a molecule spends over a paramagnetic site while moving as a two-dimensional gas in the adsorbed layer, Harrison and McDowell developed an absolute rate expression. This expression predicts in agreement with experiment a negative temperature dependency of the rate constant and independence of the rate constant with pressure. Absolute rate calculations for the case of low surface coverage were in agreement with experiment when reasonable values were used for the various constants involved.

The present work is concerned with an experimental study of the variation of the rate constant with temperature, pressure and number of paramagnetic sites for the case of high surface coverages. The rate investigations were carried out by the static method on impregnation catalysts of several concentrations of Cr_2O_3–Al_2O_3 with most of the work being done on 0.05 and 0.24% chromia–alumina.

Theoretical Development

The conversion follows the usual unimolecular rate law

$$u_t = u_0 e^{-k_H t} \tag{1}$$

where $u_t = x_t - x_e$ and $u_0 = x_0 - x_e$ in which x_t, x_0 and x_e are the percentages of parahydrogen at time $t = t$, 0 and ∞, respectively; and k_H is the rate constant. In order to compare theoretical and experimental results the rate constant and the variables upon which it theoretically depends are given below; but no reproduction of the considerations leading to this rate expression is given here. The general expression Harrison and McDowell obtained for the rate constant for a parahydrogen conversion taking place in a physically adsorbed layer is given by

$$k_H = \frac{sK\rho a\,(RTM)^{1/2}\overline{l^2}G(T)}{\sqrt{2}r_s^2 N p v \beta_0 l_m}\left(\frac{\alpha_0\mu e^{Q/RT}}{1+\frac{\alpha_0\mu}{\beta_0\nu}e^{Q/RT}}\right) \tag{2}$$

where s is the total surface area in sq. cm.; ρ is the number of active sites per sq. cm.; a is the area per paramagnetic site in sq. cm.; ν is the number of hydrogen molecules per sq. cm. in a complete monolayer; r_s is the mean distance of a hydrogen molecule from the surface in a physically adsorbed layer; p is the pressure; v is the volume of the system; T is the absolute temperature; M is the molecular weight of hydrogen; R is the gas constant; N is Avogadro's number; $\overline{l^2}/l_m$ is the ratio of the mean square path to the mean path across an idealized circle of interaction for a molecule of hydrogen moving in the adsorbed layer. Also in equation 2, α_0 is the condensation coefficient, which is independent of temperature assuming no activation energy of adsorption; β_0 is a desorption coefficient, which is independent of temperature and $\mu = pN/(2\pi MRT)^{1/2}$ is the rate molecules of hydrogen strike one sq. cm. of surface per sec.; Q is the activation energy of desorption. Again, in equation 2, K is given by

$$K = \frac{24\mu_a^2\mu_p^2 I\pi^2}{h^2 m} \tag{3}$$

where μ_a is the magnetic moment of each paramagnetic surface site; μ_p is the proton magnetic moment; I is the moment of inertia of a hydrogen molecule of mass m; and h is Planck's constant. $G(T)$ in equation 2 is given by

$$G(T) = \left\{1 + \frac{n_p(T)}{n_0(T)}\right\}\left\{\frac{\sum_{J=0,1,2,\ldots} J\exp(-E_J/kT)}{\sum_{J=0,2,4,\ldots}(2J+1)\exp(-E_J/kT)}\right\} \tag{4}$$

where $n_p(T)$ and $n_0(T)$ are the equilibrium concentrations of para- and orthohydrogen, respectively, at the temperature T; J is the rotational quantum number and E_J is the rotational energy of the molecule in the state J given by

$$E_J = J(J+1)h^2/(8\pi^2 I) \tag{5}$$

Substitution of $\mu = pN/(2\pi MRT)^{1/2}$ in equation 2 yields

$$k_H = \frac{ACT^{1/2}G(T)}{T^{1/2}e^{-Q/RT} + Bp} \tag{6}$$

where

$$A = \frac{NKa\alpha_0\overline{l^2}}{2\pi^{1/2}\nu\beta_0 r_s^2 l_m} \text{ and } B = \frac{\alpha_0 N}{\beta_0\nu(2\pi MR)^{1/2}}$$

The total number of moles, C, of paramagnetic sites exposed on the surface to hydrogen conversion is given by $C = s\rho/N$.

Noting that the half-life $\tau_{1/2} = \ln 2/k_H$ and utilizing equation 6, the half-life time is given by

$$\tau_{1/2} = \frac{\ln 2}{AG(T)C}\left(\frac{Bp}{T^{1/2}} + e^{-Q/RT}\right) \tag{7}$$

As approximations, at sufficiently low pressures the first term in equation 7 can be neglected; at sufficiently high pressures the second term can be neglected. Thus for high pressures approximately

$$\tau_{1/2} = \frac{Bp\ln 2}{AT^{1/2}G(T)C} \tag{8}$$

These equations (particularly equation 7) will be examined subsequently in the light of the experimental determination of the pressure, concentration and temperature dependencies of the heterogeneous ortho–parahydrogen conversion at low temperatures under pressure in contact with chromia–alumina catalysts.

Experimental

Rate Apparatus.—The apparatus for the rate determinations consisted essentially of a stainless steel cylinder 1 in. i.d. of 200-cc. volume, suspended from a brass cover plate which closed the end of a standard brass cryostat typical of those used in this Laboratory. Unsilvered slit windows in the glass dewar were visible through opposing Lucite windows in the cryostat. In a run specially purified hydrogen under pressure could be expanded from a 1.5-l. calibrated cylinder on to the catalyst previously conditioned in the catalyst chamber. Liquid nitrogen was the cryostating bath in the majority of the runs. Samples of hydrogen were withdrawn through a 0.009 in. i.d. stainless steel capillary tube extending into the mid-region of the chamber. A capillary lock between two specially designed valves allowed eight locks of purge preceding each of twelve samples to be taken with a total hydrogen depletion of less than 0.1% of the total amount of hydrogen in the chamber. Pressures before and after expansion of the hydrogen were read by means of a Bourdon laboratory test gage which had been calibrated under dead weight gage.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Analytical Apparatus.—Samples stored in a series of Pyrex bulbs over mercury were analyzed using the Farkas microthermal conductivity method, employing a pressure of 0.05 mm.[6,7] The cell was calibrated with mixtures prepared volumetrically from normal and 50% parahydrogen. The calibration curve showed a maximum deviation of 2% at a concentration corresponding to $u_t/u_0 = 0.5$. The precision of the cell was approximately 0.2% in u_t/u_0 at 0.5.

Surface Area Apparatus.—Surface areas were measured volumetrically at liquid nitrogen temperature using the BET[8] method in which the volume of nitrogen required to form a monolayer on the catalyst surface was estimated from the adsorption isotherms.

Hydrogen Purification.—Hydrogen obtained from the hydrogen liquefaction cycle of this Laboratory was initially purified by passage through a liquid nitrogen trap, over platinized asbestos at 400° and through another liquid nitrogen trap. This procedure removed the condensable impurities, converted oxygen to water and removed the water formed, respectively. The platinized asbestos also served to equilibrate the hydrogen to normal with respect to its ortho–parahydrogen composition. Final purification was effected by liquefaction, filtration through glass wool to remove any solid nitrogen present, gasification, second liquefaction and distillation. High pressure pure hydrogen was obtained by condensing this hydrogen into a heavy copper chamber immersed in liquid hydrogen with subsequent isolation and then by heating the copper chamber while it was connected to a storage cylinder at room temperature.

Catalyst Preparation.—Special Bayer-process alumina in the form of 1/8 in. pellets of low iron content was prepared in a 50 lb. lot by the Harshaw Chemical Company. The composition was stated by the manufacturer to be as follows: SiO_2, 0.03%; Fe_2O_3, 0.008%; TiO_2, 0.007%; Na_2O, 0.4%; and Al_2O_3, 99.+%. This carrier was heated to 600° for 16 hours, appeared snow white, and will be called the unleached carrier. Leached carrier was prepared by agitating 450 g. of the unleached carrier with 500 ml. of 1 N HNO_3 for 16 hours. This was followed by washing overnight with 7.5 gallons of double distilled water, drying and calcining at 600° for 16 hours. The surface area decreased from 94.9 to 87.4 sq. m./g. The loss in weight due only to acid action was not determined. Catalysts of various chromia concentrations in the range 0–2% were prepared by agitating 228.3 g. of the carrier with 200 ml. of chromic acid solution of the appropriate concentration. Reagent grade CrO_3 from Baker and Adamson Chemical Company was used. The stated maximum impurity of Fe, Al, Ba, etc., was 0.03%. The carrier and chromic acid were sealed in a liter glass-stoppered bottle and rolled slowly for 16 hours, then washed with 4 l. of double distilled water. The bright yellow pellets were dried at 110° for several hours and heated for 16 hours at 300°. The product at this point was bright with small dark patches which were thought due to partial reduction. Reduction to a uniform green chromic oxide was accomplished by passing hydrogen over the catalyst at 350° for 5 hours.

Chromium Analysis.—Solutions of chromic acid were analyzed by adding a known excess of ferrous ammonium sulfate and back titrating with standard potassium dichromate in a 1.5 M phosphoric–5 M sulfuric acid media with diphenylamine sulfonate indicator.[9] Chromia–alumina catalysts were analyzed by the same method after fusion with sodium peroxide followed by careful neutralization with 6 N sulfuric acid.

Pretreatment of Catalysts.—The usual pretreatment procedure was to pump at room temperature for 24 hours on approximately 175 g. of catalyst sealed in the high pressure chamber. This was followed by pumping 24 hours at 200°. Hydrogen from the purification train previously mentioned was passed slowly over the catalyst at 200° for 3 hours. Then the catalyst was pumped while cooling down to "run" temperature. At this temperature the catalyst was purged several times with some of the specially prepared high pressure hydrogen. The chamber was pumped after this treatment until the start of a catalytic run, which usually took place within a few hours after the final purge. The only treatment between runs on the same catalyst was to evacuate the chamber at low temperatures.

Catalytic Runs.—Specially purified hydrogen was expanded onto the evacuated catalyst from a calibrated cylinder. The drop in pressure and the cylinder temperature were used to calculate the amount of gas delivered to the catalyst chamber. Temperature was measured with a copper–constantan thermocouple.

Results

Catalysts.—Nitrogen surface areas on the catalysts prepared from the leached carrier were very nearly independent of chromia concentration. Surface areas for 0.00, 0.0486 and 1.08% chromia–alumina catalysts were 87.4, 87.6 and 86.7 sq. m./g., respectively. Adsorption isotherms for the up-take of chromic acid on the leached and unleached alumina carrier during the preparation of the chromia–alumina catalysts showed an increase of amount of chromic acid adsorbed with increasing final chromic acid concentration. Adsorption on the leached carrier was approximately five to ten times that on the unleached carrier for a given final concentration of chromic acid at lower (less than 0.05 mole/l.) concentrations. The isotherm for the unleached carrier leveled off at a chromic acid adsorption corresponding to a catalyst composition of 1.78% chromia–alumina by weight. It is assumed that essentially all chromic acid molecules or ions that are adsorbed on the alumina will do so in pores which are large enough for hydrogen to penetrate in the dried catalyst so that analysis of the finished catalyst for chromium is an effective measure of the number of paramagnetic sites available for reaction. Cunningham and Johnston[10] found that the rate constant in the heterogeneous liquid hydrogen conversion on several of the same catalysts used in this work varied linearly with the chromia concentration. This would seem to indicate that the chromic acid is adsorbed on the alumina in essentially a monolayer.

Rate Data.—Rate constants for the ortho–parahydrogen conversion on chromia–alumina catalysts were obtained from the slope of the line produced by plotting $\ln (u_0/u_t)$ *vs.* t (equation 1). Figs. 1, 2 and 3 show these plots for 0.0486 and 0.237% chromia–alumina under several conditions of temperature and pressure. In these plots time has been adjusted so as to give coincidence with the origin.

A summary of the rate data is given in Tables I and II. The first column gives the run designation. The 28 series runs were made on the unimpregnated leached alumina carrier which was used in the majority of the runs. The carrier and catalysts were in the form of 1/8 in. pellets. The 28 series blank runs were used to correct the low concentration runs for the catalytic activity of the carrier. Conditions of temperature and pressure for the runs within a series were changed in the order given by the second number in the first column. The total number of g.-atom of chromium in the catalyst chamber and assumed to be available for interaction with the hydrogen is given in the second

lives calculated from rate constants corrected for the blank alumina runs (series 28) are shown in the fifth column. The number of moles of hydrogen delivered to the chamber is given in the sixth column.

Pressure Dependency.—The data for the 1.11×10^{-3} g.-atom chromium (0.0486% chromia–alumina) and 5.30×10^{-3} g.-atom chromium (0.237% chromia–alumina) at 77°K. plotted as half-life *vs.* pressure can be represented by two straight lines given approximately by the equations

$$\tau_{1/2} = 0.136p + 1.18 \text{ and } \tau_{1/2} = 0.0391p + 0.82 \quad (9)$$

respectively, as shown in Fig. 4.

Temperature Dependency.—For the 1.11×10^{-3} g.-atom chromium runs (Table II) a plot of half-life *vs.* $1/[T^{1/2}\,G(T)]$ as suggested by equation 8, shown in Fig. 5, at approximately 29.5 atm. can be represented by the solid straight line. The half-life values were corrected approximately to a pressure of 29.5 atm. by utilizing the first of equations 9.

Paramagnetic Site Dependency.—The rate data for runs (Table I) made at approximately 29 atm. and 77°K. are shown in Fig. 6 in which half-life is plotted against reciprocal site content C of the catalyst chamber.

Discussion of the Results

A summary of the rate data can be seen in Fig. 7 in which half-life *vs.* $p/[CT^{1/2}G(T)]$ is plotted. It is to be noted that while the plots of pressure and site content dependencies shown in Figs. 4 and 6 are made to test agreement with the general equation 7, the plot of the temperature dependency in Fig. 5 is not necessarily made to correspond to the

high coverage case given by equation 8, since Q the activation energy of desorption is unknown.

The data in general support the theory of Harrison and McDowell; however it may be pointed out that the temperature dependency plot appears to intersect the origin (Fig. 5) while the plots of pressure and site content [illegible] (Fig. 4, 6) do not. This appears to indicate an inconsistency between the data and theory. It would, of course, be desirable to make additional runs in which the temperature dependency was determined under various pressures and site contents.

Harrison and McDowell make a rough calculation of the absolute value of the rate constant k_H by assigning reasonable values to the variables in equation 6 and neglecting the pressure term in the denominator valid for the case of low surface coverage. Their calculated value compares well with their experimental value (5.1×10^{-3} and $3.1 \times$ [illegible], respectively).

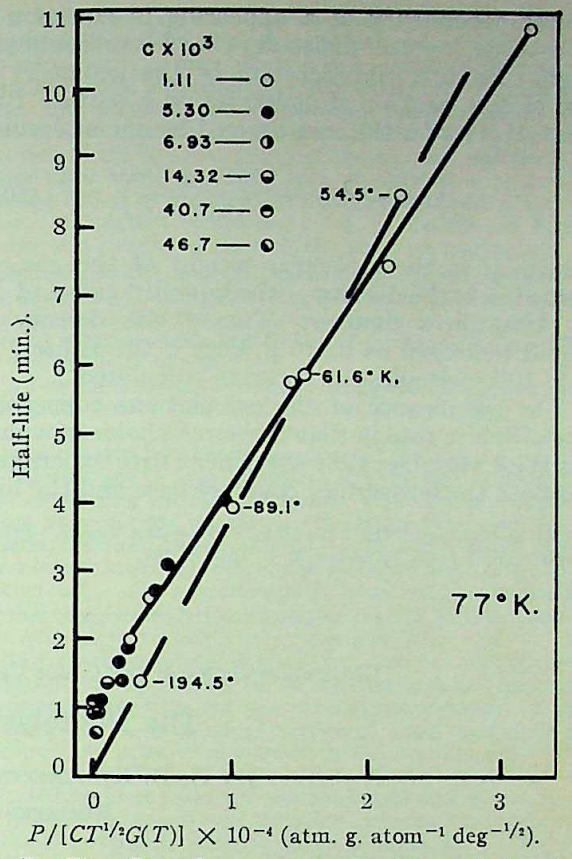

Fig. 7.—The effect of pressure, temperature and chromium content in chromia–alumina catalysts on the ortho-parahydrogen conversion.

While many of the variables appearing in equation 8 are not known with much accuracy, it was thought nevertheless of some value to make an absolute rate calculation using the same choice of the variables that Harrison and McDowell made in their calculation for the low coverage case. Harrison and McDowell used the following values: $\overline{l^2}/l_m$ was taken as 10^{-8} cm.; r_s was taken as 3 Å.; μ_a, the magnetic dipole equal to one Bohr magneton was 9.27×10^{-21} erg gauss^{-1}; μ_p, the proton magnetic moment, was 1/1840 Bohr magneton; s, the surface area, was 20 m.^{2}; v, the volume of the reaction vessel, was 200 ml.; T was 200°K.; a, the fraction of the surface active, was taken as 0.1; p was 10 cm.; θ, the fraction of the surface covered, was taken as 0.02; and ν, the number of molecules corresponding to a complete monolayer, was 10^{16} molecules cm.$^{-2}$. The calculated K from equation 3 was 3.3×10^{-48} c.g.s. units.[11]

The additional data necessary for an absolute rate calculation for the case of the ortho–parahydrogen conversion on 0.0486% chromia–alumina at 195°K. and 29.5 atmospheres are as follows: μ_{Cr}, the magnetic dipole moment for trivalent chromium using the spin only formula, is 3.87 Bohr magnetons[12]; $C = s\rho/N = 1.11 \times 10^{-3}$ moles trivalent chromium; v is taken as 120-cc. dead space volume; and the radius of an active center was taken as 2 Å. This last value was chosen by Harrison and McDowell for the radius of the paramagnetic site of a free radical and is adopted here for chromium for the purposes of this calculation. From the above the following is calculated: from equation 3, $K = 2.6 \times 10^{-48}$ c.g.s. units; using equations 4 and 5 together with the equilibrium para–ortho ratios[13] $T^{1/2}G(T) = 7.81$ deg.$^{1/2}$ and, finally, $\tau_{1/2} = 1.2$ min. The experimental half-life shown in Table II for run no. 26–6 is 1.4 min. The closeness of agreement is, of course, fortuitous in view of the accuracy with which the various values in the calculation are known.

For the case of 0.0486% chromia–alumina at 28.8 atmospheres and 55°K. the following is calculated: $T^{1/2}G(T) = 1.16$ deg.$^{1/2}$ and $\tau_{1/2} = 7.7$ min. The experimental half-life is shown in Table II for run no. 26–8: $\tau_1/_2 = 8.5$ min.

For the case of 0.0486% chromia–alumina at 71.3 atmospheres and 77°K., the following is calculated: $T^{1/2}G(T) = 2.00$ deg.$^{1/2}$, $s\rho/N = 1.11 \times 10^{-3}$ mole trivalent chromium in the chamber; $\tau_{1/2} = 11.5$ min. compared to an experimental value of 11.0 shown in Table I, run 26–2.

For 0.237% chromia–alumina at 100.3 atmospheres and 77°K., the following is calculated: $s\rho/N = 5.30 \times 10^{-3}$ g.-atom; $\tau_{1/2} = 3.5$ min. compared to an experimental value of 4.0 min. shown in Table I, run 27–6.

In Fig. 5 the dashed line represents the calculated half-life *vs.* $1/[T^{1/2}G(T)]$. It is seen that all the calculated half-lives are well within the variation which is possible in view of the eighth

(11) It appears that K should be one-half this value, making the calculated rate constant $k_H = 2.5 \times 10^{-3}$ min.$^{-1}$.

power dependency of r_s appearing in equation 8. The value $\nu = 10^{16}$ molecules cm.$^{-2}$ is undoubtedly high. From a consideration of the geometry of the closest packing of molecules on a surface Brunauer[14] gives for the area covered by one molecule

$$\text{Area} = (4)(0.866)\left(\frac{M}{4\sqrt{2}N_A\delta_l}\right) \qquad (10)$$

where M is the molecular weight of the gas adsorbed, δ_l is the density of the liquefied gas, and N_A is Avogadro's number. Taking the density of liquid hydrogen as 0.070 g. cm.$^{-3}$, the value $\nu = 7 \times 10^{14}$ molecules cm.$^{-2}$ can be calculated.

The significance of the calculations concerning the absolute rate is that the same choice of values for these variables gave agreement with experiment for both the low surface coverage case and the high surface coverage case, using different catalyst systems.

The agreement of the theoretical and experimental temperature dependencies both for the low surface coverage cases such as that investigated by Harrison and McDowell and for the higher surface coverage case investigated here, together with the pressure dependencies investigated for these two cases strengthens the model assumed in the theory for the conversion. This agreement is all the more striking in view of the fact that the theory predicts a negative temperature dependency for the low surface coverage case and a positive temperature dependency for the high surface coverage case.

It is a pleasure to acknowledge the assistance of Dr. Clarence M. Cunningham in the preparation of the catalysts and of Mr. L. E. Cox, foreman of the Cryogenic Laboratory Shop, in the construction of the catalyst chamber.

The Photolysis of Methyl Ketene

BY G. B. KISTIAKOWSKY AND BRUCE H. MAHAN[1]

RECEIVED DECEMBER 19, 1956

The gas phase photolysis of methyl ketene was investigated using light of 3650, 3130 and 2400 Å. wave length. The principal photolytic products were found to be CO, C_2H_4 and C_4H_8. The experimentally determined effects of temperature, wave length of light, methyl ketene and inert gas concentrations are explained by a mechanism involving vibrationally excited ethylidene radicals rearranging at measurable rates into ethylene. The alternative mechanism involving only photo-excited methyl ketene molecules is shown to be inconsistent with observations.

Introduction

Extensive investigations of the photolysis of ketene[2-7] have demonstrated the formation of the methylene radical and have provided some information on its kinetic behavior. The photolysis of the next homolog, methyl ketene, has not been described in the literature. By analogy, it should result in the formation of the ethylidene radical, CH_3CH. Previous attempts to study the chemistry of this radical have involved the pyrolysis and photolysis of diazoethane, CH_3CHN_2, and acetaldazine, $CH_3CHNNCHCH_3$. The decomposition of the latter was found to be quite complicated[8] and apparently does not involve the ethylidene radical to any important extent. Investigations of the properties of the ethylidene radical produced from diazoethane have been hampered by the hazards involved in handling this material.

Rice and Glasebrook[9] observed no reaction of the ethylidene radical with antimony mirrors when pyrolyzing diazoethane at 650° and higher. The only decomposition products detected were ethylene and nitrogen. The authors concluded that if ethylidene was formed at all under their conditions, it isomerized to ethylene so fast as to exclude all other reactions.

Barrow, Pearson and Purcell[10] observed the removal of selenium and tellurium mirrors when pyrolyzing diazoethane at 400°. As the furnace temperature approached 600° the rate of mirror removal progressively decreased, thus confirming the speculation of Rice and Glasebrook on the thermal instability of the ethylidene radical. The products resulting from the reaction with selenium mirrors were shown by Barrow, *et al.*, to have the properties of selenoacetaldehyde. The same product was obtained when the authors decomposed diazoethane photochemically in the presence of selenium mirrors.

The ultraviolet photolysis of diazoethane was also studied by Brinton and Volman[11] who detected small amounts of butene-2, hydrogen and acetylene among the products, in addition to ethylene and nitrogen. The authors suggested that butene-2 originated from the reaction

$$CH_3CH + CH_3CH \longrightarrow CH_3CHCHCH_3$$

Repeated explosions of diazoethane led to the discontinuation of this work. As the following will

show, the photolysis of methyl ketene provides a more satisfactory source of ethylidene radicals.

Experimental Details

Methyl ketene was prepared by the method of Jenkins.[12] The vapor of propionic anhydride was pyrolyzed at low pressure in a quartz tube heated externally to 600°. The products passed through a trap cooled to −78° where unreacted anhydride and propionic acid were condensed. Methyl ketene was collected in a subsequent trap which was cooled to −161°, more volatile gases being removed continuously by a diffusion pump. The contents of the second trap were analyzed as 99% methyl ketene and were further purified by two slow bulb-to-bulb distillations. The delivery bulb was kept at −78° and the receiver bulb at −111°, continuous pumping by a diffusion pump assisting in the removal of non-condensables. The first and last quarters of each distillation were discarded. The freshly distilled product was 99.9% absorbed by Ascarite and no ethylene or other lower boiling gases were ever detected as impurities. Although the purified methyl ketene was stored in a trap cooled with liquid nitrogen, the amount of impurity non-absorbable in Ascarite slowly increased with the age of the preparation and could not be removed by a repetition of the purification procedure described above. The impurity was not identified chemically but the mass spectrum of older preparations suggested the presence of some C_3 and C_5 hydrocarbons. An attempt to remove these impurities by a low pressure column fractionation failed, since methyl ketene rapidly polymerized in the still pot and on the column packing. The presence of the impurities in methyl ketene, which may have amounted to 0.5% in some kinetic experiments, made it advisable to express the results of photochemical experiments mainly in terms of carbon monoxide and ethylene yields, since analyses for these products were not complicated by the above-mentioned impurities.

The ketene which was used as an internal actinometer for the quantum yield measurements was prepared by the pyrolysis of acetic anhydride and was purified and stored in an identical manner to methyl ketene.

Hydrogen used in the analytical procedure was Matheson Extra Dry grade (99.8%), which was passed over heated platinized silica gel and $Mg(ClO_4)_2$ to remove oxygen and water vapor.

Oxygen from an Airco tank was treated similarly before use in the combustion analyses.

The *n*-butane was Phillips Petroleum Company Research Grade material (99.9%) and was used after removing non-condensables at −161°.

Sulfur hexafluoride, Matheson C.P. Reagent grade, was distilled twice from −111 to −161°, the first and last quarters of each distillation being discarded.

Carbon dioxide, Matheson Bone Dry grade (99.8%), was used after the removal of non-condensables at −161°.

Diethyl ketone, used for actinic measurements, was Eastman White Label grade, subjected to two bulb-to-bulb vacuum distillations before use.

The photochemical experiments were carried out in a static system. This consisted of the usual pumping arrangement, cold traps and bulbs for the storage of the required chemicals, a gas mixing manifold, a reaction cell, a quartz spiral manometer and a semi-micro gas analytical system.

The light source for almost all the experiments was a low pressure mercury arc of the type described by Bates and Taylor.[13] Its high intensity made it especially suited for this research, since enough products could be obtained for analysis after only five minutes irradiation time. Methyl ketene dimerizes at a measurable rate in the vapor phase. By keeping the pressure of methyl ketene at 30 mm. and below and limiting the runs to five minutes, dimerization was kept to negligible proportions (considerably less than 0.5% in the reaction cell).

The lamp consisted essentially of three concentric quartz tubes. The discharge was maintained in the outermost annular space by a 20 Å. direct current, at a 47-volt potential drop. The light intensity was kept reasonably constant by a servo-mechanism controlled by an RCA 935 photoelectric cell.

A Pyrex reaction cell was axially located in the innermost space of the lamp. To maintain a constant temperature, either water or a filter solution was circulated through the annular space immediately surrounding the reaction cell. The other annular space of the lamp could be filled with a second filter solution, the thickness of each layer being 7 mm. To isolate the 3130 Å. group of the mercury spectrum the outer filter space was filled with an aqueous solution containing 300 g. of $NiSO_4 \cdot 6H_2O$ and 75 g. of $CoSO_4 \cdot 7H_2O$ per liter. A solution containing 0.5 g. of K_2CrO_4 per liter of water was circulated through the inner compartment. To isolate the 3650 Å. spectral region the circulated medium was an aqueous solution containing 0.02 g. of 2,7-dimethyl-3,6-diazacyclohepta-1,6-diene hydrochloride per liter while the second solution contained 500 g. of $CuSO_4 \cdot 5H_2O$ and 75 g. of $CoSO_4 \cdot 7H_2O$ per liter.

A few experiments were made using the strongly reversed resonance line of a British Thomson–Houston high pressure mercury lamp. The radiation from this almost point source was collimated by a quartz lens, passed through a 3 cm. filter of chlorine gas (1 atm. pressure) and through another filter cell containing nitrogen saturated with mercury vapor at room temperature. Following the filters were a cylindrical quartz reaction cell of 12 cm. length and a front surface aluminized mirror to reflect the radiation back into the reaction cell. The asymmetrically broadened resonance line of this lamp extended from approximately 2550 to 2300 Å., the average wave length being about 2400 Å.

The reaction mixtures were prepared by admitting the components successively into a one-liter flask and measuring their pressures with the quartz spiral manometer. A glass stirrer, driven magnetically, ensured rapid mixing of the components prior to admission to the reaction cell. Since the rate of thermal dimerization of methyl ketene was affected by inert gases and was subject to wall effects, it was impossible to prepare and keep inert gas–methyl ketene mixtures of accurately predetermined composition. This mixture was therefore made up to the approximate composition desired and a sample of it was analyzed while the irradiation was taking place.

The progress of the (dark) dimerization of methyl ketene and of the photochemical reaction were followed manometrically, using the quartz spiral manometer, but reliance was placed on the chemical analysis of the reaction mixtures. This was carried out in a system similar to that described by Nash.[14] The product gases were passed through a trap cooled by liquid nitrogen and the non-condensables separated, measured and analyzed by combustion over CuO. Methyl ketene was separated from the condensables by passing them through either Ascarite or anhydrous magnesium perchlorate. The latter agent proved to be an excellent absorber of methyl ketene and thus provided means for analyzing mixtures of methyl ketene and carbon dioxide. The condensable reaction products were then separated into two fractions, one volatile at −161°, and both fractions were analyzed by combustion with added oxygen on platinized silica gel, or catalytic hydrogenation. Samples could be withdrawn for infrared or mass spectrometric analysis. The performance of the entire analytical system was checked repeatedly with known gas mixtures.

Experimental Results

1. The Absorption Spectrum and the Nature of the Products.—The absorption spectrum of methyl ketene was compared with that of ketene using a Cary recording spectrophotometer. As Fig. 1 shows, the two spectra are very similar, except that the absorption of methyl ketene is slightly shifted to lower frequencies. The low resolution tracings showed no evidence of vibrational structure in either spectrum.

Figure 1 shows that with the radiation of a mercury arc filtered only by the Pyrex walls of the reaction cell, the effective radiation must consist of the 3130, 3440 and 3650 Å. line groups. Experiments designed to determine the nature of the reaction products were carried out with this polychromatic

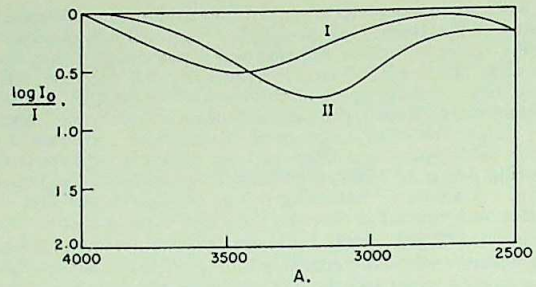

Fig. 1.—Absorption spectra of methyl ketene (I) and of ketene (II), both in a 10 cm. layer at 86 mm. pressure.

radiation. Followed manometrically, the reaction was observed to be accompanied by a pressure increase, the rate decreasing with irradiation time in a manner quite similar to that observed with ketene. This fact suggests that the intermediates formed in the photochemical decomposition of methyl ketene react with the stable products of the reaction just as methylene reacts with the ethylene formed in the decomposition of ketene. Subsequent experiments on the methyl ketene system showed that ethylene was one of the reaction products, and that the rate of pressure increase was lowered by adding ethylene to the reaction mixture.

Gaseous products which were not condensed in a trap at −196° were found analytically to be pure carbon monoxide. A mass spectrometric examination of this fraction indicated the presence of traces of methane.

The fraction non-condensable at −161° was shown by catalytic hydrogenation to be a pure mono-olefin or an equimolar mixture of acetylene and ethane. A mass spectrometric analysis showed it to be ethylene with at most 0.5% ethane and no higher hydrocarbons. The infrared spectrum of the sample showed the 10.52 μ band of ethylene and no other bands, because of the small size of the sample available.

The hydrogenation of the fraction non-volatile at −161° showed it to contain on the average one double bond per mole. Combustion with oxygen, the results of which are shown in Table I, identified

Table I

Two Combustion Analyses of the Product Fraction Condensable at −161°

All quantities are in micromoles

	I	II
Condensable at −161°	0.636	0.586
Mole no. change on combustion	−1.82	−1.70
Calcd. for C_4H_8	−1.91	−1.75
CO_2 in products	2.41	2.64
Calcd. for C_4H_8	2.54	2.34

the material as a C_4 hydrocarbon. A mass spectrometric analysis was consistent with the identification as a C_4 mono-olefin, but the size of the sample precluded the identification of the butene isomer present.

The results of these analyses were taken to mean that, within the accuracy of the measurements, methyl ketene is decomposed by ultraviolet light into a mixture of carbon monoxide, ethylene and butene

$$2CH_3CHCO + nh\nu \longrightarrow 2CO + (2 - x)C_2H_4 + \frac{x}{2}C_4H_8 \quad (1)$$

Table II shows that this is quantitatively correct and also demonstrates that the composition of the hydrocarbon fraction depends on the pressure of methyl ketene in the reaction cell. The higher the pressure the less ethylene and the more butene is obtained, but the sum of ethylene plus twice the amount of butene remains equal to carbon monoxide, as indicated by eq. 1.

2. Quantum Yields.—Primary quantum yields of ketene and methyl ketene decompositions under exposure to 3130 Å. radiation at 24° were determined using diethyl ketone as the internal actinometer. The absorption coefficients of all three were determined with the Cary spectrophotometer. Only the ratios, of course, were required for the calculations. The quantum yield of diethyl ketone was found to be approximately unity[15] at room temperature and low radiation intensities. At higher intensities, comparable to those used here, the yield may be as low as 0.6.[16] The latter experiments were made with diethyl ketone concentrations one-half to one-third as great as those of Table III, thus favoring radical recombination processes. The value to be used in the calculations thus lies between 1.0 and 0.6 and Table III shows therefore that the primary quantum yield of ketene decomposition is between 1.12 and 0.67. Experiments were made with different pressures of ketene at this wave length and the ratio of carbon monoxide production to the pressure of ketene was found to be independent of pressure. Since the fraction of absorbed radiation was small, this shows the independence of the quantum yield of pressure and so suggests, but does not prove, that the quantum yield is unity. In any case, the uncertainty does not affect the validity of the conclusions to be made below.

To determine the primary quantum yield of methyl ketene decomposition some assumption

must be made regarding secondary reactions. Consideration of the data presented in Table II and analogy with the ketene mechanism suggest the set of reactions

$$CH_3CHCO + h\nu \longrightarrow CO + CH_3CH$$
$$CH_3CH \longrightarrow CH_2CH_2 \qquad (2)$$
$$CH_3CH + CH_3CHCO \longrightarrow C_4H_8 + CO$$

The amount of carbon monoxide directly resulting from the primary process is therefore

$$CO_{primary} = C_2H_4 + 1/2(CO_{obsd} - C_2H_4) \qquad (3)$$

Use of this equation in the quantum yield calculations avoids the least accurately determined quantity, the yield of butene. On this basis, the primary quantum yield of carbon monoxide, using 3130 Å. wave length radiation, is found to depend slightly on the pressure of methyl ketene and to tend to the same value as that of ketene (unity?) at low pressures, as shown in Fig. 2.

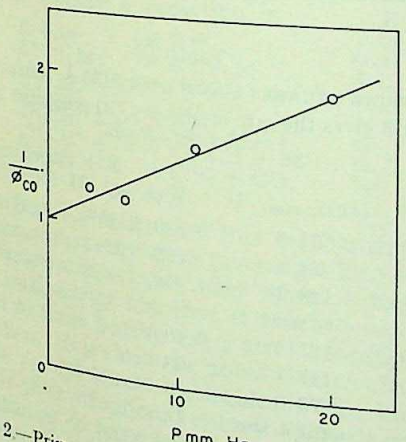

Fig. 2.—Primary quantum yields of methyl ketene decomposition by radiation of 3130 Å. wave length, calculated assuming that of ketene is unity.

The primary quantum yield of methyl ketene decomposition in the 3650 Å. wave length region was determined at 24° using ketene as the internal actinometer. The quantum yields for ketene at this wave length were interpolated from the graph given by Strachan and Noyes.[5] The results are shown in Fig. 3. The total light intensity entering the reaction cell at this wave length was 2×10^{18} quanta/second. The decrease of the quantum yield with increasing pressure of methyl ketene is seen to be more exaggerated than the corresponding behavior of ketene reported by Strachan and Noyes.

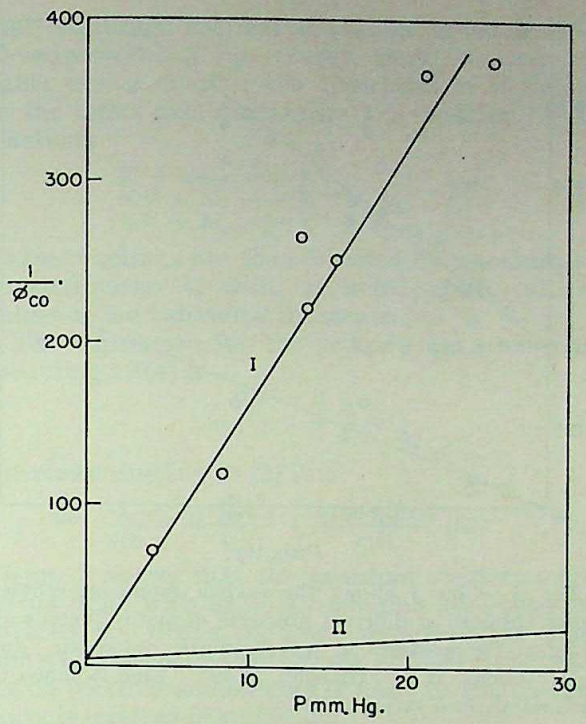

Fig. 3.—Primary quantum yields (I) of methyl ketene decomposition in radiation of 3650 Å. wave length. Line II shows data of Strachan and Noyes (ref. 5) obtained with ketene at this wave length.

3. Effects of Temperature.—The provisional reaction mechanism specified above suggests that if the unimolecular rearrangement of the ethylidene radical into ethylene and the competing step (attack on a methyl ketene molecule) have different activation energies, the carbon monoxide–ethylene ratio should change with temperature at constant methyl ketene concentration. Experiments were therefore carried out at 5 and 49° using polychromatic radiation. The results, together with those of Table II obtained at 24°, are plotted in Fig. 4. The carbon monoxide–ethylene ratio is seen to be a linear function of the concentration of methyl ketene. Temperature has no observable effects.

For purposes of comparison the butene–ethylene ratio is also plotted in this figure. The data are consistent with a straight line having zero intercept. As already noted in a preliminary publication,[17] the forms of the relations between the methyl ketene concentration and the carbon monoxide–ethylene and butene–ethylene ratios are consistent with the provisional mechanism proposed above.

4. The Effects of Radiation Frequency.—Separate measurements of the carbon monoxide–ethylene ratio in the initial stage of the reaction were made using spectrally isolated radiation of 3650, 3130 and 2400 Å. wave length. The results are presented graphically in Fig. 5. It is seen that while the behavior remains qualitatively the same over this entire spectral region, the probability of forming ethylene, rather than butene, at a

of the total pressure to the pressure of methyl ketene. While it seemed highly probable that sulfur hexafluoride and carbon dioxide would not participate chemically in the reaction, butane might be suspected of reacting with ethylidene radicals. A sample of the products non-condensable at −161° was therefore subjected to a mass spectrometric examination, which showed only a negligible amount of ethane to be present. This does not prove the absence of an addition reaction[18] but it does make more legitimate the inclusion of butane in Fig. 6.

An attempt was made to determine the effect of inert gas when the mixture was irradiated with 3650 Å. light. Preliminary runs indicated that the total yield of CO was decreased and the ratio of carbon monoxide to ethylene was increased by the addition of an inert gas (carbon dioxide and *n*-

(18) See for example, H. E. Buttery, R. G. Laughlin and N. Chakkiburi, THIS JOURNAL, 78, 3224 (1956).

Digitized by Arya Samaj Foundation Chennai and eGangotri

butane just as with 3130 Å. radiation). The amounts of products obtained under these conditions were so small that quantitative separation from the large excess of inert gas was extremely difficult. These experiments were not pursued further.

Discussion

The experimental data show that the products of the photochemical decomposition of methyl ketene are carbon monoxide and a mixture of ethylene and butene in varying proportions. An increase of collisional frequency, either through addition of an inert gas or through an increase of the methyl ketene concentration lowers the primary quantum yields, far more so with 3650 Å. radiation than at 3130 Å. The limiting (zero pressure) quantum yield is approximately unity for 3130 Å. radiation but may be less than unity with 3650 Å. radiation. The carbon monoxide–ethylene ratio is increased by increasing the wave length of absorbed radiation and by increasing the concentration of methyl ketene and inert gases, but is independent of temperature.

These observations are readily explained by a reaction mechanism which involves ethylidene radicals. It must be postulated that the ethylidene radicals are produced with excess vibrational and translational energies and have reactivities which depend on the wave length of radiation used to produce them. Denoting by K a molecule of methyl ketene, by M any molecule, including methyl ketene, by * the electronic excitation of methyl ketene, and by $'$, $''$, increasing amounts of vibrational energy, the mechanism applicable to 3130 Å., and undoubtedly to 2400 Å. radiation, is

$$\begin{array}{lll} K + h\nu = K^{*''} & & I_{abs} \\ K^{*''} + M = K^{*} + M & & k_2 \\ K^{*''} = CH_3CH'' + CO & & k_3 \\ CH_3CH'' = CH_2CH_2 & & k_4 \\ CH_3CH'' + K = C_4H_8 + CO & & k_5 \\ CH_3CH'' + M = CH_3CH + M & & k_6 \\ CH_3CH + K = C_4H_8 + CO & & k_7 \\ K^{*} + M = K + M & & k_8 \end{array} \qquad (4)$$

The essential feature of this mechanism is the assumption that ethylidene rearranges into ethylene with measurable velocity only when it has excess vibrational energy but that it reacts with methyl ketene to form butene even after vibrational deactivation. It is also to be noted that electronically excited methyl ketene molecules which have lost most of their vibrational energy through collisions are assumed to have only one possible fate: loss of electronic energy by some further collision process. This assumption recognizes the experimental fact that the quantum yields obtained with 3650 Å. radiation were two orders of magnitude lower than those obtained at 3130 Å., indicating that photo-excited molecules with small amounts of vibrational energy dissociate only rarely compared with molecules which have a large amount of excess vibrational energy.

If the uncertain limiting quantum yield with 3650 Å. radiation is actually unity, mechanism 4 applies here also, but with altered rate constants because of the lower excitation energy of the ethylidene radicals. If the limiting quantum yield at this wave length is below unity, it may be supposed that additional thermal activation[5] is required for decomposition. This energy may be acquired either before or after the absorption of radiation. In the latter case mechanism 4 is modified by the reactions

$$\begin{array}{lll} K + h\nu_{3650} \longrightarrow K^{*\prime} & & I_{abs} \\ K^{*\prime} + M \longrightarrow K^{''*} + M & & K_1 \\ K^{*\prime} + M \longrightarrow K^{*} + M & & k_{-1} \end{array} \qquad (5)$$

These reactions are then followed by reactions 2–8 of mechanism 4, with, as noted above, altered values of the individual constants.

The expression for the primary quantum yield according to (4) is

$$1/\phi_{CO} = 1 + \frac{k_1}{k_3}(M) \qquad (6)$$

whereas according to (5) it is

$$\frac{1}{\phi_{CO}} = \frac{k_1 + k_{-1}}{k_1} + \frac{k_2(k_1 + k_{-1})}{k_1 k_3}(M) \qquad (7)$$

Figure 2 shows that the quantum yield measurements done with 3130 Å. radiation are consistent with eq. 6. Either eq. 6 or 7 represents the quantum yield measurements made at 3650 Å. depending on whether an intercept of unity or greater than unity is inferred from Fig. 3.

The expressions for the ratios $(CO)/(C_2H_4)$ and $(C_4H_8)/(C_2H_4)$ given by mechanism 4 or 5 are

$$\frac{(CO)}{(C_2H_4)} = 1 + \frac{2k_5}{k_4}(K) + \frac{2k_6}{k_4}(M) \qquad (8)$$

$$\frac{(C_4H_8)}{(C_2H_4)} = \frac{k_5}{k_4}(K) + \frac{k_6}{k_4}(M) \qquad (9)$$

The data of Figs. 4 and 5 show that these ratios are linear functions of the methyl ketene pressure, and that the slopes of the two lines are in the ratio of two to one. Furthermore, the intercepts are one and zero, exactly as predicted by eqs. 8 and 9.

The proposed free radical mechanism is completely consistent with the experimental data but it is not unique in this respect. A mechanism based on photo-excited methyl ketene molecules leads to formally identical rate equations

$$\begin{array}{lll} CH_3CHCO + h\nu \longrightarrow CH_3CHCO^{*''} & & I_{abs} \\ CH_3CHCO^{*''} + M \longrightarrow CH_3CHCO + M & & Mk_2 \\ CH_3CHCO^{*''} \longrightarrow CH_2CH_2 + CO & & k_9 \\ CH_3CHCO^{*''} + CH_3CHCO \longrightarrow C_4H_8 + 2CO & & k_{10} \\ CH_3CHCO^{*} + CH_3CHCO \longrightarrow C_4H_8 + 2CO & & k_{11} \\ CH_3CHCO^{*} + M \longrightarrow CH_3CHCO + M & & Mk_8 \end{array} \qquad (10)$$

Aside from the fact that no free radicals are involved here, this mechanism differs from the mechanism 4 in an extremely important detail. The reactivity of a photo-excited molecule in a bimolecular step such as 10 cannot be expected to be overwhelmingly dependent on the amount of vibrational energy possessed by such a molecule. Therefore step 11, the reaction of a vibrationally deactivated but electronically excited molecule, must be included in the mechanism 10. However, to account for the decreased quantum yields found experimentally at 3650 Å., it must be concluded that k_{11} is much smaller than k_{10} in mechanism 10; that is, the bimolecular reactivity of the excited molecule must be strongly dependent on its vibrational excitation. Despite this inconsistency, let us examine the behavior predicted by the excited molecule mechanism when an inert gas is present

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in the reaction mixture. Mechanism 10 gives the expression

$$\frac{\frac{(CO)}{(C_2H_4)} - 1}{(K)} = 2\frac{k_{10}}{k_9} + 2\left(\frac{k_{11}}{k_9}\right)\left[\frac{k_2(M)}{k_{11}(K) + k_8(M)}\right] \quad (11)$$

Since the quantum yields obtained at 3650 Å. were generally less than 0.01, k_{11} is necessarily much smaller than k_8. In the presence of a large amount of inert gas, $k_8(M)$ is very much greater than $k_{11}(K)$, and so we may, to a very good approximation, eliminate the latter term from the denominator of the last term in eq. 11. The excited molecule mechanism is then seen to predict that the quantity $(CO)/(C_2H_4) - 1/(K)$ is independent of the pressure of inert gas. This prediction is to be contrasted to the expression obtained from the free radical mechanism

$$\frac{(CO)/(C_2H_4) - 1}{(K)} = 2\frac{k_5}{k_4} + 2\frac{k_6}{k_4}\frac{(M)}{(K)} \quad (12)$$

Reference to Fig. 6 shows that the quantity $[(CO)/(C_2H_4) - 1]/(K)$ is indeed a linear function of the ratio of total pressure to the pressure of methyl ketene, as predicted by the free radical mechanism 4 and eq. 12. The excited molecule mechanism, carried to its logical conclusion, predicts the effect of inert gases incorrectly.

Equations 8 and 12, and Figs. 5 and 6 give the ratio k_5/k_6 as 1.8 when the quenching gas is *n*-butane or sulfur hexafluoride and 7.5 for carbon dioxide. Varied information in the literature referring to rates of intermolecular energy exchange, suggests that a vibrationally excited ethylidene radical probably does not lose most of its excess energy in a single collision, but does so after a small number, when collisions are with a complex molecule. Hence a value of $10^{-1}Z_0$ for k_5 appears to be reasonable and therefore (see eq. 8 and Fig. 5) $k_4 \cong 10^8$ sec.$^{-1}$ when ethylidene radicals are produced by the 3130 Å. radiation.

If the quenching rate constant, k_6, is the same for radicals produced by the 3650, 3130 and 2400 Å. radiation, the isomerization rate constants, k_4, are in the ratio 1:2.9:4.7, as shown by Fig. 5. Qualitatively, this is readily understood because radicals produced by radiation of higher frequency undoubtedly acquire larger vibrational energy and the specific unimolecular rate constant of a molecule having energy E, when E_0 is the minimum energy required for the reaction, has been estimated[19] to be proportional to

$$\left(\frac{E - E_0}{E}\right)^{n-1} \quad (13)$$

Here n denotes the number of internal degrees of freedom among which the energy is randomly distributed. A quantitative application of the expression 13 to the two ratios of k_4 obtained above is questionable because it is not known what fraction of the total energy of the radiation is present as vibrational energy of the ethylidene radical. An extreme assumption can be made that this energy is equal to the energy of the light quanta less the dissociation energy of the C–C double bond in methyl ketene. A consistent answer can then be obtained only if the dissociation energy is taken to be about 68 kcal., which gives $E_0 \cong 3$ kcal. if $n = 6$. This value of the dissociation energy is probably too low because, assuming that the dissociation energies of ketene and methyl ketene are the same, it gives 79 kcal. for the heat of formation of the methylene radical. From this it follows that the energies of successive separation of hydrogen atoms from methane are: 102, 98, 118, 80 kcal., a rather improbable sequence. Undoubtedly some of the radiation energy is converted into translational energy of the two fragments resulting from the decomposition of methyl ketene. Qualitatively, these calculations are important because they show that the formation of vibrationally excited ethylidene radicals from methyl ketene molecules, which have absorbed 3650 Å. radiation, is consistent with the experimental data; this in turn shows that E_0, the minimum activation energy for rearrangement into ethylene, is quite small. The small value of E_0 suggests, according to mechanism 4, which neglects thermal activation, that the reaction of quenched ethylidene radicals with methyl ketene (reaction 7) is very fast. In this respect, ethylidene behaves very much like methylene.[20]

In conclusion a few comments should be made on the primary quantum yields. From the dependence of the quantum yield on pressure with 3130 Å. radiation, the lifetime before decomposition (the reciprocal of the specific dissociation probability) of an excited methyl ketene molecule can be estimated as 3×10^{-9} second if every collision results in deactivation. The specific dissociation probability after absorption of 3650 Å. radiation is 230 times smaller if quenching occurs on every collision. If the quantum yields extrapolated to zero pressure are less than unity, fluorescence or radiationless transitions to a long lived electronic state (which is quenched even at the lowest pressures investigated), as well as the previously mentioned possibility of thermal excitation (mechanism 5) might be responsible. One of the present authors (BHM) and Dr. R. Williams failed to observe any fluorescence from solutions of ketene in a rigid medium at −195° upon irradiation with 3650 Å. light. This suggests that if the limiting quantum yields for these molecules are indeed less than one at 3650 Å., internal conversion to the ground state is responsible.

It is interesting to note that comparison of the pressure dependence of the quantum yield of carbon monoxide from ketene irradiated with 3650 Å. light[5] with our similar data obtained with methyl ketene indicates that the dissociative lifetime of ketene is shorter than that of methyl ketene by a factor of 25. All these dissociative lifetimes are short compared with the radiative lifetimes, which may be estimated from the integrated absorption coefficients as 3×10^{-6} and 7×10^{-6} sec. for ketene and methyl ketene, respectively. The near ultraviolet absorption of ketene probably represents a singlet–singlet transition, and it has been recently demonstrated[20] that methylene radicals resulting from the photochemical decomposition of ketene are in a singlet state. Therefore the

May 20, 1957

relatively long lifetimes to decomposition of ketene and methyl ketene molecules are not due to electronic multiplicity correlation rules. The lifetimes of these molecules can be likened to those of thermally activated molecules, the delay in both cases being due to migration of vibrational amplitude among several bonds of the molecule. On this basis, the lifetime of the photo-excited molecules behave as qualitatively predicted by eq. 13; the lifetimes decrease with total energy and increase with the complexity of the molecule.

Reactions of Gaseous Ions. I. Methane and Ethylene

BY F. H. FIELD, J. L. FRANKLIN AND F. W. LAMPE

RECEIVED OCTOBER 1, 1956

At elevated pressures in a mass spectrometer ion source reactions occur between certain ions and the neutral species present. We have studied the various secondary ions formed in methane and ethylene at elevated pressures and have determined the reactions by which they are formed and the rates of these reactions. The rates are all extremely fast. The reaction rates have been treated by classical collision theory and it has been shown that to a fair approximation the cross-sections and reaction rate constants can be predicted from a simple balance of rotational and polarization forces.

Introduction

Secondary processes in mass spectrometers were first observed by early workers in the field[1] but were treated, for the most part, as nuisances due to experimental difficulties that had to be overcome in the development of analytical mass spectrometry. In recent years, however, a number of studies of secondary processes have been reported[2] which are of considerable interest because of the information afforded concerning the gaseous reactions of ions with molecules. Tal'roze and Lyubimova[3] reported the formation of CH_5^+ in methane. Stevenson and Schissler[4] published specific reaction rates for the formation of CD_5^+ in deuterated methane, D_3^+ in deuterium, and for the reactions of A^+ with H_2, D_2 and HD. In a recent note Schissler and Stevenson[5] have reported many more ion–molecule reactions included in which are reactions forming $C_2H_5^+$ and $C_2D_5^+$ in methane and deuterated methane, respectively, and $C_2H_5^+$, $C_3H_3^+$ and $C_3H_5^+$ in ethylene. These reactions were reported to exhibit cross-sections that decreased to zero at finite values of ion-energy and small negative temperature coefficients.

This paper comprises a detailed study of the ion–molecule reactions taking place in methane and ethylene when these compounds are subjected to ionization by electron impact in a mass spectrometer.

Theoretical

Consider the reaction of a primary ion with a neutral molecule to consist of the formation of a transition-state ion which then decomposes unimolecularly to various product ions and neutral fragments. That is

$$P^+ + M \xrightarrow{k_1} PM^+ \qquad \text{(R1)}$$

$$PM^+ \xrightarrow{k_{S_j^+}} S^+_j + F_j \qquad \text{(R2)}$$

where there will be a set of the above reactions for each primary ion that reacts with neutral molecules. If the time of decomposition of the transition-state ion is short compared with ionic residence times in the ionization chamber, the number of secondary ions of the jth type that are formed will be

$$n_{S_j^+} = \frac{k_{S_j^+}}{\sum_j k_{S_j^+}} n_{PM^+} \qquad (1)$$

where the n's are the number of ions of the various kinds formed per unit time. Since the primary ions are formed in the electron beam at a constant rate, in the following for the sake of simplicity we shall in general refer to the n's as the number of ions formed, the rate aspect of the process to be kept in mind at all times. The number of transition-state ions formed is equal to the product of the number of primary ions formed, the number of collisions made by one primary ion with neutral molecules during its ionization chamber residence time, and the collision efficiency or

$$n_{PM^+} = fQ[M]n^0_{P^+} \qquad (2)$$

where

$n^0_{P^+}$	=	number of primary ions formed
f	=	collision efficiency for the formation of PM^+
Q	=	total no. of collisions made by a single primary ion with neutral molecules at unit concn.
[M]	=	no. of molecules per unit volume

Combining (1) and (2) and introducing τ, the time in which the primary ion makes collisions with neutrals (the primary ion residence time), gives

$$n_{S_j^+} = \frac{k_{S_j^+}}{\sum_j k_{S_j^+}} n^0_{P^+} f \frac{Q}{\tau_{P^+}} [M]\tau_{P^+} \qquad (3)$$

Q/τ_{P^+} is the time-average collision rate, and the product of this quantity and the collision efficiency is the rate constant for the formation of the transition-state ion. Recognizing this and rearranging (3) gives

$$\frac{n_{S_j^+}}{n^0_{P^+}} = \frac{k_{S_j^+}}{\sum_j k_{S_j^+}} k_1 [M]\tau_{P^+} \qquad (4)$$

Thus the various types of primary ions formed will be propor-

tional to the number of primary ions collected plus the number of secondary ions (derived from the primary ions) collected. Thus, if we assume equal collection efficiencies for all ions we can write (remembering that the n's are really numbers of ions per unit time)

$$\frac{I_{S_j^+}}{I_{P^+} + \sum_j I_{S_j^+}} = \frac{k_{S_j^+}}{\sum_j k_{S_j^+}} k_1 [M] \tau_{P^+} \qquad (5)$$

where the I's are the observed ion-currents. In addition, it is easily shown that

$$\frac{I_{S_j^+}}{I_{S_k^+}} = \frac{k_{S_j^+}}{k_{S_k^+}} \qquad (5a)$$

To determine specific reaction rates from experimental measurements it is necessary to calculate the average residence time of the primary ions in the ionization chamber. In these calculations an idealized model of the ionization chamber is used, in that we ignore the effects of: (1) the magnetic field in the ionization chamber, (2) potential penetrations through the various ionization chamber orifices, (3) space charge effects, and (4) surface charge effects. The electron beam is assumed to be of infinitesimal thickness and the potential gradient in the ionization chamber (due to the ion-repeller) is taken as uniform.

Consider the primary ion to be formed in the electron beam at a distance d_0 from the ion-exit slit and at the moment of its formation to be moving with average thermal velocity in a direction making an angle ϕ with the perpendicular directed from the electron beam to the slit. It easily can be shown from the laws of motion that the residence time, τ, of an ion reaching the ion-exit slit is given by

$$\tau = \frac{1}{A}\sqrt{2Ad_0 + B^2\cos^2\phi} - \frac{B}{A}\cos\phi \qquad (6)$$

where

$A = eV/m$
$B = \sqrt{8kT/\pi m}$
e = electronic charge
V = voltage gradient in the ionization chamber
m = mass of the ion

Since all values of ϕ are equally probable, the average ion residence time is obtained by integration as

$$\bar{\tau} = \frac{1}{4\pi}\int_0^{\pi} \tau(2\pi \sin\phi)\, d\phi \qquad (7a)$$

or

$$\bar{\tau} = \frac{1}{2A}\sqrt{B^2 + 2Ad_0} + \frac{d_0}{2B}\ln\frac{\sqrt{B^2 + 2Ad_0} + B}{\sqrt{B^2 + 2Ad_0} - B} \qquad (7b)$$

This equation does not apply accurately at ionization chamber voltage gradients less than about 1 volt/cm. since at lower fields some of the ions will be lost by striking the ion repeller.

The reaction rate constant k_1 can be evaluated from the observed ion currents by the use of equations 5, 5a and 7b.

By means of the following analysis the observed ion currents can be used to determine the cross section for the reaction $P^+ + M \rightarrow PM^+$. By combining equations 1 and 2 and converting to currents we obtain

$$\frac{n_{S_j^+}}{n_{P^+}} = \frac{I_{S_j^+}}{I_{P^+} + \sum I_{S^+}} = \frac{k_{S_j^+}}{\sum k_{S^+}} fQ[M] \qquad (8a)$$

Q, the total number of collisions made by a single primary ion with neutral molecules at unit concentration can be written

$$Q = \sigma Q' \qquad (8b)$$

where

Q' = total no. of collisions made by a primary ion during its ionization chamber lifetime with neutral molecules at unit concn. taking the collision cross-section to be unity
σ = collision cross-section for a primary ion and neutral molecule

Substituting (8b) in (8a) gives

$$\frac{I_{S_j^+}}{I_{P^+} + \sum_j I_{S_j^+}} = \frac{k_{S_j^+}}{\sum_j \Sigma_{S_j^+}} k f\sigma Q'[M] \qquad (8c)$$

For a reaction with no activation energy, $f\sigma$ constitutes the reaction cross-section. Equation 8c permits the evaluation of this quantity from experimental measurements if Q' is known.

To obtain an expression for Q', we again consider the primary ion to be formed in the electron beam at a distance d_0 from the slit and at the moment of its formation to be moving with average thermal velocity in a direction making an angle ϕ with the perpendicular directed from the electron beam to the side of the chamber containing the slit. We assume that the number of ions of each type emerging from the slit is proportional to the number of that type in the ionization chamber. If this is true the position of the ion, at the instant of its formation, along an axis parallel to the electron beam is arbitrary and we take this coördinate to be zero. The velocity of any ion at time t after its formation can then be shown to be

$$v = \sqrt{B^2 + A^2t^2 + 2ABt\cos\phi} \qquad (9)$$

where the symbols are as defined previously. The average ion velocity is obtained by integration over all directions as before and is

$$\bar{v}_1 = \left(B + \frac{A^2t^2}{3B}\right) \qquad (10)$$

for the region in which $B > At$.

$$\bar{v}_2 = \left(At + \frac{B^2}{3At}\right) \qquad (11)$$

for the region in which $At > B$.

Similarly, the average relative velocity of two species α and β moving at different velocities is

$$\bar{\xi}_1 = \left(v_\alpha + \frac{v_\beta^2}{3v_\alpha}\right) \text{ for } v_\alpha > v_\beta \qquad (12)$$

$$\bar{\xi}_2 = \left(v_\beta = \frac{v_\alpha^2}{3v_\beta}\right) \text{ for } v_\beta > v_\alpha \qquad (13)$$

where ξ denotes relative velocity.

Substituting (10) and (11) for the ion velocity, v_β, and B for the average thermal velocity, v_α, of the neutral molecules into (12) and (13) results in

$$\xi_1 = \frac{1}{3}\left(4B + \frac{2A^2t^2}{3B} + \frac{A^4t^4}{9B^3}\right) \text{ for } At < B \qquad (14)$$

$$\xi_2 = \frac{1}{3}\left(3At + \frac{B^2}{At} + \frac{3AtB^2}{3A^2t^2 + B^2}\right) \text{ for } At > B \qquad (15)$$

Therefore, for unit cross-section, the total number of collisions made by one primary ion with neutral molecules at unit concentration during the time

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$$Q' = \int_0^{B/A} \xi_1\, dt + \int_{B/A}^{\tau} \xi_2\, dt \qquad (16)$$

where B/A is the time at which the ion and molecule velocities are equal. Integration of (16) gives

$$Q' = \frac{A\bar{\tau}^2}{2} + \frac{B^2}{A}\left[\frac{247}{382} + \frac{1}{3}\ln\frac{1A\bar{\tau}}{\sqrt{B^2+3A^2\bar{\tau}^2}}\right] \qquad (17)$$

where $\bar{\tau}$ is given by (7b).

In the above derivation it was assumed the neutral molecules were all moving with average thermal velocity. Actually there exists a distribution of velocities. However, it has been shown[6] that consideration of this distribution leads to a small difference in relative velocities that is well within our experimental error.

Experimental

Three types of measurements were made: (1) the variation of ion intensities with pressure (pressure studies), (2) the variation of ion intensities with ion repeller voltage (repeller studies), and (3) the appearance potentials of various ions. The first two types of measurements were made with a slightly modified Consolidated Electrodynamics Corp. (CEC) Model 21-620 cycloidal focussing mass spectrometer. The appearance potential measurements were made with a Westinghouse Type LV mass spectrometer.

The pertinent dimensions and operating characteristics of the CEC instrument are as follows. The distance between the ion repeller electrode and the ion exit slit is 1.0 mm., and the electron beam (thickness = 0.17 mm.) passes midway between the two. The length of the repeller electrode in the direction of the electron beam is 5.63 mm. The instrument as received from the manufacturer was modified by by-passing the pressure sensitive filament protection circuit and by altering the ion repeller circuit to permit the application of constant, predetermined repeller voltage. It is not provided with an adjustment for the electron accelerating voltage, and consequently all measurements were made at the manufacturer's pre-set value of about 75 volts. Similarly, no control over the ionization chamber temperature is provided (although the temperature can be measured), and temperature variations of 20–25° occurred from one experiment to another and even in the course of a single experiment. The actual value of the temperature may be taken as 150 ± 10°. The electron current was maintained at 2 μamp.

The methane and ethylene were of Phillips reagent grade, and they were condensed in liquid nitrogen and subjected to a bulb-to-bulb distillation. A middle fraction constituting about half the material condensed was collected for the measurements.

Pressure Studies.—The pressure studies involved the determination of the mass spectra of methane and ethylene at different values of the reservoir pressure. In the CEC mass spectrometer secondary ions begin to be formed in detectable amounts at a reservoir pressure of about 1 mm. In most of the experiments the reservoir pressure was varied between 1 and 30 mm. in steps of 2–5 mm. The reservoir pressure was determined by a small mercury manometer read with a cathetometer, and values obtained in this way were reproducible to 0.1 mm. In all pressure studies the repeller voltage was maintained at 1.0 volt, an arbitrarily selected value.

The quantitative interpretation of the results requires a knowledge of the pressure in the ionization chamber. To determine this quantity as a function of the more easily measured reservoir pressure, the ion repeller of the mass spectrometer was biased negatively with respect to the ionization chamber and the collected ion current measured with an RCA millimicroammeter. The repeller currents (I_i) for various reservoir pressures (p_r) were determined for argon and neon, and plots of I_i/p_r against p_r were constructed. For reservoir pressures up to about 4 mm. I_i/p_r remained constant with pressure and then increased. From this behavior and from a rough comparison of the atomic mean free paths with the known diameter of the gas leak into the ionization chamber (1 μ), we conclude that for relatively low molecular weight gases at reservoir pressures up to about 4 mm. the gas flow through the leak is molecular in character, but above this pressure mass flow occurs. In the region where molecular flow occurs, the ionization chamber atom concentration (N_i) can be expressed as $N_i = \gamma p_r$, and substituting in the relation $I_i/I_e = N_i Q_i l$ we get $\gamma = I_i/I_e Q_i l p_r$ (I_e = electron current, Q_i = total cross-section for ionization, and l = length of the repeller). From this equation, values of Q_i obtained from the data tabulated by Massey and Burhop,[7] and our experimental currents we find $\gamma_{Ne} = 7.7 \times 10^{12}$ and $\gamma_A = 7.3 \times 10^{12}$. These are equal to within experimental error, as is to be expected theoretically.

To establish the total cross-section for ionization for methane and ethylene it is assumed that in the molecular flow range of pressures the average of the values of γ for argon and neon can be applied to methane and ethylene. Then the Q_i values for these substances can be calculated from the observed currents in this pressure range. Knowing the Q_i values the ionization chamber concentration corresponding to any reservoir pressure can be calculated from the observed currents.

The Q_i values obtained are $Q_i(CH_4) = 4.8_3 \times 10^{-16}$ cm.² and $Q_i(C_2H_4) = 6.9_2 \times 10^{-16}$ cm.². Recently Otvos and Stevenson[8] have determined the relative total ionization cross-sections for a number of compounds, and from their data one calculates that $Q_i(C_2H_4)/Q_i(CH_4) = 1.55$. Our value for this ratio is 1.43, in satisfactory agreement. However, from Otvos and Stevenson, $Q_i(CH_4)/Q_i(Ne) = 4.28$, whereas our value is 7.75. Partially as a consequence of this discrepancy, we determined the total ionization cross-section of acetylene, obtaining the value $5.6_0 \times 10^{-16}$ cm². This agrees reasonably well with the value of 4.98×10^{-16} cm.² quoted by Massey and Burhop. Unfortunately, Otvos and Stevenson do not give a value for the total ionization cross-section for acetylene by low energy electrons. However, their relative value for ethylene can be converted to an absolute value of 4.13×10^{-16} cm.² using the Massey and Burhop value for $Q_i(Ne)$, and this ethylene value is appreciably lower than both our acetylene value and that given by Massey and Burhop. This seems quite suspicious, and consequently we have used our values of the methane and ethylene cross-sections in the determination of the ionization chamber concentrations.

An example of the variation of the intensities of primary and secondary ions as a function of the ionization chamber molecular concentrations, N_i, is given in Fig. 1. We think that the observed deviations from first- and second-order behavior are to be attributed to scattering of the ion beam in the analyzer and, if this be true, the intensity variation of CH_4^+, for example, should be represented by the relations

$$I_{CH_4^+} = aN_i e^{-\sigma_s L N_a} \qquad (18a)$$

$$\log (I_{CH_4^+}/N_i) = -\sigma_s L N_a/2.303 + \log a \qquad (18b)$$

where σ_s is the scattering cross-section, L is the path length in the analyzer (taken to be 8.0 cm. in our instrument), and N_i and N_a the molecular concentrations in the ionization chamber and the analyzer, respectively. Since the experimental plot of $\log (I_{CH_4^+}/N_i)$ against N_a is approximately a straight line (a small amount of curvature exists), we conclude that indeed the form of the CH_4^+ curve in Fig. 1 is for practical purposes completely accounted for by scattering in the analyzer, and we infer that all observed deviations from expected first- or second-order behavior can be attributed to this source. The values of N_a used in the plot of eq. 18b were calculated from pressures indicated by an ionization gage located on the envelope of the analyzer. The gage was not calibrated. From the mean slope of the plot we calculate that for the scattering of CH_4^+ in CH_4 in our instrument $\sigma_s = 4.0 \times 10^{-15}$ cm.².

To enable us to assess the extent to which scattering affects the values of the current ratios $I_s/(I_p + I_s)$ needed in the kinetic calculations, we have derived[9] an approximate expression for the scattering of an ion beam in the analyzer of a mass spectrometer. The scattering is assumed to re-

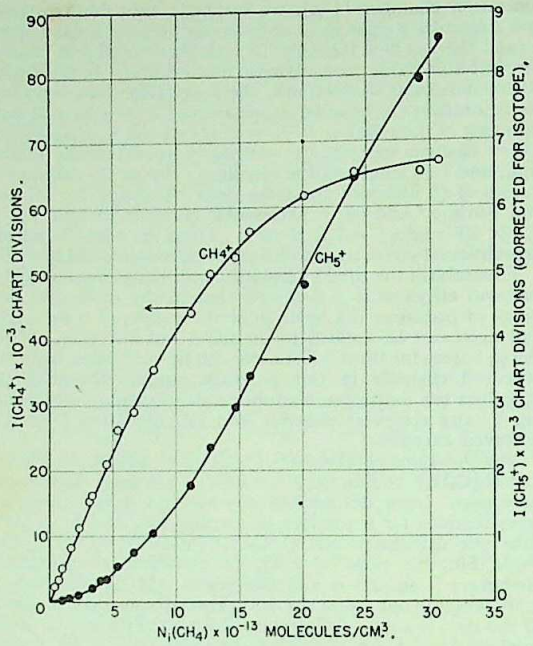

Fig. 1.—Primary and secondary ion currents against ion chamber concentration.

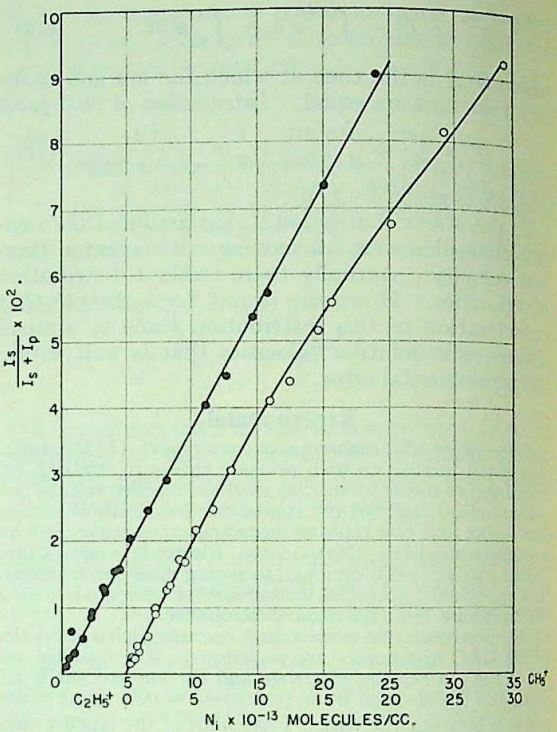

Fig. 2.—Typical curves of current ratios against ion chamber concentration.

sult solely from ion–molecule polarization interaction. The expression is

$$\sigma_s = \left(\frac{3\pi^3\alpha eL}{16 S_{eff}\, V_{esu}}\right)^{1/2} = 41.8\left(\frac{\alpha eL}{S_{eff}\, V_{pract.}}\right)^{1/2} \quad (19)$$

where

α = polarizability of the scattering gas
e = electronic charge
L = ion path length in analyzer in cm.
V = ion accelerating voltage
S_{eff} = av. distance from center of collector slit to edges of slit in cm.
$S_{eff} \cong \lambda/4$ where λ = length of collector slit in cm.

For the scattering of CH_4^+ in CH_4 in our mass spectrometer we calculate from equation 19 that $\sigma_s = 2.0 \times 10^{-15}$ cm.^{2}, to be compared with the experimental value of 4.0×10^{-15} cm.^{2}. The agreement is sufficiently satisfactory to lead us to believe that the theoretical dependence of σ_s on α and V is substantially correct, and thus we write $\sigma_s = b(\alpha/V)^{1/2}$. The constant b is evaluated from the experimental value of σ_s, and the semi-empirical expression $\sigma_s = 1.45 \times 10^{-2}(\alpha/V)^{1/2}$ results.

For the formation of the CH_5^+ ion from methane we have the relation

$$\frac{I_{CH_5}}{I_{CH_4^+} + I_{CH_5^+}} \approx \frac{I_{CH_5^+}}{I_{CH_4^+}} \alpha N_i e^{-N_a L(\sigma_{CH_5^+} + \sigma_{CH_4^+})} \quad (20)$$

and using scattering cross-section values calculated from our semi-empirical expression we calculate that a graph of $I_{CH_5^+}/(I_{CH_4^+} + I_{CH_5^+})$ *versus* N_i should not depart from linearity by as much as 10% until $N_a = 8.2 \times 10^{13}$ molecules/cc. Since the N_a value corresponding to the highest N_i value used in our experiments is 3.4×10^{13}, noticeable deviations of the current ratio from linearity should not be observed. As Fig. 2 shows, this prediction is correct. Similar calculations lead to the prediction that the graph of $I_{C_2H_5^+}/(I_{CH_5^+} + I_{C_2H_5^+})$ *vs.* N_i should depart from linearity by 10% at $N_i = 4 \times 10^{13}$ molecules/cc., which is in approximate agreement with the behavior of the experimental graph given in Fig. 2. From these and similar results we feel that differential scattering effects are not important at ion source concentrations below about $N_i = 5 \times 10^{13}$ molecules/cc. The rate constants reported in this paper are calculated only from current ratios at concentrations below this value. Two other factors which will affect the accuracy of $I_s/(I_s + I_p)$ are (1) mass discrimination in the analyzer and (2) primary and secondary ions are formed in different regions of the ionization chamber. From discrimination information reported by Robinson[10] we estimate that the largest discrimination effect occurring in our experiments is 12%. The second factor might give rise to a difference in collection efficiency for the two types of ions, but we do not know the magnitude of the resulting error, if any, in the current ratio value.

Repeller Studies.—The repeller studies involved the determination of primary and secondary ion mass spectra at different values of the ion repeller voltage (V_R) at a known, essentially constant value of the reservoir pressure (about 5 mm.). Three types of variation of ion intensities with increasing repeller voltage are to be observed (Fig. 3). That for primary ions is illustrated by the plot of $I_{CH_4^+}$, while the two types observed for secondary ions are illustrated by the plots of $I_{CH_5^+}$ and $I_{C_2H_5^+}$. We are unable to explain these differences in behavior.

None the less, the forms of the intensity variations with repeller voltage can be used in interpreting the observed secondary spectrum of methane. By comparing Figs. 3 and 4 we conclude that the mass 29 and 17 ions are formed by one type of process, namely, a bimolecular gas phase ionic reaction, but that the mass 26, 27, 28 and 16 ions are formed by another type of process, namely, ionization by electron impact in the electron beam. Since the intensity of the mass 28 ion shows a first-order pressure dependence, it seems likely that it results from a small amount of impurity, probably N_2. However, the mass 26 and 27 intensities are second order in methane pressure and must be formed from methane by some kind of secondary reaction. The appearance potential of the mass 26 ion is 11.5 e.v., which, within the limits of experimental error, is equal to the ionization potential of acetylene. This suggests that the methane undergoes a bimolecular reaction (probably on the filament) to produce acetylene, which diffuses into the ionization chamber and undergoes ionization in the electron beam. The mass 27 ion probably is formed in the same way, although the observed appearance potential (12.1 e.v.) is of no help in elucidating the nature of the ion or the reaction by which it is formed.

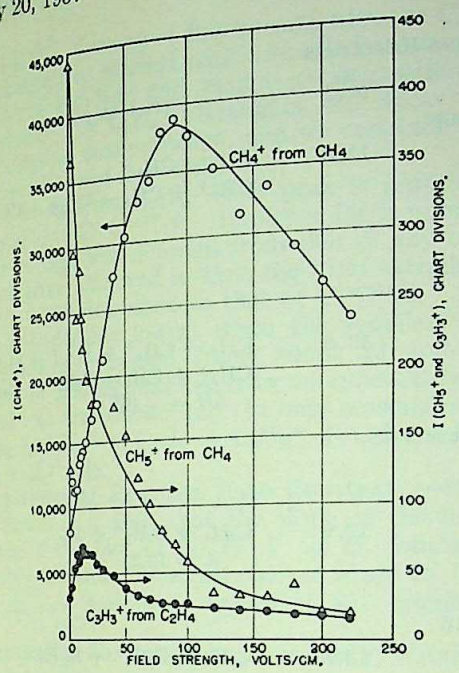

Fig. 3.—Primary and secondary ion currents against ionization chamber field strength.

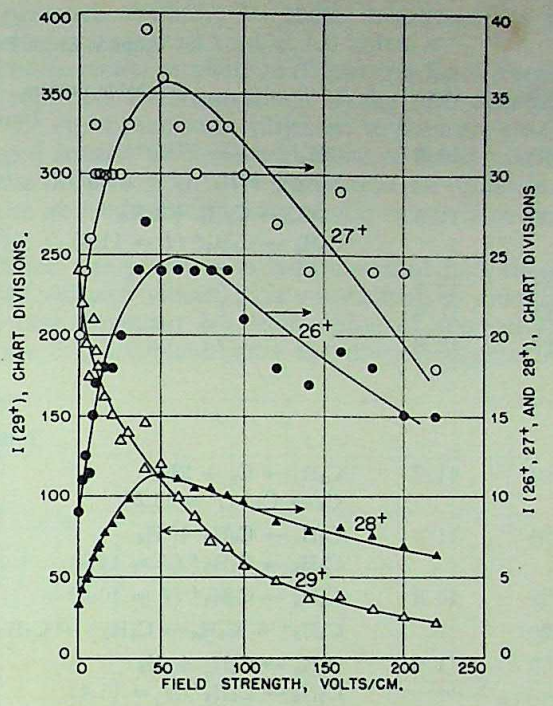

Fig. 4.—Plots of various ion currents from CH_4 against field strength.

Results obtained from repeller studies are subject to an uncertainty stemming from the possible variation in ion collection efficiency with repeller voltage. In addition, results at quite low values of V_R (less than 1 volt) are particularly suspect because the conditions in the ion source at these low voltages are probably ill-defined. Potential penetrations through the ion exit slit and the electron beam slits, the potential depression in the electron beam, surface charges, etc., could cause the actual potential in the ionization chamber to be several tenths of a volt different from that calculated on the basis of only the applied repeller voltage.

An observation which may be related to problems of ion collection efficiency is that at values of $V_R > 2.5$ volts the observed intensity of the mass 29 ion from ethylene becomes smaller than the intensity of the $C^{12}C^{13}H_4^+$ ion as calculated from the observed intensity of the mass 28 ion. On the surface this means that the secondary ion contribution to the mass 29 intensity vanishes above $V_R = 2.5$ volts and is probably erroneous even below this value. We can offer no explanation for this behavior.

Appearance Potential Measurements.—Measurements of appearance potential were made in a Westinghouse Type LV mass spectrometer using the vanishing current technique. For most of the measurements O_2 introduced along with the material under investigation was used to calibrate the electron energy scale, but in a few measurements CO_2 was used. The methane or ethylene pressure in the gas reservoir was kept at about 10 mm., which gave about maximum secondary ion currents. Experimental difficulties prevented the determination of the ionization chamber pressure to which this reservoir pressure corresponds. The electron current was maintained at 3.0 μamp. and the ion repeller at 1.9 volts.

The ionization efficiency curves sometimes show breaks (discontinuities) which are attributable to the high pressures. These arise from two sources: (1) contributions to the ion current at a given mass from ions one or two mass units different as a result of scattering and (2) pyrolysis of the sample yielding products which upon ionization contribute to the ion current at the mass being investigated. The difficulty stemming from the first process can be circumvented by obtaining the appearance potentials by repeatedly scanning across the mass spectral region of interest at small increments of the ionizing voltage. The ion intensities free from scattered contributions can then be obtained by reading the peak heights from the means of the adjacent valleys. The occurrence of pyrolysis can be inferred from the form of the ionization efficiency curve, from the value of the lowest appearance potential, and from some knowledge of the chemical properties of the substance under investigation.

From the observed agreement of replicate determinations we estimate the uncertainty in the appearance potential values to be about 0.3 volt except for the values for the mass 50 and 51 ions from ethylene, which are probably uncertain to about 1 volt.

Results[11]

Typical high pressure mass spectra (reservoir pressure = 10 mm.) of methane and ethylene are given in Table I. Table II contains the appearance potentials of the more important ions and the

[a] Ionization potentials (I) and appearance potentials (A) in e.v. Values taken from tabulation given in reference 2. [b] Reaction previously observed by Tal'roze and Lyubimova, reference 3. [c] Reaction previously observed by Schissler and Stevenson, reference 5. [d] Heats of reaction in kcal./mole. Values are calculated from ionic heats of formation tabulated in reference 2.

reactions by which they are formed. A_1 and A_2 refer to the lower and higher critical potentials found in a given ionization efficiency curve. The identification of the reactant ions has been made by considering the energetics of possible reactions, the appearance potentials of the various ions, and the dependence of the ion abundance upon pressure and repeller voltage. All the reactions involving the gas phase reactions of ions show second-order pressure dependence, and their repeller voltage dependence corresponds to that of a secondary ion. The accepted values of the primary ion ionization and appearance potentials with which the secondary ion appearance potentials are to be compared are given parenthetically in Table II. It is assumed that only exothermic secondary reactions will be observed, and this assumption can be justified by detailed considerations. The heats for the secondary reactions thought to occur are given in Table II.

Additional Comments on Table II: $m/e = 24$ and 26 from C_2H_4.—The appearance potentials of these ions were determined to learn the technique of making appearance potential measurements at high pressures. The ethylene mass 28 ion was used to calibrate the ionizing voltage scale. The two high pressure critical potentials observed for the mass 26 ion agree closely with the accepted values for the ionization potential of C_2H_2 and the appearance potential for the electron impact process $C_2H_4 \rightarrow C_2H_2^+ + H_2$, respectively; and this agreement indicates strongly that the lower high pressure value refers to acetylene molecules formed by pyrolysis from ethylene. Similarly, since the appearance potential for the formation of mass 24 ion from ethylene by fragmentation under electron impact is 26.5 volts,[2] the high pressure appearance potential for this ion refers to C_2 formed by pyrolysis and really constitutes a measure of the ionization potential of the C_2 molecule. As such it confirms the value of $I(C_2) = 11.5 \pm 1.0$ volts found by Chupka and Inghram.[12] By contrast, we found no evidence that products of mass 25 or 27 are produced in the pyrolysis of ethylene.

$m/e = 39$ from C_2H_4.—Two appearance potentials of $C_3H_3^+$ were found, the lower one corresponding to, although slightly greater than, $I(C_2H_2)$, and the upper falling midway between $A(C_2H_2^+)$ and

$A(C_2H_3^+)$. Because of this uncertainty, the $C_3H_3^+$ abundance was studied with a small, fixed concentration of ethylene and various concentrations of acetylene. The $C_3H_3^+$ abundance was linear with the acetylene concentration, and we conclude that this ion is formed from $C_2H_2^+$.

m/e = 29 from C_2H_4.—This peak in part is attributable to $C^{12}C^{13}H_4^+$. Its dependence upon repeller voltage was different from that of any other ion we have observed in that the total abundance of m/e = 29 decreased to that of $C^{12}C^{13}H_4^+$ (and even considerably lower) when the repeller voltage gradient increased above about 25 volt/cm. In view of this peculiar behavior no appearance potential was determined, but the only reasonable reaction is $C_2H_3^+ + C_2H_4 \rightarrow C_2H_5^+ + C_2H_2$, $\Delta H = -16$ kcal./mole.

Experimental Reaction Rate Constants.—From equation 5 it is seen that the slope of the linear portion of the plot of $I_S/(I_P + I_S)$ *vs.* ionization chamber molecular concentration is equal to $(k_{s_j^+}/\sum_j k_{s_j^+})k_1 \tau_{P^+}$, and using values of τ_{P^+} calculated from equation 7b, $(k_{s_j^+}/\sum_j k_{s_j^+})\, k_1$ is readily obtained. When only one product ion is formed from a given transition state ion $(k_{s_j^+}/\sum_j k_{s_j^+})k_1$ reduces to k_1, the bimolecular rate constant. When several product ions are formed k_1 is obtained by taking $\sum_j (k_{s_j^+}/\sum_j k_{s_j^+})k_1$. Table III contains the rate constants for all the reactions of methane and ethylene subjected to pressure studies. In these measurements the repeller voltage was kept at 1.0 volts.

The percentage average deviations from average for replicate determinations of the rate constants for the eight reactions subjected to pressure studies ranged from 0 to 19%, with most of the deviations of the order 3–5%. We guess that an upper limit to the absolute uncertainty of the values is perhaps 15%.

When the pressure is held constant and the repeller voltage varied it is convenient to calculate the rate constant for each value of the voltage. Figure 5 is a typical curve showing the dependence

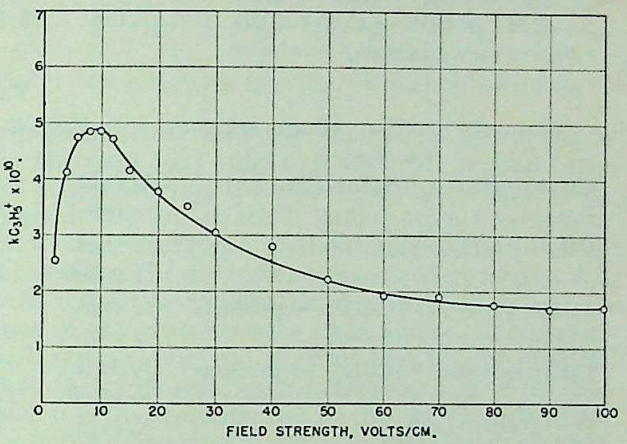

Fig. 5.—Rate constant for $C_2H_4^+ + C_2H_4 \longrightarrow C_3H_5^+ + CH_3$ against ion chamber field strength.

of the rate constant upon the ionization chamber electric field strength, and Table IV contains the rate constants at several field strengths, for all of the reactions subjected to repeller studies. The reservoir pressure was kept at 5 mm. The values tabulated are the averages of replicate measurements. As a matter of interest, measurements on the reaction $CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$ were made at field strengths up to 220 volts/cm. The form of the curve up to a field strength of 100 volts/cm. was like that of Fig. 5, and above 100 volts/cm. the value of the rate constant remained essentially constant with a value of about 2.2×10^{-10} cc./molecule sec.

The agreement between replicate determinations of the rate constants from repeller voltage studies (making comparisons at 10 volts/cm.) is generally satisfactory, the percentage deviations from average ranging from 1 to 15% with most of the deviations of the order of 5–10%. The agreement between the rate constant values determined from repeller studies (Table IV, 10 volt/cm. values) and pressure studies (Table III) is acceptable, the percentage differences between average values ranging from 0 to 15% for all values but one (42%) with most of the values falling between 0 and 10%.

It is interesting to note from Tables III and IV that the values of k_1 of all of the reactions differ from each other by at most about a factor of 2.5. These rate constants correspond to extremely fast reactions, and such fast reactions cannot have any appreciable energy of activation. This is in accordance with observations of Stevenson and Schissler and of Schissler and Stevenson,[5] who measured

	σ calcd.	13	16	19	25	32	34	37	40	45

the rates of several such reactions at various temperatures. Unfortunately, we were unable to vary the temperature in our reaction zone. Stevenson and Schissler[4] have reported a value of $1.3_8 \times 10^{-9}$ cc./molecule sec. for the rate constant for the reaction $CD_4^+ + CD_4 \rightarrow CD_5^+ + CD_3$. The ionization chamber field strength is not stated. The agreement with our value for the reaction of CH_4 is good.

Experimental Reaction Cross-sections.—The reaction rates can be expressed in terms of reaction cross-sections, $f\sigma$. Experimental values of $f\sigma$ have been calculated from the current ratios using equation 8c taking Q' values from equation 17, and these values (the averages of replicate determinations) are listed in Table V. Theoretical values of the cross-sections calculated from equation 29 described below are also listed in Table V. A graph of experimental and theoretical cross-sections against ionization chamber field strength is given in Fig. 6.

Schissler and Stevenson[5] report the following cross-sections

Reaction	Cross-sections ($\times 10^{16}$) in cm.^{2} at ion energy 0.10 e.v.	1.00 e.v.
$CH_3^+ + CH_4 \rightarrow C_2H_5^+ + H_2$	165 ± 5	39 ± 1
$C_2H_4^+ + C_2H_4 \rightarrow C_3H_5^+ + CH_3$	112 ± 3	21 ± 1
$C_2H_2^+ + C_2H_4 \rightarrow C_3H_3^+ + CH_3$	24 ± 3	6 ± 1

The agreement with our experimental results (comparing Schissler and Stevenson's 0.10 and 1.00 e.v. values with our values at 4 and 40 volts/cm.) is not bad, particularly when it is remembered that the reactions to be compared are slightly different. Here we consider the total reactions for $C_2H_4^+$ and $C_2H_2^+$. Schissler and Stevenson[5] report that for the reactions tabulated the cross-sections decrease to zero at finite values of the average speed of the ion. We cannot deduce exactly how they calculate their average speed, and so we cannot make a definite comparison of our results with theirs. However, within the voltage range that we investigated, the cross-sections for all reactions but one remained finite. The exception is the formation of $C_2H_5^+$ from ethylene. Its behavior was very strange, and although we do not understand it, we are inclined to attribute it to unknown instrumental effects.

Our reaction cross-sections are quite large and relatively invariant from one reaction to another. By comparison, the gas kinetic cross sections of CH_4 and C_2H_4 at 423°K. are[13] 47.8×10^{-16} cm.^{2} and 66.5×10^{-16} cm.^{2}, respectively.

Theoretical Reaction Cross-sections.—It is of interest to attempt to explain these large cross-sections theoretically. Following the general approach introduced by Eyring, Hirschfelder and Taylor,[14] we assume that the cross-section is determined by the distance, r, at which the centrifugal force tending to separate ion and molecule is exactly counterbalanced by the attractive force due

to polarization of the molecule by the ion. In our calculation it is assumed that all of the initial energy of the system (KE of ion and molecule and potential energy of the polarization interaction) is converted into rotational energy of the ion–molecule complex; we neglect any translational energy of the center of gravity of the complex. Thus, the theory is approximate, and cross-sections obtained from it constitute lower limits to the true values.

The rotation is treated classically. The centrifugal force away from center of mass must be the same for both ion and molecule, so

$$\frac{m_1 v_1^2}{r_1} = \frac{m_2 v_2^2}{r_2} \qquad (21)$$

The center of mass of the system is defined by $m_1 r_1 = m_2 r_2$ with $r_1 + r_2 = r$, the distance between ion and molecule. From the definition of the center of mass, r, and equation 21

$$m_1 v_1 = m_2 v_2 \qquad (22)$$

that is, the linear momentum of the molecule and ion must be equal when rotating. The energy must be conserved so

$$\frac{\alpha e^2}{2r^4} + T_1^0 + T_2^0 = T_1^f + T_2^f \qquad (23)$$

where T_1^0 and T_2^0 are the initial average kinetic energy of the ion and molecule, respectively, T_1^f and T_2^f are the kinetic energies of the ionic and neutral components, respectively, of the transition state, and α is the polarizability of the molecule. From (22) and (23)

$$T_1^f = \frac{m_2}{m_1 + m_2}\left[\frac{\alpha e^2}{2r^4} + T_1^0 + T_2^0\right] \qquad (24)$$

The average initial kinetic energies are

$$\overline{T}_1^0 = \left[\frac{eVd_0}{3} + \frac{3kT}{2}\right] \qquad (25)$$

$$\overline{T}_2^0 = 3/2kT \qquad (26)$$

In (25) and (26) k is the Boltzmann constant, T is the temperature, and the other terms are as defined previously. Combining equations 24, 25 and 26

$$T_1^f = \frac{m_2}{m_1 + m_2}\left[\frac{\alpha e^2}{2r^4} + 3kT + \frac{eVd_0}{3}\right] \qquad (27)$$

The attractive force due to polarization is given by $2\alpha e^2/r^5$, and equating polarization force to centrifugal force

$$\frac{2\alpha e^2}{r^5} = \frac{2T_1^f}{r_1} \qquad (28)$$

Substituting for T_1^f and r_1 and taking $\sigma = \pi r^2$

$$\sigma = \frac{e\pi\sqrt{\alpha}}{\sqrt{6kT + \frac{2eVd_0}{3}}} \qquad (29)$$

Theoretical cross-section values calculated from equation 29 are given in Table V and a plot is given in Fig. 6. The polarizability values used for CH_4 and C_2H_4 are 2.55×10^{-24} cm.^{3} and 4.06×10^{-24} cm.^{3}, respectively, as calculated from molar polarization values given in Landolt–Börnstein.[15] The theoretical and experimental cross-sections disagree at worst by about a factor of two, which is satisfactory for calculations of this kind. We

(15) Ref. 13, 3 Teil, p. 515.

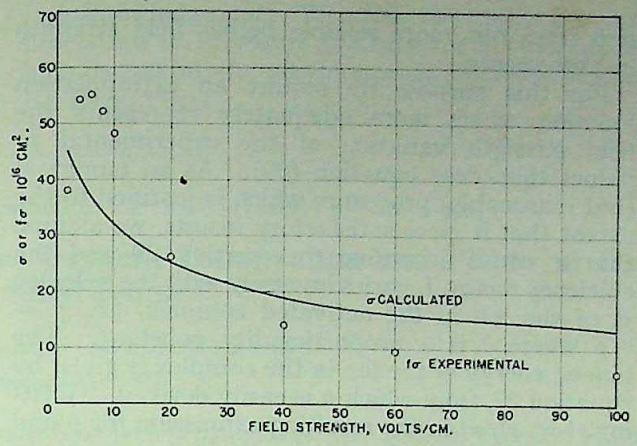

Fig. 6.—Cross-sections for $C_2H_4^+ + C_2H_4 \longrightarrow [C_4H_8^+]$.

conclude, then, that the theoretical treatment is for the most part valid and that the dominant factor in determining the cross-sections for these reactions is the ion–molecule polarization interaction. However, in addition to the disagreement in absolute values, theory and experiment do not agree well with respect to (1) the detailed functional dependence of the cross-sections upon ionization chamber field strength and (2) the fact that theory predicts that the cross-sections for the reactions of all ions with a given molecule will be the same, while in actuality some variation from one reaction to another does occur. While we are inclined to the belief that these disagreements result largely from inadequacies in the theory, some of the difficulty may result from experimental error and/or a variable experimental efficiency factor, f. In particular, we do not think that the maximum observed in the experimental $f\sigma$ *vs.* field strength relation at low field strengths is significant, but rather that it results from a lack of knowledge of the true conditions existing in the ionization chamber at low repeller voltages.

Stevenson and Schissler[4] and Schissler and Stevenson[5] find a small negative temperature coefficient (for the cross-section ?) for some reactions, while for others the rate constant is independent of the temperature. It may be seen from equation 29 that the cross-sections theoretically should depend inversely on the temperature, and at low ionization chamber field strengths the cross-sections are approximately proportional to $T^{-1/2}$. From equations 5, 7b, 8c, 17 and 29 it may be seen that the dependence of the rate constant, k_1, on temperature will be very complicated and cannot be predicted. However, the theory cannot account for the occurrence of temperature coefficients in some reactions but not in others.

Rate Constants for Thermal Speed Ions.—We are not aware of the existence of any values based on experiment of bimolecular rate constants of gaseous thermal speed ions, and it is of considerable interest to attempt to get such values. We do not think that the rate constants we have obtained at zero repeller voltage correspond to thermal speed ions because of the previously discussed lack of definition of the potentials in the ionization chamber at very low voltages. Consequently, we prefer to obtain the rates by extrapola-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tion from our more reliable higher field strength measurements.

For this purpose we require an extrapolation function which more adequately represents the field strength variation of the experimental $f\sigma$ values than does equation (29). As an empirical (but reasonable) procedure which is justified to the extent that it gives satisfactory results, we assume that σ varies according to equation 29 and the efficiency factor, f, varies inversely with the velocity p, of the ion in the activated complex, *i.e.*, $f = \theta/p$ where θ is a proportionality constant. The kinetic energy of the ion in the complex is given by equation 27, from which p is easily derived. Writing $r^4 = \sigma^2/\pi^2$ in the resulting expression for p and taking σ from equation 29, we obtain

$$f = \frac{1}{2}\left(\frac{m_1(m_1 + m_2)}{m_2}\right)^{1/2} \frac{\theta}{(3kT + eVd_0/3)^{1/2}} \quad (30)$$

where the indices 1 and 2 refer to the ion and the molecule, respectively. Then $f\sigma$, the experimental cross-section, is

$$f\sigma = \frac{1}{2}\left(\frac{m_1(m_1 + m_2)}{m_2}\right)^{1/2} \frac{\theta e\pi\alpha^{1/2}}{(3kT + eVd_0/3)} \quad (31)$$

The proportionality constant θ can be evaluated from one experimental value of $f\sigma$ or preferably from the slope of a plot of $f\sigma$ *vs.* $1/(3kT + eVd_0/3)$. The resulting function represents nicely the field strength variation of $f\sigma$ except for the dubious points at low field strengths, as is illustrated by the typical plot given in Fig. 7.

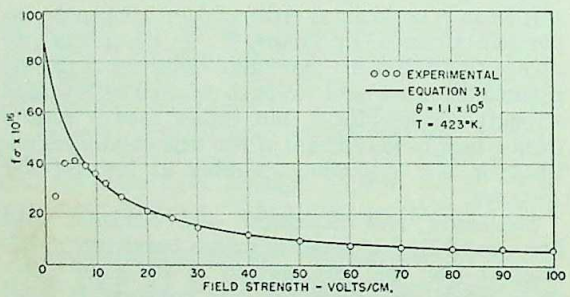

Fig. 7.—Typical plot of $f\sigma$ *vs.* field strength for $C_2H_2^+ + C_2H_4 \longrightarrow [C_4H_6^+]$.

The relationship between rate constant and cross-section is

$$k = f\sigma\bar{\xi} \quad (32)$$

where $\bar{\xi}$ is the relative velocity of the ion and molecule. Taking $f\sigma$ from equation 31 for $V = 0$ and $\bar{\xi}$ from equation 12 evaluated for thermal velocities, we obtain for the rate constant for thermal speed ions

$$k_{V=0} = \frac{\theta e}{6}\left(\frac{8\pi\alpha}{kT}\right)^{1/2}\left(\frac{m_\alpha + m_\beta}{m_\beta}\right)^{1/2} \quad (33)$$

The index α always refers to the lighter particle.

Eyring, Hirschfelder and Taylor[14] have developed an expression for the rate constant of thermal speed ions, namely

$$k = 2\pi\kappa e\alpha^{1/2}\left(\frac{m_\alpha + m_\beta}{m_\alpha m_\beta}\right) \quad (34)$$

where κ is the transmission coefficient. In Table VI we list thermal cross-sections and rate constants calculated by our extrapolation method and rate constants calculated from the Eyring, Hirschfelder and Taylor[14] expression taking $\kappa = 1$.

TABLE VI

CROSS-SECTIONS AND RATE CONSTANTS FOR THERMAL REACTIONS

TABLE VII

COMPARISON OF PRIMARY AND SECONDARY MASS SPECTRA (BASED ON LARGEST OF THE PEAKS COMPARED)

Ion	Primary 1-Butene	Primary *cis*-Butene-2	Primary Isobutene	Primary Cyclobutane	Secondary from $C_2H_4^+ + C_2H_4$
$C_3H_4^+$	6.5	7	11	6.5	1.5
$C_3H_5^+$	100	100	100	100	100
$C_4H_6^+$	2.5	4	2.5	3	0.2
$C_4H_7^+$	18	22	16	21	8.8
	1,2-Butadiene	1,3-Butadiene	1-Butyne	2-Butyne	From $C_2H_2^+ + C_2H_4$
$C_3H_3^+$	100	100	100	57	100
$C_4H_4^+$	28	11	10	23	7
$C_4H_6^+$	100	59	57	100	54

With thermal rate constants and cross-sections of this magnitude it is self-evident that the occurrence of ionic reactions must be seriously considered in any process in which the formation of ions is a possibility, *e.g.*, in radiation chemistry processes. The agreement between our rate constants and those from Eyring, Hirschfelder and Taylor[14] is satisfactory, but it should be noted that our treatment predicts a weak ($T^{-1/2}$) dependence of the rate constant on temperature, which is not found in the EH&T expression. We do not know which of these predictions is correct.

Comparison of Secondary and Primary Mass Spectra.—In those cases where a known intermediate such as $C_4H_8^+$ or $C_4H_6^+$ is formed it is interesting to compare the primary mass spectrum from various C_4H_8 and C_4H_6 compounds with our observed secondary spectrum. Thus the intensities of those peaks in the secondary mass spectrum of ethylene which might have resulted from the reaction of $C_2H_4^+$ and C_2H_4 are compared to those of the same peaks in the primary spectra of various C_4H_8 compounds. Similarly the secondary spectra that might have resulted from the reaction of $C_2H_2^+$ and ethylene are compared to those of several C_4H_6 compounds. Such comparisons are made in Table VII taking the primary spectra from the API tabulation. There is an approximate correspondence which indicates that the intermediate ions (activated complex) must be at least qualitatively similar to the respective parent ions in the

primary spectra. In fact, it is tempting to decide that the $C_4H_6^+$ intermediate is more similar to the 1,3-butadiene or 1-butyne ions than to the other two primaries shown.

Acknowledgment.—We wish to express our appreciation to Mr. Burl L. Clark for his invaluable help in making the measurements and calculations.

Effects of Structure, Product Concentration, Oxygen, Temperature and Phase on the Radiolysis of Alkyl Iodides

BY EVALYN O. HORNIG AND JOHN E. WILLARD

RECEIVED DECEMBER 20, 1956

The yields of elemental iodine as a function of radiation dosage have been determined for the radiolysis with Co^{60} γ-rays of seven purified degassed alkyl iodides. Doses $>16 \times 10^{20}$ e.v./ml. were used in some cases. Although six of the iodides show linear dependence of G_{I_2} on radiation dosage at low doses, all depart from linearity at higher doses, and the G_{I_2} for isobutyl iodide decreases with increasing dose even at the start of irradiation. The linear dependence is attributed to a balanced competition between HI and I_2 for thermal radicals and, consistent with this concept, the rate of exchange with radioiodine during radiolysis is found to be dependent on the concentration of added I_2 or O_2. The dependence of G_{I_2} on the β-hydrogen content of the alkyl iodides is confirmed and ascribed to increased probability of HI formation by decomposition of excited molecules as the number of β-hydrogens per molecule increases. Added O_2 increases the initial G_{I_2} for C_2H_5I by an amount independent of the O_2 pressure from 2 to 188 mm., but as the I_2 concentration increases with increased dosage G_{I_2} returns to its degassed level at a rate inversely dependent on the oxygen pressure. With added iodine present at a concentration elevenfold greater than the dissolved oxygen, the initial G_{I_2} was the same as that in the absence of additives. G_{I_2} for four iodides tested is essentially independent of temperature in the liquid phase from 20 to $-78°$ and for C_2H_5I from 108 to $-78°$, but the G_{I_2} values for both CH_3I and C_2H_5I have a positive temperature coefficient in the crystalline solid phase. G values for two iodides studied in both the glassy and crystalline states at $-190°$ were higher in the glassy state, a result which is tentatively ascribed to molecular orientation favoring a stereospecificity for hot radical reactions.

Introduction

The purpose of the work of this and the following paper[1] was to elucidate further[2] the mechanisms of radiolysis of the alkyl iodides. The investigations have included studies of: (1) the competitive reactions of O_2, I_2 and HI with thermal radicals produced in the radiolyses and (2) the effects of temperature, molecular structure and irradiation in the solid crystalline and glassy states on the yields of elemental iodine.

Experimental

The alkyl iodides, Eastman or Matheson best grade, were purified by passage through activated alumina, followed by distillation through a two-foot Vigreux column, the middle 50% being retained. Identical iodine yields were obtained from the irradiation of samples of ethyl iodide purified as above, and from those purified by shaking with concentrated H_2SO_4 and washing with Na_2SO_3 solution prior to distillation. The purified iodides were degassed by several cycles of freezing, pumping and thawing on a vacuum system, and then were vacuum-distilled through P_2O_5 into the irradiation vessels and sealed off.

During the irradiation, the samples (5 ml.) were contained in an annular vessel,[4] which surrounded a 40-curie Co^{60} γ-ray source.[4] The radiation intensity on the samples was 2×10^5 roentgens/hr., the absorption of energy in the alkyl iodides being at the rate of about 2×10^{19} e.v. per ml. per hr.

Iodine analyses were made with a Beckman DU spectrophotometer. A spectrophotometer cell made from square Pyrex tubing was attached to the annular vessel so that iodine analyses could be made between successive irradiations of the same sample without exposing it to the air. Concentrations were read at the absorption maximum at 478 mμ and for high concentrations at 550 and 625 mμ. The high concentration readings were checked at 478 mμ in methyl and ethyl iodide irradiations by using 0.98 and 0.95 cm. silica inserts in the analysis cells. Determinations of molar extinction coefficients were made at the three wave lengths for methyl, ethyl and *n*-propyl iodides, the values obtained being 1280, 356 and 72.8 l./mole cm., respectively. Since the extinction coefficients were the same for the three iodides, it was assumed that the same values would also be applicable to the other iodides.

To irradiate samples at -78, -123 and $-190°$, they were surrounded during the irradiation by baths of solid CO_2 and acetone, butyl chloride slush, and liquid air, respectively. A thermostatically controlled bath of mineral oil was used for the irradiations at 108°.

Oxygen of known pressure was admitted to degassed samples of ethyl iodide on a vacuum line, either from a cylinder or by heating $KClO_3$ containing MnO_2. The number of moles oxygen introduced to the sample vessel was determined from the pressure change in a known volume of the vacuum apparatus, measured with a phosphoric acid manometer. The solubility of oxygen in ethyl iodide was found to be 8×10^{-6} mole/l. per mm. pressure at 23°,[5] so that the concentration of dissolved oxygen in the samples could be determined from the gas pressure.

Iodine labeled with I^{131} was prepared from carrier-free iodine solutions by adding the desired amount of KI and oxidizing with acidified KIO_3. The iodine was transferred into the irradiation vessels by vacuum distillation through P_2O_5. A solution-type Geiger counter was used to measure

(2) Previous investigators have determined the relative yields of I_2 from X-ray and α-particle irradiation of air-saturated ethyl iodide,[3a] from γ-irradiation of eight air-saturated alkyl iodide,[3b] from fast electron irradiation[3c] of degassed CH_3I, CH_3I_2, C_2H_5I and *n*-C_3H_7I, and from X-ray irradiation of degassed CH_3I,[3c,d] C_2H_5I,[3c,d,h] propyl[3d,h] and butyl iodides.[3d] The yields of various products from the X-ray irradiation[3e,h] and very low intensity Co^{60} γ-ray irradiation[3e] of degassed CH_3I have also been determined. Similarities and contrasts between the radiolysis and photolysis of the alkyl iodides have been considered.[3c,d,e,f] Distillation with added carriers following irradiation in the presence of radioiodine has been used to identify intermediate free radicals.[3g,h]

Results

Variation of Iodine Yields with Radiation Dosage.—Figure 1 shows the change of iodine concentration with time of irradiation for seven alkyl iodides. Six of these showed no change in slope up to radiation doses as high as 4.5×10^{19} e.v./ml.[6] The seventh, isobutyl iodide, gave yields which dropped from 3.36 I atoms (as $^1/_2$ I_2) produced per 100 e.v. absorbed initially to 1.89 after 0.64×10^{19} e.v./ml. was absorbed (see insert of Fig. 1). Identical results were obtained with each of three separately purified *i*-C_4H_9I samples. For the much higher radiation doses plotted in the main portion of Fig. 1, all of the iodides except methyl showed a region of decreasing rate of I_2 production. For those compounds which were subjected to the largest dosage (isobutyl, isopropyl, *n*-propyl) the values of G_{I_2} for increments of irradiation after the samples had been exposed to 16×10^{20} e.v./ml., all came to the same value of 0.95 ± 0.03. The curvature is of interest because it is indicative of competing reaction steps which change in importance with changing concentration of the radiolysis products, and because previous investigators[3c,d,e] of the radiolysis of alkyl iodides using X-rays or fast electrons and small total dosage (maximum I concentrations of about 10^{-3} mole/l.) have reported that the iodine production is linear or nearly linear[3h] with absorbed energy for all the iodides which they studied.

G Values.—Table I shows the values of *G* we have obtained for low radiation doses ($< 1.3 \times 10^{-3}$ mole/l. of I_2 produced), and also the literature values for similar systems. To determine the energy absorbed, $FeSO_4$ in 0.8 *N* H_2SO_4 was exposed to the source under conditions identical to those used for the alkyl iodide samples. A value of 15.6 Fe^{++} oxidized per 100 e.v. absorbed was assumed.[7] The absorption in the aqueous $FeSO_4$ solution (1.33×10^{19} e.v./ml. hr.) was multiplied by factors[5] to correct for the difference between its density and average atomic number and those of each of the iodides. The rates of energy absorption so obtained were 2.64×10^{19} e.v./ml. hr. for CH_3I, 2.26×10^{19} for C_2H_5I, 2.05×10^{19} for *n*-C_3H_7I, 2.02×10^{19} for *i*-C_3H_7I, 1.94×10^{19} for *n*-C_4H_9I, 1.92×10^{19} for *i*-C_4H_9I and 1.91×10^{19} for *s*-C_4H_9I. For four of the iodides, the *G* values for the liquids were determined on at least three separate samples from two different purifications, and several irradiations were made on each sample.[5] The results were usually reproducible to closer than ± 2%.

TABLE I

G VALUES[a] FOR IODINE PRODUCTION IN THE RADIOLYSIS OF LIQUID ALKYL IODIDES

	Present work, Temperatures, °C					Other work, room temp.
	Room	108	−78	−120	−190	
CH_3I	2.52			0.94[f]	0.64[f]	3.3,[b] 2.7,[c] 2.4[d]

obtained after correction[3h] for $G_{Fe^{+++}} = 15.6$ is in good agreement with our result of 2.5 obtained at 550-fold higher radiation intensity. Absolute yields of iodine production from the X-ray[3c,h] and electron irradiation[3e] of CH_3I, C_2H_5I and n-C_3H_7I are in good agreement with the γ-ray yields, considering differences in dosimetric methods used.

Structure Effects.—From Fig. 1 and Table I, it may be seen that the initial values of G for the radiolysis of the iodides are related as follows: i-C_3H_7I > s-C_4H_9I > C_2H_5I > n-C_3H_7I ≅ n-C_4H_9I > CH_2I > i-C_4H_9I. A similar sequence of relative yields has been observed by Cochran, Hamill and Williams[3d] for the radiolysis with low energy X-rays and for photolysis with ultraviolet light and they have suggested that the order may be correlated with the fraction of the hydrogen atoms in the molecule which is in the β position to the C–I bond. Our data plotted in Fig. 2 as a function of both the fraction of hydrogen atoms in the β-position and the number of hydrogen atoms per molecule in the β-position give a smoother correlation with the latter plot. CH_3I, which has no β-hydrogen atoms, does not fall in line on either plot.

Temperature and Phase Effects.—From Table I it may be seen that the G values for liquid C_2H_5I at 108, 20 and −78° are indistinguishable and that there is likewise little or no temperature effect on the radiolysis of liquid i-C_3H_7I, i-C_4H_9I or s-C_4H_9I in going from 20 to −78°. By contrast, the three iodides for which determinations were made at two temperatures in the crystalline state, all show a higher yield at −120° than −190° (Table I and Table II).

TABLE II

EFFECT OF TEMPERATURE AND STATE ON G VALUES

Cpd.	$G_{liquid}/G_{cryst.}$ Cryst. −120°	Cryst. −190°	$\frac{G_{cryst.}\ -120°}{G_{cryst.}\ -190°}$	$\frac{G_{liquid}}{G_{glass}\ -190°}$	$\frac{G_{glass}\ -190°}{G_{cryst.}\ -190°}$
CH_3I	2.7	3.9	1.5

i-$C_4H_{10}I$			1.3	0.4	1.6

[a] The C_2H_5I glass may have crystallized before the completion of the irradiation.

Iodine yields in the solid phase irradiations were determined by spectrophotometric measurements on the liquid after melting. Identical G values were obtained for long and short solid phase irradiations and for irradiations after melting and refreezing a previously irradiated solid.

Of special interest is the fact that in the two cases where determinations were made both on the glassy[8] state and the crystalline states of a compound at the same temperature, the yields in the glassy state were much higher (Table II). Isobutyl iodide in the crystalline state at −190° showed a lower initial G_{I_2} than the liquid but no curvature corresponding to that illustrated for the liquid in the insert on Fig. 1. After the absorption of about 8×10^{18} e.v./ml. the value for the crystals is higher than that for the liquid.

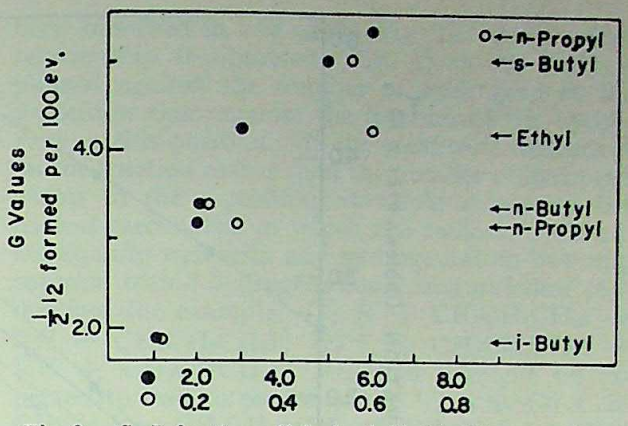

Fig. 2.—G_{I_2} for the radiolysis of alkyl iodides, as a function of the β-hydrogen content: ●, number of β-hydrogen atoms per molecule; ○, fraction of hydrogen atoms in the β-position.

Effect of Oxygen.—The fact that iodine tagged with I^{131} exchanges with alkyl iodides undergoing radiolysis,[3c,e,h] is strong evidence for the presence of thermal alkyl radicals which return iodine to organic combination by the $R + I_2 \rightarrow RI + I$ reaction. At sufficiently high concentration, oxygen would be expected to compete with the I_2 for these radicals and thus increase the net I_2 yield. Such an increase has been demonstrated by Schuler and Petry[3h] for air-saturated and oxygen-saturated CH_3I and C_2H_5I. We have also investigated this effect with ethyl iodide using a series of different oxygen pressures ranging from 2 to 188 mm. (a variation of dissolved oxygen concentration from 1.6×10^{-5} mole/l. to 1.5×10^{-3} mole/l.). In agreement with the observations of Schuler and Petry,[3h] the *initial* rate of iodine production at all of the oxygen pressures was about 2.3 times that for degassed samples and it decreased with increasing radiation dose (Fig. 3). The higher the initial oxygen concentration the greater was the dose required to bring about a given decrease in rate toward the degassed value. This is consistent with the conclusion[3h] that the initial rate in the presence of oxygen represents the case where all

(8) When degassed samples of the alkyl iodides are cooled rapidly in liquid air, they often form transparent, glassy solids instead of opaque crystals. The glassy form is least stable for the iodides with 1, 2 and 3-carbon atoms. It is relatively easily obtained and can be indefinitely maintained at low temperatures in the cases of n-C_4H_9I and i-C_4H_9I. Similar observations on the relative stability of glasses as a function of chain length have been reported for the alkyl bromides.[9] The glasses sometime crack without crystallizing. C_6H_5I glass has been found to crystallize always when raised above about −165°.[10] It can be obtained and maintained at lower temperatures only in very clean degassed vessels with freshly annealed surfaces.

In order to be sure that the visible differences between apparently crystalline and apparently glassy samples indicate a true difference in state, we have frozen samples of n-C_4H_9I and i-C_4H_9I to the glassy state at −190° with thermocouples imbedded in them. The samples were then placed in Dewar flasks and allowed to warm slowly (15 minutes) to room temperature. During this time, the temperature of the thermocouples was recorded on a chart recorder. For both compounds the gradual slope of the warming curve changed to a vertical rise at about −125° indicating a sudden evolution of heat as a result of the conversion of the glass to the crystalline form. If, following this transition, the solid was cooled to −190° and again allowed to warm, no such heat evolution was observed, but each time the solid was melted and refrozen to the glass, the warming curves showing the crystallization process could be reproduced.[8]

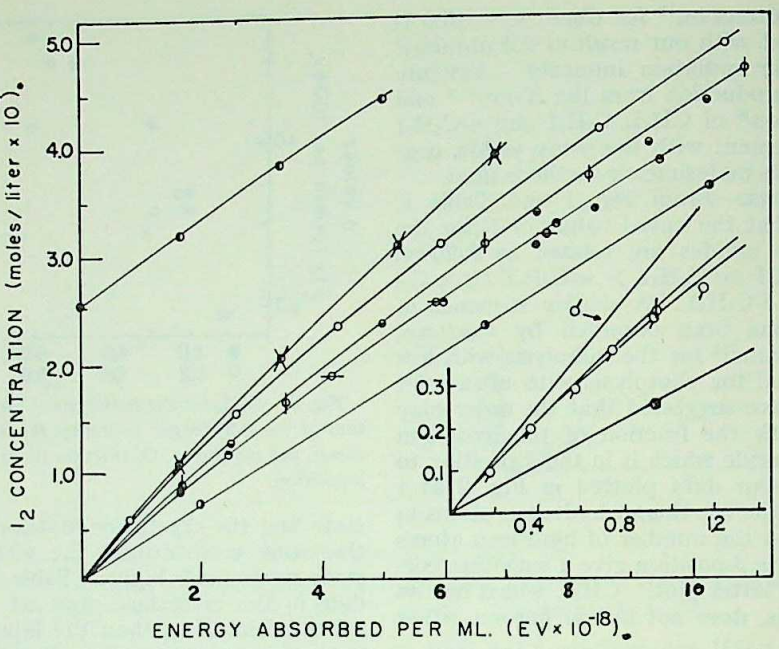

Fig. 3.—Iodine production in the radiolysis of ethyl iodide as a function of energy absorbed and of oxygen pressure. Initial oxygen pressures in mm.: ◑, degassed; ◓, 2.7; ◔, 4.7; ●, 5.6; ◒, 10.9; ◕, 10.5; ○, 18; ⊗, 42.8; σ, 188; ◐, 7.5 (I_2 present at the start of radiolysis); ρ, 5.8, using 10 cm. light path.

thermal radicals are scavenged by the dissolved gas and none have the opportunity to return iodine to organic combination by reaction with I_2. As the I_2 concentration builds up, this species competes more and more effectively for the radicals thus reducing the rate of iodine production. The HI formed probably is oxidized by the oxygen.

The above concept of the mechanism is substantiated by the fact that the accelerating effect of O_2 can be counteracted by adding I_2 prior to irradiation (Fig. 3). At an initial mole ratio of I_2 to dissolved O_2 of 11, the rate was equal to that of degassed samples with no additives.

Estimates of the consumption of O_2 during irradiation in the experiment of Fig. 3 indicate that the decrease in its accelerating effect with time of irradiation cannot be attributed to depletion of the O_2. If it is assumed that one molecule of O_2 was consumed for each $^1/_2$ I_2 formed in excess of that formed in degassed samples, the depletion of O_2 after the rates had returned essentially to the degassed value was less than 10%. It is probable that the ratio of O_2 consumed to I_2 formed is actually less than 1/0.5, as a result of reactions of peroxy radicals to liberate I_2 from HI.

Information from Irradiation in the Presence of Radioiodine.—When it was first observed that oxygen accelerated the production of iodine from C_2H_5I and that the maximum initial rate was independent of the O_2 concentration over a wide range, it was thought that the only important reaction steps governing I_2 production were: (1) a hot radical production of $^1/_2$ I_2, such as $C_2H_5 + C_2H_5I \rightarrow C_2H_4 + C_2H_6 + I$, which was not sensitive to additives, and (2) a thermal radical step of the type $C_2H_5 + I_2 \rightarrow C_2H_5I + I$ which returned $^1/_2$ I_2 to organic combination and was sensitive to radical scavengers. According to this mechanism, the rate of exchange of radioiodine during radiolysis in the absence of oxygen should be independent of iodine concentration and should equal the increase in rate of iodine formation caused by an excess of oxygen. Also, the ratio of the G value for exchange to that for I_2 production should be constant, in the absence of oxygen.

Experiments designed to test these predictions gave the data of Table III which indicate that there must be another species in addition to iodine which competes for the thermal radicals in degassed samples. It may be seen that (1) the G value for exchange with both C_2H_5I and i-C_3H_7I increases with increasing initial iodine concentration, (2) the G

value for I_2 production decreases with increasing initial iodine concentration, and (3) the ratio of the G value for exchange to that for iodine production in degassed samples increases with increasing concentration of initially added iodine.

Below we report evidence that HI is a radiolysis product of the alkyl iodides. In the following paper it will be shown that the effect of initial I_2 concentration on the G values for iodine production and exchange may be quantitatively explained on the basis of a competition between HI and I_2 for alkyl radicals, similar to the competition which has been shown to occur in the photolysis[11] of ethyl iodide.

Evidence That HI is a Product.—In order to determine HI production, samples of alkyl halides which had been irradiated in the presence of radioiodine were frozen with liquid air before breaking the vacuum, and were then shaken with a mixture of CCl_4 and H_2O. The HI dissolved in the water while the I_2 stayed predominantly in the CCl_4. The water was washed three times with fresh aliquots of CCl_4 and counted, the ratio of its activity to the total inorganic activity indicating the fraction of the latter which was HI. Ratios of HI/I_2 formed ranging from less than unity for C_2H_5I and i-C_4H_9I to considerably higher for i-C_3H_7I were found. In view of present knowledge of the role of HI in the mechanism[1] these would be expected to vary with the initial iodine concentration and the duration of the irradiation.

Discussion

The evidence presented above advances our knowledge of the radiolysis of alkyl iodides in several respects.

1. **Competitive Radical Reactions.**—By showing (Fig. 3, Table III) that the rate of iodine production and the rate of exchange of radioiodine are dependent on the ratio of oxygen concentration to iodine concentration and also on the ratio of iodine concentration to some other product (shown later to be HI), the results indicate that the yields, both with and without oxygen present, are determined by competitive reactions which consume thermal radicals.

2. **Absence of Intensity Effect.**—The fact that the G values for iodine production (Table I) are the same for irradiation at 2×10^5 r./hr. with a 40 c. Co^{60} source as at 350 r./hr. with a 300 mc. source[3e] confirms the fact that the radiolysis is independent of the intensity of γ-radiation. This is consistent with the conclusion, which may be reached from a consideration[12] of relative concentrations of radicals and iodine scavenger molecules, that there is no interaction between radicals produced in different tracks.

3. **Structure Effects.**—The fact, reported by Cochran, Hamill and Williams,[3d] that $G_{1/2\ I_2}$ for the radiolysis of alkyl iodides increases as a function of the hydrogen atoms on the carbon atoms adjacent to the one containing the iodine has also been observed in our work (Fig. 1). A smoother relationship is obtained (Fig. 1) if the yield is plotted against the number of hydrogens in the β-position than against the fraction of the hydrogens in this position. If the yield were dependent on the fraction rather than the number of hydrogen atoms in the β-position, it would suggest a hot radical mechanism in which the radicals could react equally well with any hydrogen atom but only reaction with β hydrogens could lead to iodine production, for example: (1) $\underline{R} + CH_3CH_2CH_2I \rightarrow RH + CH_2CH_2CH_2I$; (2) $\underline{P} + CH_3CH_2CH_2I \rightarrow RH + CH_3CHCH_2I$. Reaction 2 might be expected to lead to production of $^1/_2$ I_2 by (3) $CH_3CHCH_2I \rightarrow CH_3CH{=}CH_2 + I$, but the product of (1) could not form a double bond by elimination of I and would probably react by (4) $CH_2CH_2CH_2I + I_2 \rightarrow CH_2ICH_2CH_2I + I$. Evidence from characterization experiments[3g,h] with radioiodine indicates little or no diiodide formation and so argues against the sequence of reactions 1 and 4 which would be expected to be prominent if the suggested hot radical hypothesis were responsible for the β-hydrogen effect.

In view of the evidence[1] that a large portion of the iodine produced in the radiolysis of ethyl iodide results from the step $C_2H_5 + HI \rightarrow C_2H_6 + I$ in competition with $C_2H_5 + I_2 \rightarrow C_2H_5I + I$, it may be speculated that the increase in rate of iodine production with increase in the number of β-hydrogen atoms is a result of an increase in the probability that *excited molecules* can eliminate HI and thus increase the ratio of HI to I_2 in the system. This could be a one-step process such as $CH_3CHICH_3 \rightarrow CH_2{=}CHCH_3 + HI$. As noted above, we have found that the yield of HI from i-C_3H_7I is considerably greater than from C_2H_5I and i-C_4H_9I.

4. **Non-linear Dependence of Yield on Energy Input.**—Figure 1 shows that all of the iodides except i-butyl show a linear increase in iodine concentration with absorbed energy up to about 10^{-3} M, in accordance with previous observations,[3] but that all of these show a curvature in the direction of lower G values if the irradiation is continued to 10^{-2} M I_2 or higher. It appears[1] that in the linear region, iodine production is the result of a hot reaction, plus a competition between I_2 and HI for thermal radicals, with the fraction of radicals which are used up by each path in the competition remaining constant because the ratio of HI produced to I_2 produced remains constant. It would appear that the most probable cause of deviation from linearity, at concentrations where direct energy absorption by the reaction products is negligible, is a reaction between HI and some other reaction product to decrease the rate of HI accumulation and hence favor the reaction $R + I_2 \rightarrow RI + I$ over that of $R + HI \rightarrow RH + I$. If olefins are produced which can react with HI ($C_2H_4 + HI \rightarrow C_2H_5I$) this process, being bimolecular, might become apparent only after these reactants had built up appreciably in concentration. Scavenging of radicals by a product other than I_2 or HI is not a satisfactory explanation of the curvature since such a species would be in constant ratio

to the HI and I_2 throughout an experiment. It is possible that electron attachment or charge transfer processes which can lead to the net removal of HI or increased return of I_2 to organic combination become more important as the I_2 and HI concentrations increase.

Temperature and Phase Effects.—The fact that samples of the same solid alkyl iodide at the same temperature give different G values for I_2 production when they are in the glassy state than when they are in the crystalline state seems to indicate that the orientation of the molecules with respect to each other at the time energy is absorbed is an important factor in determining the chemical consequences of the energy absorption. In the ordered arrangement of a crystal hot C_2H_5 radicals formed from C_2H_5I may preferentially attack certain parts of adjacent C_2H_5I molecules, while in the random arrangement of a glass there can be no such specificity. Such preferential attack or various other sterically sensitive hot reactions may account for the difference in the G_{I_2} values in the different states.

For reactions activated by radiative neutron capture[12-14] the "organic yield" has been observed to increase, decrease or remain essentially unchanged with change of phase, depending on the compound, but with no obvious correlation with the molecular structure or the density.[12-14] In view of the contrast between the iodine yields for the glass and the crystalline phases in the present work, it seems plausible that the primary factor in determining the effect of freezing on the organic yields of activation by nuclear processes may be the orientation of the molecules in the crystal lattice.

The absence of a temperature effect in the radiolysis of liquid C_2H_5I from -78 to 108° suggests that the pattern of radical recombination reactions which occurs is not governed by the ease of diffusion of the radicals. This behavior is in contrast to that of CCl_3Br where G_{Br_2} is temperature sensitive, the apparent activation energy being about 3 kcal./mole.[15]

Quantitative Treatment of the Elementary Processes in the Radiolysis of Alkyl Iodides by γ-Rays

BY ROBERT J. HANRAHAN AND JOHN E. WILLARD

RECEIVED DECEMBER 20, 1956

The mechanism of radiolysis of alkyl iodides with Co^{60} γ-rays includes the production of HI, I_2, alkyl radicals and hydrocarbons within the "hot spots" of the radiation tracks, and reaction of the thermalized radicals outside the tracks with HI and I_2 to abstract H and I, respectively. From the effects of added HI and I_2 on the rates of I_2 production and radioiodine exchange, it is possible to deduce the rates of the elementary reactions. For ethyl iodide, integrated rate equations which predict the rates of I_2 and HI production and of exchange have been obtained. The predicted rates are in agreement with the experimental results.

Introduction

The yield of iodine per unit of energy absorbed in the radiolysis of degassed ethyl iodide[1] is independent of the concentration of iodine built up during the radiolysis[1,2] and is independent of the temperature from -78 to 108°.[2] It has been thought that the iodine yield is independent of initially added iodine[3,4] although the data presented might be interpreted to indicate a small decrease for such addition.[3] These facts have led to the assumption that iodine production does not occur by any reaction involving the thermalized radicals, *i.e.*, occurs only by hot processes.

In the present work a careful re-examination of the effect of I_2 added prior to radiolysis has shown that it reduces the initial rate of iodine production by nearly 50%. This, together with the observation that HI is a product of the radiolysis,[2] has indicated that an important part of the mechanism is a reaction in which thermal alkyl radicals abstract hydrogen from HI, as it is in the photolysis of ethyl iodide reported by Bunbury, Williams and Hamill.[5] A quantitative study has therefore been made of the role played by HI and I_2 in competing for thermalized radicals.

Experimental

The methods of purification and irradiation of alkyl iodides were similar to those described in the preceding paper.[2] Mallinckrodt reagent grade iodine was used without further purification. All reaction mixtures were degassed by vacuum line techniques.

Dry HI was prepared from a 55% aqueous solution of HI (Merck) from which the free iodine was removed with red phosphorus. The water was removed by covering the frozen solution with P_2O_5, and allowing it to melt after evacuation. The HI gas was then passed through more

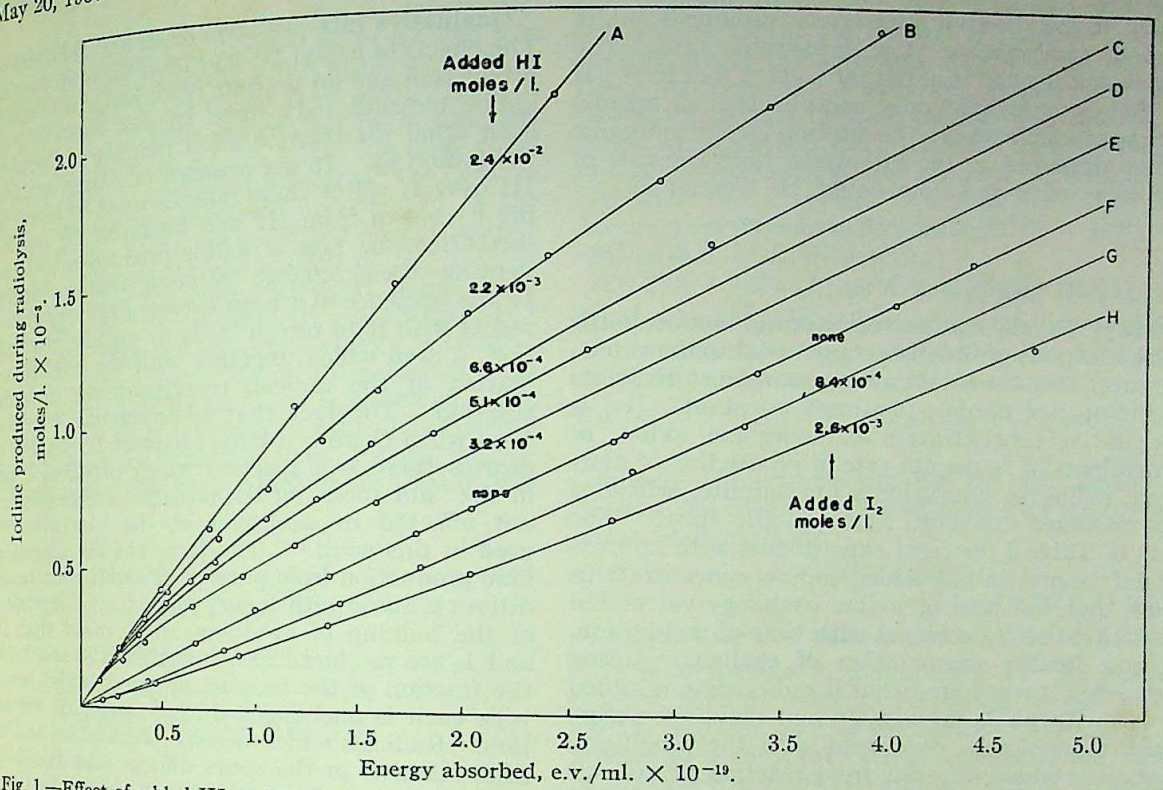

Fig. 1.—Effect of added HI and I_2 on the γ-radiolysis of ethyl iodide. Points are from experimental data[22]; curves are calculated by equation 27.

P_2O_5, supported on glass wool, on the vacuum line. Its pressure was measured with a mercury manometer, which reacted with it only slightly. Fluorocarbon grease was used on the stopcocks; silicone grease appeared to react to give volatile products. To tag the HI, carrier free I^{131} as aqueous iodide was added to the aqueous HI before the P_2O_5. To tag I_2 a similar iodide solution was added to I_2 and the latter distilled through P_2O_5.

Iodine concentrations were determined with a Beckman D.U. spectrophotometer provided with a photomultiplier tube as the detector to increase the sensitivity, and a Baird interference filter to cut out stray light coming through the monochromator. With this equipment it was possible to determine optical densities accurately up to a value of nearly 5 by taking readings against a set of standard solutions having optical densities of 1, 2 and 3. All readings were taken at 4780 Å. (visible absorption maximum; molar extinction coefficient 1280 l./mole cm.). Since the absorption spectrum of iodine in alkyl iodides is temperature sensitive,[6] rough thermostating was provided during later runs by controlling the room temperature at 24 ± 1°.

When it was desired to analyze for radioiodine in the forms of HI, I_2 and organic combination, the reaction cell was broken open while the contents were frozen at liquid air temperature and the reaction mixture was dissolved in CCl_4 and extracted with water to remove HI, and with aqueous sulfite to remove I_2. The water, sulfite and organic solutions were counted, and density corrections were applied when necessary. Solutions treated in this way which had not been irradiated showed about 1% exchange between organic and inorganic forms when opened the same day and 5% exchange when opened after two weeks. All samples were stored in the dark at all times.

Results and Discussion

Evidence for Competitive Reaction Steps.—Three lines of evidence establish the fact that organic radicals born during the radiolysis of degassed ethyl iodide do not all react with I_2 but may undergo a competing reaction which produces rather than consumes inorganic iodine. These are the decrease in iodine yield (G_{I_2}) caused by added iodine, the increase in G_{I_2} caused by added hydrogen iodide, and the increase in exchange yield ($G_{exch.}$) caused by added iodine.

Effect of Added I_2 on G_{I_2}.—The effect of added iodine on the initial rate[7] of iodine production in the radiolysis of ethyl iodide was determined in 14 experiments with initial iodine concentrations ranging from 2.6×10^{-3} to 4.3×10^{-4} M. In all cases the initial rate was, within experimental error, 54% of the rate in the absence of added iodine and increased toward the normal rate as the run continued. This is illustrated by typical results plotted as curves G and H of Fig. 1.

Effect of Added HI on G_{I_2}.—When HI is added to ethyl iodide prior to radiolysis, the effect on the rate of I_2 production is opposite to that produced by added I_2. This is illustrated by the curves above the straight line of Fig. 1. All the curves approach the same maximum rate at zero time and fall off toward the rate for ethyl iodide without additives at longer irradiation times, the falling off being slower the higher the concentration of HI. The initial rate with added HI was 2.55 times the rate without additive and 4.73 times the initial rate with added I_2. Solubility determinations for ethyl iodide solutions showed that about 95% of the HI present in a standard irradiation vessel was always in the liquid phase.

Effect of Added I_2 on Exchange Reaction.—It is known from previous work[1,2] that radioiodine

(6) D. E. Schuler and R. H. Schuler, This Journal, 76, 3092 (1954).

(7) Evaluated by plotting the average rate from time zero to time t *vs.* time of irradiation t and extrapolating to zero t. "Rate" as used in this paper is directly proportional to "G value," *i.e.*, number of molecules which react per 100 e.v. absorbed. For ethyl iodide a rate of 0.0312 μ equivalent per min. per 5-ml. sample equals a G value of 1.

added to ethyl iodide undergoing radiolysis enters organic combination at a measurable rate. The compound formed is about 90% ethyl iodide.[4,8] If in this exchange the only complication of normal exchange kinetics were the dilution by the inorganic iodine produced in the radiolysis, then the rate of exchange of radioiodine could be treated as

$$-d[I^*]/dt = K([I^*]/([I_0] + [I] \text{ produced})) = K([I^*]/([I_0] + Rt)) \quad (1)$$

$$\log([I^*]/[I_0^*]) = K/R \log([I_0]/([I_0] + Rt)) \quad (2)$$

where $[I^*]$ is the concentration of radioiodine in the inorganic phase (directly proportional to the counting rate), K is the total exchange rate in equivalents of iodine per minute (assumed constant), $[I_0]$ is the initial concentration of inorganic iodine in equivalents, R is the net rate of production of inorganic iodine in equivalents per minute, which is also assumed constant, and t is the time.[9] The data of Table I for eight experiments with approximately equal initial added iodine concentrations show that the rate of iodine exchange calculated from equation 2 decreases with time of irradiation.

In a further examination of exchange during radiolysis, it was found that if radioiodine is added as HI with no I_2 initially present exchange occurs much more slowly, consistent with the conclusion that the exchange results from reaction of radicals with I_2 but not with HI. As I_2 is formed the radioiodine would be expected to equilibrate with it rapidly by HI–I_2 exchange.

TABLE I

RESULTS OF EXCHANGE EXPERIMENTS

[a] Based on two runs; all others based on one run. [b] Rates given in equivalents $\times 10^6$ per min. per 5-ml. sample volume, at an energy absorption rate of 3.77×10^{17} e.v./ml. min.

Absence of Effect by Added C_2H_4 and $C_2H_4I_2$.—Ethyl iodide containing 0.07 mole/l. of ethylene gave essentially the same G_{I_2} value as ethyl iodide with no additives and showed no back reaction with products to alter the HI/I_2 ratio during two days of standing after irradiation.

Ethylene iodide[10] at a concentration of about 10^{-3} M in ethyl iodide did not affect the rate of I_2 production in the radiolysis. In unirradiated samples of this type, slow decomposition of the $C_2H_4I_2$ occurred over a period of two months, producing iodine. No such build-up ever occurred in irradiated samples of pure C_2H_5I.

Qualitative Interpretation of HI and I_2 Effects.—The effects of added HI and I_2 on the rate of iodine production and on the rate of exchange with radioiodine indicate that these species compete with each other for thermal alkyl radicals produced in the radiolysis. In the presence of a large excess of HI over I_2, all of these radicals react by abstracting hydrogen from HI and liberating $^1/_2$ I_2, thus increasing the rate of iodine production and preventing the exchange reaction from occurring. In the presence of a large excess of I_2 every radical reacts with it to return $^1/_2$ I_2 to organic combination, a step which, together with the original formation of the radical, constitutes the exchange reaction. The fact that I_2 production continues even when there is a large excess of I_2 over HI indicates there is a reaction which produces iodine in the "hot spots" of the radiation tracks which is not affected by additives at the concentrations used in this work.[11] The fact that the rate of iodine production from pure ethyl iodide without additives is linear with energy input (*i.e.*, independent of the buildup of products) must mean that HI and I_2 are produced in a constant ratio and hence the fraction of the radicals produced which reacts with each is unchanged during continued irradiation. Radicals which become thermalized and escape reaction in the spurs diffuse into the body of the solution where they must react with HI or I_2 rather than with other radicals. The concentrations of I_2 and HI produced by even very short irradiations of pure ethyl iodide are far greater than the steady-state radical concentration in the bulk of the solution.[16]

A set of reaction steps adequate to explain the observations discussed above is given below. Underlined formulas indicate excited molecules or radicals. It is assumed that the initial excitation and ionization produced by the high energy electrons resulting from the γ-ray absorption lead to

(11) The main mechanism of energy dissipation by Co^{60} γ-rays (1.1 and 1.3 mev.) is the ejection of Compton electrons (average energy *ca.* 440 kev.) which in turn eject electrons of low energies (*ca.* 100 e.v.) which loose their energy in small regions called "hot spots" or "spurs." These spurs are of the order of 1000 Å. apart. With scavenger concentrations of less than about 10^{-3} mole fraction, the only reactions which occur in the spurs are reactions of excited molecules or radicals or ions with the solvent, or reactions between radicals immediately after thermalization and before diffusion. At concentrations of the order of 10^{-3} mole fraction or somewhat higher, the probability of an additive molecule being in the solvent cage with an excited molecule or radical begins to be great enough so that alterations in hot processes may be observed. This has been illustrated by the effects of halogen scavengers on the organic yields of reactions activated by radiative neutron capture,[12,13] the probability for the case of two particle recombinations processes has been discussed and evaluated,[14,15] and observations of such effects have been made in the photolysis of liquid ethyl iodide.[5b]

(12) S. Goldhaber and J. E. Willard, THIS JOURNAL, **74**, 318 (1952).

(13) G. Levey and J. E. Willard, *ibid.*, **74**, 6161 (1952).

(15) J. C. Roy, R. R. Williams, Jr., and W. H. Hamill, *ibid.*, **76**, 3274 (1954).

(16) The fact that the initial increase in rate of I_2 production caused by added HI is independent of the concentration of added HI and that the initial decrease in rate of I_2 production caused by added I_2 is independent of the concentration of added I_2 over the range tested (Fig. 1) indicates that, within the sensitivity of the experiments, each of these additives affects the rate only by competition with the other for free radicals and not by interfering with some independent process such as the combination of radicals with other radicals or atoms. The latter process, which is a sensitive function of scavenger concentration, has been observed in other systems.[12,13]

excited ethyl iodide molecules (step 3) which may decompose by step 4 to produce HI or by step 5 to produce hot ethyl radicals which either react by 6 to liberate $^1/_2$ I_2 or are thermalized by 7. Ionic or ion-molecule reactions which led to a constant rate of production of HI, $^1/_2$ I_2 and thermal ethyl radicals could account equally well for the data on the thermal radical reactions investigated in the present work. The reactions listed do not include C-C bond cleavage or elimination of H_2, both of which are minor processes.[4] If C–H bond cleavage occurs, the H atoms probably react with C_2H_5I to form HI, since the activation energy is small[17a] and they must undergo 10^3 or 10^4 collisions with solvent before meeting an HI or I_2 molecule. The recombination of ethyl radicals with iodine atoms in the spurs is not included, since it is not experimentally observable by the techniques used in this work.

Reactions in spurs

$$C_2H_5I \rightsquigarrow \underline{C_2H_5I} \quad (3)$$

$$\underline{C_2H_5I} \longrightarrow C_2H_4 + HI \quad (4)$$

$$\underline{C_2H_5I} \longrightarrow \underline{C_2H_5\cdot} + I\cdot \quad (5)$$

$$\underline{C_2H_5\cdot} + C_2H_5I \longrightarrow C_2H_4 + C_2H_6 + I\cdot \quad (6)$$

$$\underline{C_2H_5\cdot} + M \longrightarrow C_2H_5\cdot + M \quad (7)$$

Thermal radical reactions

$$I\cdot + I\cdot \longrightarrow I_2 \quad (8)$$

$$C_2H_5\cdot + I_2 \xrightarrow{k_{I_2}} C_2H_5I + I\cdot \quad (9)$$

$$C_2H_5\cdot + HI \xrightarrow{k_{HI}} C_2H_6 + I\cdot \quad (10)$$

Quantitative Interpretation of HI and I_2 Effects.—On the basis of the above data and reaction scheme, it is possible to derive equations which allow the prediction of the rates of I_2 production, HI production and exchange for any concentration of added HI or I_2. For this purpose we shall let A = rate of production of thermal alkyl radicals which escape from the spurs; B = total[18] rate of production of I_2 by hot processes (reactions 5 and 6); and C = the rate of HI production *via* reaction 4. A, B and C are constants if the energy absorbed per cc. per sec. is constant. Then setting the rate of thermal radical production equal to the rate of removal by reactions 9 and 10

$$A = k_{I_2}[I_2][C_2H_5] + k_{HI}[HI][C_2H_5] = [C_2H_5](k_{I_2}[I_2] + k_{HI}[HI]) \quad (11)$$

and

$$[C_2H_5] = A/(k_{I_2}[I_2] + k_{HI}[HI]) \quad (12)$$

The C_2H_5 radicals do not become homogeneously distributed through the solution but in general react with HI or I_2 before they have proceeded far from the radiation tracks.[13] Therefore, the $[C_2H_5]$ term does not represent a homogeneous steady-state concentration in the usual sense but nevertheless does represent the number of radicals per unit volume, when volumes large compared to the distance between the tracks are considered. The treatment is valid because the fate of a radical depends solely on the $[HI]/[I_2]$ ratio and not on the radical concentration, because radical–radical reactions are not involved.[13] The rate of iodine production may then be expressed as

$$d[I_2]/dt = B - (k_{I_2}/2)([I_2][C_2H_5]) + (k_{HI}/2)([HI][C_2H_5]) \quad (13)$$

The factor of $^1/_2$ is introduced by the use of molar concentrations. After substituting the expression for $[C_2H_5]$ and rearranging this becomes

$$d[I_2]/dt = B + (A/2) - A[[I_2]/([I_2] + (k_{HI}/k_{I_2})[HI])] \quad (14)$$

Similarly the expressions for the production of HI and the rate of return of iodine to the organic phase (exchange) are

$$d[HI]/dt = C - A + A[[I_2]/([I_2] + (k_{HI}/k_{I_2})[HI])] \quad (15)$$

$$d[C_2H_5I]_{exch}/dt = A[I_2]/([I_2] + (k_{HI}/k_{I_2})[HI]) \quad (16)$$

It is a necessary consequence of the stoichiometry of the system, according to our mechanism, that the sum of the moles of HI and I_2 increases at a constant rate regardless of the values of the rate constants k_{HI} and k_{I_2}. Thus, on adding equations 14 and 15 one obtains

$$d([HI] + [I_2])/dt = C + B - A/2 \quad (17)$$

or

$$([HI] + [I_2]) - ([HI] + [I_2])_0 = (C + B - A/2)t \quad (18)$$

The experimental data on the initial rates of I_2 production with added I_2 (minimum rate),[19] with added HI (maximum rate), and without additives may be used to evaluate A and B. These rates expressed as microequivalents of product per 5-ml. sample per min., at an energy absorption rate of 3.77×10^{17} e.v./ml. min., are: without additives, 0.0654; maximum, 0.1670; minimum, 0.0353. From equation 14 it may be seen that when HI is in large excess

$$d[I_2]/dt = B + {}^1/_2A = 0.1670 \quad (19)$$

and when I_2 is in large excess

$$d[I_2]/dt = B - {}^1/_2A = 0.0353 \quad (20)$$

These equations yield A = 0.1317 μequivalent/min. as the rate of thermal radical production and B = 0.1012 μequivalent/min. as the total rate of iodine production by hot processes, including that which normally back-reacts *via* reaction 9.

The constant C (*i.e.*, the total rate of HI formation including that which back reacts) can be evaluated if it is assumed that the rate constants

(17) E. W. R. Steacie, "Atomic and Free Radical Reactions," Reinhold Publ. Corp., New York, N. Y., 1954, (a) p. 733; (b) pp. 742-743.

(18) The *total* rate of I_2 production by hot processes is the rate of reaction 5 and any hot processes such as (6) which ensue. It includes the rate of production of I_2 which subsequently returns to organic combination by reaction with thermalized ethyl or other radicals. It does not include the formation of I_2 *via* reaction 10. The *net* rate of I_2 production by hot processes is the "total" rate minus that which back reacts with thermal radicals in the presence of excess I_2 scavenger.

(19) If the only possible steps in the radiolysis were those represented by equations 3 through 10, the minimum rate of iodine production observed with added I_2 would be the rate of the sequence of hot reactions 5, 6 since the sequence 5, 7, 9 does not affect I_2 concentration. If, however, any ethyl iodide molecules are dissociated by steps such as $C_2H_5I \rightarrow CH_3 + CH_2I$ or $C_2H_5I \rightarrow C_2H_4I + H$, rather by rupture of a C–I bond, and the fragments then react with I_2, the sequence will consume I_2. The minimum rate is therefore the rate of the sequence 5, 6 minus the rates of any sequences of the latter type. Such sequences do not alter the quantitative treatment presented unless the assumption made below that $k_{I_2} = k_{HI}$ is not valid for them; at most the effect will be small since about 90% of the radicals produced are ethyl radicals.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

for reactions 9 and 10 (*i.e.*, k_{I_2} and k_{HI}) are equal. This assumption is not unreasonable since the activation energy for each of these processes is near zero[17b] and there are many collisions per encounter in the liquid phase,[20] so that both HI and I_2 may react with ethyl radicals on nearly every encounter. Using this assumption, the following relation, derived from equations 14, 19 and 20, may be evaluated

$$\left(\frac{[HI]}{[I_2]}\right)_{Normal} = \frac{k_{I_2}(\text{norm. rate} - \text{min. rate})}{k_{HI}(\text{max. rate} - \text{min. rate})} = 0.296 \quad (21)$$

where the ratio applies to the radiolysis of initially pure ethyl iodide, and the normal, maximum, and minimum rates refer to the radiolysis with no additives, with excess HI, and with excess I_2, respectively. Multiplying this ratio by the iodine production rate for ethyl iodide with no additives gives

$$d[HI]/dt = ([HI]/[I_2])d[I_2]/dt = 0.296 \times 0.0654 = 0.0193\ \mu\text{mole/min.} \quad (22)$$

Substitution of the value for the HI production rate into equation 15 together with the value of the ratio $[I_2]/([I_2] + [HI])$ for a run with no additives yields the value of C as 0.0493 μmole/minute.

The differential equations for the various rates can now be written

$$d[I_2]/dt = 0.1671 + 0.1317\ [I_2]/([I_2] + [HI]) \quad (23)$$

$$d[HI]/dt = -0.0824 + 0.1317[I_2]/([I_2] + [HI]) \quad (24)$$

$$d[HI + I_2]/dt = 0.0847 \quad (25)$$

$$d[C_2H_5I]_{exch}/dt = 0.1317\ [I_2]/([I_2] + [HI]) \quad (26)$$

The approximation $k_{I_2}/k_{HI} = 1$ has been assumed in all the above equations except (25). The equations can be integrated only when this assumption is made; the resulting equations are[21]

$$[I_2] = 0.0654t + 0.772([HI]_0 + [I_2]_0) + (0.228[I_2]_0 - 0.772[HI]_0)\left(1 + \frac{0.0847t}{[HI]_0 + [I_2]_0}\right)^{-1.55} \quad (27)$$

$$[HI] = 0.0193t + 0.228([HI]_0 + [I_2]_0) + (0.772[HI]_0 - 0.228[I_2]_0)\left(1 + \frac{0.0847t}{[HI]_0 + [I_2]_0}\right)^{-1.55} \quad (28)$$

$$[HI] + [I_2] = 0.0847t + [HI]_0 + [I_2]_0 \quad (29)$$

$$[C_2H_5I]_{exch} = 0.1017t + (0.228[I_2]_0 - 0.772[HI]_0)\left(1 + \frac{0.0847t}{[HI]_0 + [I_2]_0}\right)^{-1.55} \quad (30)$$

The last equation refers to the quantity of ethyl iodide re-formed by the back reaction, a process which can be observed only when radioiodine is present.

Comparison of Predicted Rates of I_2 and HI Production with Experimental Results.—From Fig. 1 it can be seen that values for the iodine concentration as a function of time of irradiation calculated from equation 27 agree well with the experimentally determined values for all initial concentrations of HI and I_2 tested.[22]

The rate of production of HI during radiolysis is a good test of the assumptions in deriving equations 27–30 since experimental data on HI production were not used in the derivation. In two experiments on ethyl iodide without additives, the $[HI]/[I_2]$ ratio was determined after irradiation by adding radioiodine prior to extraction in the manner described above for the exchange experiments. The values obtained for the HI production rate were 0.018 and 0.019 μmole/min. which can be compared with the predicted value of 0.0193 μmole/min.

These experimental results can be used to solve equation 21 for k_{I_2}/k_{HI}; the values obtained are 0.94 and 0.99. The difference between these values and 0.34 recently reported by Bunbury, Williams and Hamill[5b] for the same radical reactions in the photolysis of C_2H_5I is probably greater than our experimental error. The agreement of the iodine production and exchange rates predicted by equation 27–30 with the experimental results also supports the validity of the conclusion that $k_{I_2}/k_{HI} \cong 1$.

Analysis for HI during the exchange experiments shown in Table I indicated an average HI production rate of 0.037 ± 0.009 μmole/min. Under the same conditions the predicted values range from 0.046 μmole/min. at 5 min. to 0.031 μmole/min. at 60 min., giving an average value of about 0.038. The experimental data do not show any clear trend, since the trend expected is of the same order of magnitude as the experimental error. The reliability of these latter experiments is not good enough to consider the results as proof of the assumption that $k_{I_2} = k_{HI}$, but the results are consistent with this conclusion.

Comparison of Predicted Rate of Exchange with Experimental Results.—The rate of transfer of initially added radioiodine from inorganic to organic form may be expressed as $-d[I^*]/dt = (d[C_2H_5I]_{exch}/dt)([I^*]/([HI] + 2[I_2]))$ where $d[I^*]/dt$ is the rate at which equivalents of radioiodine are removed from the inorganic phase, $[I^*]/([HI] + 2[I_2])$ is the ratio of equivalents of ratioiodine to total iodine in the inorganic phase (the probability that a given iodine atom encountered by an alkyl radical is radioactive) and $d[C_2H_5I]_{exch}/dt$ is the total rate of reaction of thermalized ethyl radicals with I_2 from the bulk of the medium. Since $[I^*]$ occurs on both sides of the equation the conversion factor from concentration to counting rate cancels, and $[I^*]$ may be taken as the counting rate of the inorganic phase. It is possible to substitute for these quantities using equation 26 for the total rate of re-formation of ethyl iodide and the integrated equations 27 and

(20) E. Rabinowitch, *Trans. Faraday Soc.*, **33**, 1225 (1932).

(21) Integrate eq. 25 first and substitute in 23 and 24 giving equations in the variables $[I_2]$ and t only; integrate 23 and 24. Substitute the expressions for $[I_2]$ and $[I_2] + [HI]$ from 23 and 25, respectively, into 26 and integrate.

(22) The values for the initial I_2 concentration used in the calculation of curves G and H of Fig. 1 were determined by spectrophotometric measurement. The value of the HI concentration used for curve D was accurately determined by using radioiodine of known specific activity. In the experiment shown by curve A, there was a sufficient excess of HI over I_2 to give the maximum rate for the entire experiment, hence knowledge of the exact concentration is not critical. The experimental values of HI added for runs B, C and E were less accurately known because they depended on measuring the PV product of about 10^{-5} mole of HI and transferring it quantitatively through the vacuum line. For these cases the values for the initial HI concentration used with equation 27 for the calculations were 10 to 30% different from the experimental values, a choice being made which gave a fit with the data for iodine production. As a result curves F, G and I are only a semi quantitative verification of the mechanism.

[a] ½ I_2 produced per 100 e.v. absorbed. [b] For alkyl iodides with no HI or I_2 added prior to irradiation. Some of these values are taken from reference 1. [c] Net rate of iodine production by hot processes.[18] [d] The factor ½ is required to convert from G_I to $G_{free\ radical}$ because in the presence of excess HI two iodine atoms are formed for each thermal radical, as indicated by equations 5 and 10 of the text. [e] Total rate of production of iodine by hot processes.[18] [f] Given by $(G_{norm} - G_{min})/(G_{max} - G_{min})$. [g] This column is the value of column 3 minus column 5 and represents the G value for the reaction of thermal radicals with HI in the absence of initially added scavengers.

28 for the concentrations of HI and I_2 as a function of the time of radiolysis, but the equation obtained cannot be integrated. (Iodine must be added initially to study the exchange, hence the HI, I_2 and total exchange rates will all vary with the time of irradiation.) By assuming that the various rates are constant over short periods of irradiation and using iterative calculations, the fractional exchange which will be observed over longer periods may be predicted. This calculation was performed using an initial iodine concentration of 8.4 μmoles for comparison with the data in Table I. The results of the calculation are shown by curve A of Fig. 2. The predicted exchange rate averaged over the first 5 minutes was 0.128 and over the first 60 minutes 0.113 μmole/min. The experimental points of curve B of Fig. 2 show that exchange occurred considerably faster than predicted.

The solid line of curve B, which fits the experimental data, was obtained in a semi-empirical manner as follows: the iterative calculations described above were repeated, assuming that there is a constant component to the exchange rate of 0.020 μequivalents/min. which is independent of HI or I_2 concentration, *i.e.*, which is the result of exchange by a "hot" process. Thus the rate over the first 5 minutes was taken to be 0.148 and over the first 60 minutes 0.133 μequivalent/min.; values are given in Table I for comparison with the earlier calculations. It is believed that these numbers represent better values for experimental exchange rates than those calculated from equation 2. The short irradiation values based on the latter are unduly influenced by exchange induced in preparing and analyzing the samples (about 0.5 to 1%) and the long irradiation values are subject to error because equation 2 does not take into account the competition of HI with I_2 for C_2H_5 radicals.

There is no obvious reason why the exchange rate predicted by equation 26 (curve A, Fig. 2) should be in error by as much as 20% unless some step which contributes to exchange but does not affect HI or I_2 concentrations has been omitted from the postulated mechanism. This point of view is strengthened by the fact that the derived equations predict the iodine production rate during the same set of exchange experiments within 1 or 2%. Various speculations as to the basis for the discrepancy are possible. For example, it might be explained if excited ethyl iodide molecules with too little energy to produce radicals have a much higher "rate constant" for undergoing exchange with I_2 than for degradation of the energy in non-reactive collisions with other ethyl iodide molecules.

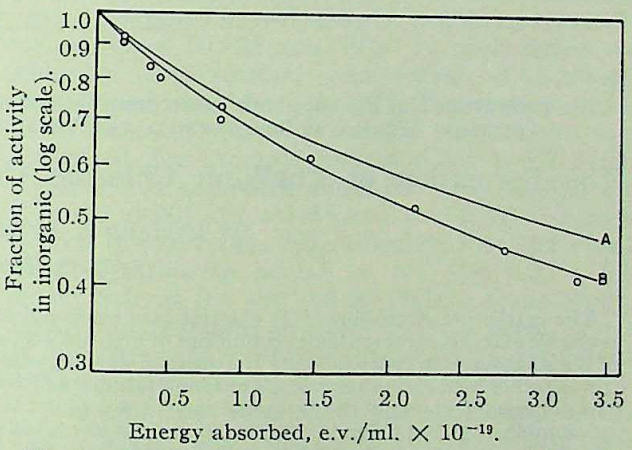

Fig. 2.—Exchange of radioiodine during the radiolysis of ethyl iodide solutions which initially contained about 8.4 × 10^{-4} molar iodine. Points are from experimental data. Curve A was calculated by equation 30; curve B was calculated by a semi-empirical method described in the text.

This hypothesis is attractive because the high energy electrons in the system undoubtedly dissipate much of their energy in producing low lying excited states of ethyl iodide. It might predict a concentration dependence but this would probably be difficult to observe because the excess exchange in only a small fraction of the total exchange yield. If thermal ethyl radicals can abstract I as well as H from HI, the rate of exchange in the presence of HI would be higher than predicted but the increase would be expected to be a function of the [HI]/[I_2] ratio.

Effect of Added HI and I_2 on the Radiolysis of Other Alkyl Iodides.—The data of Table II show that the influence of added HI and I_2 on the radiolysis of six additional alkyl iodides is qualitatively similar to the effect on ethyl iodide but quantitatively different.

Of particular interest is the fact that added iodine appears to reduce the iodine yield from methyl

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

iodide, since this implies that HI is a product of the radiolysis. The effect seems to be greater than can be attributed to experimental error.

According to the discussions above the rate of iodine production in ethyl iodide and presumably in the other alkyl iodides must depend on: (1) the net rate of I_2 production in the spurs; (2) the rate of production of thermal radicals in the spurs; (3) the ratio of HI to I_2 production. The question may be raised as to which of these factors is responsible for the fact that G_{I_2} with no added scavengers increases with increasing number of β-hydrogens in the molecule.[2,23] From Table II it may be seen that the effect is not attributable to the rate of thermal radical production (columns 2 and 6), that the net rate of I_2 production in the spurs does increase with increase in the β-hydrogen content, except in going from C_2H_5I to *sec*-C_4H_9I, (column 5) and that the ratio of thermal radical reaction with HI to reaction with I_2 also increases (column 7). The G value for reaction of thermal radicals with HI shows the smoothest increase as a function of the number of β-hydrogens in the molecule (column 8). Column 7 gives the total rate at which iodine is produced in the spurs by reactions 5 and 6, including the iodine which back reacts via the exchange reaction 9. As the carbon chain length of the alkyl iodide increases the number of bonds in the molecule other than the C–I bond increases. As a result of this the rate for C–I bond rupture might be expected to decrease; this was found experimentally. It can also be seen that the secondary iodides (isopropyl and *sec*-butyl) show slightly higher rates of C–I bond rupture than the corresponding primary compounds, which might be expected on the basis of bond strengths.

The Formation of Thallium Chloride Complexes and their Extraction into Ether[1]

BY DONALD L. HORROCKS AND A. F. VOIGT

RECEIVED NOVEMBER 12, 1956

The extraction of thallium(III) chloride into isopropyl ether has been studied using tracer techniques with Tl^{204}. Appreciable extraction occurs under conditions of high acidity, and the extraction is markedly dependent upon the ionic strength of the solution. In order to study the effect of varying acidity and chloride concentration over a wide range, the study was run at rather high ionic strength. The temperature coefficient and heat of extraction were determined in the range of 20–30°. The empirical formula of the extracted species was found to be $HTlCl_4$ and a higher complex, H_2TlCl_5, was found not to be extractable. At low chloride concentrations and low acidity the extraction cannot be explained completely by this mechanism and it is postulated either that $TlCl_3$ extracts or that $HTlCl_4$ ionizes in ether under these conditions.

The extraction of thallium(III) from hydrohalic acids into ether has been reported by several investigators.[2–6] It has been developed into an analytical method for separating thallium from most elements, except iron(III), gallium(III), gold(III), and some others. Aside from noting the optimum conditions for complete extraction of the thallium, no investigations of the nature of the extraction process have been made. This research was undertaken to obtain information about the thallium compound present in the ether phase, the dependence of the extraction upon the concentrations of acid and chloride, the temperature coefficient of the extraction and the extraction equilibrium constant. These should be of interest in comparison with the analogous Fe(III) which has been shown to extract into ether as $HFeCl_4$.[7]

Preliminary investigations of the extraction of thallium(III) from $HClO_4$–LiCl–$LiClO_4$ solutions into isopropyl ether showed appreciable extraction only at relatively high acid and chloride concentrations and also showed that the extraction depends very markedly upon the ionic strength. It was thus necessary to perform the investigations in solutions of constant, high ionic strength. On the other hand the sensitivity of the tracer method made it possible to do the experiments at low concentration, about 10^{-3} M, of thallium.

The results of these conditions was that the determination of the activity coefficients of the various ionic species was difficult, but not as difficult as it would have been at higher thallium concentrations. In estimating activity coefficients it was necessary to make some assumptions which may not be completely valid.

The distribution of thallium between phases was measured by tracer techniques over a range of

chloride ion, acid and total salt concentrations. In the interpretation of the data, it was found advantageous to use formation constants determined by Benoit[8] for the various thallium(III) chloride complexes up to $TlCl_4^-$. Experimentally, this species, in the form of the acid, was essentially the only thallium compound found in the ether phase. Hence the distribution could be represented by a constant

$$K = \frac{(HTlCl_4)_e}{(H^+)_w(TlCl_4^-)_w} = \frac{[Tl_e]\gamma^e HTlCl_4}{(H^+)(Tl^{+3})(Cl^-)^4 K_4} \quad (1)$$

in which ( ) represents activity, [ ] concentration, $K_4 = (TlCl_4^-)/(Tl^{+3})(Cl^-)^4$ and $\gamma^e HTlCl_4$ is the activity coefficient of $HTlCl_4$ in ether. This extraction coefficient, K, can be expressed in terms of the measured distribution ratio, $K_T = [Tl]_e/[Tl]_w$ by considering all of the aqueous chloride complexes of thallium, their formation constants of the form

$$K_n = \frac{(TlCl_n^{3-n})}{(Tl^{+3})(Cl^-)^n} \quad (2)$$

and the appropriate activity coefficients. The equation obtained is

$$K = K_T \frac{\gamma^e HTlCl_4}{(H^+)(Cl^-)^4 K_4}\left[\sum_{n=0}^{5} K_n \gamma^n_{Cl^-}[Cl^-]^n/\gamma TlCl_n^{3-n}\right] \quad (3)$$

in which K_0 is set equal to 1. Hydrolyzed forms of thallium(III) were assumed to be unimportant at the acid concentrations used. Several series of extractions were made, each one at constant acidity and ionic strength, but with varying chloride concentration. Since the concentration of the ethereal thallium species was always small its activity coefficient was assumed constant. Thus a new extraction constant could be defined, as

$$K' = \frac{K(H^+)}{\gamma^e HTlCl_4} = \frac{K_T}{(Cl^-)^4 K_4}\left[\sum_{n=0}^{5} K_n \gamma^n_{Cl^-}[Cl^-]^n/\gamma TlCl_n^{3-n}\right] \quad (4)$$

Materials.—Thallium(I) nitrate, obtained by dissolving thallium metal in HNO_3, was oxidized to thallium(III) by aqua regia. The thallium(III) chloride was extracted into ether from a 6 to 7 *N* HCl solution and precipitated as Tl-$(OH)_3$ by shaking with a dilute NaOH solution. The Tl-$(OH)_3$ was purified by repeated solution in 6 to 7 *N* HCl, extraction into ether and reprecipitation as $Tl(OH)_3$. The $Tl^{204}NO_3$ obtained from the Oak Ridge National Laboratory, Oak Ridge, Tennessee, was purified in this same manner. A desired amount of the purified active and inactive Tl_2O_3 was dissolved in excess $HClO_4$ and the resulting solution standardized, the thallium determined as Tl_2CrO_4 as reported by Kleinberg[9] and the excess $HClO_4$ by titration with standard base, allowing for the titration of the thallium. The solution was 0.0106 *M* $Tl(ClO_4)_3$ in 4.05 *M* $HClO_4$. The chloride and hydrogen ion concentrations were varied and the ionic strength was maintained constant by the use of standard solutions of LiCl, $HClO_4$ and $LiClO_4$.

(9) J. Kleinberg, "Collected Radiochemical Procedures," A.E.C. Document LA-1721, Los Alamos Scientific Laboratory, Public

Technique.—Aqueous solutions of the desired thallium(III), Cl^- and H^+ concentrations and ionic strength were extracted with equal volumes of isopropyl ether by mixing in a constant temperature bath with an automatic shaker. The temperature was 30° except for the study of temperature dependence. The solutions were shaken for 40 minutes and then allowed to separate for 30 minutes before the samples were removed with pipets. The ether samples were evaporated into 2 to 3 ml. of water. Analyses were made for acid, chloride and thallium. The acid and chloride analyses were done volumetrically, the thallium analyses radiochemically, with the addition of known amounts of carrier $Tl(NO_3)_3$ in HNO_3 to facilitate precipitation and filtration. The thallium, precipitated as Tl_2CrO_4, was filtered onto small paper discs, washed with alcohol and dried at 110°. The samples were covered with 3.3 mg./cm.² cellophane discs and mounted on cardboard backing for counting.

Discussion

The temperature dependence of the extraction was determined in two series of extractions at temperatures of 20, 25 and 30°. In each series the chloride concentration was varied at constant acidity and ionic strength. The distribution ratio, K_T, decreased markedly as the temperature was increased, for example from a solution 0.2 *M* in LiCl, 0.6 *M* in $HClO_4$ and 1.53 *M* in $LiClO_4$, K_T was 4.0 at 20°, 2.5 at 25° and 1.5 at 30°. Values of ΔH of extraction were calculated by the Van't Hoff equation to be 9.5 ± 0.7 and 9.9 ± 0.3 kcal./mole at 0.4 and 0.6 *M* $HClO_4$, respectively, at an ionic strength of 2.33. Each of these values is the average of six or more calculations at different chloride concentrations.

The empirical formula of the compound in the ether phase was determined by analyzing this phase for chloride, ionizable hydrogen and thallium. Results in Table I have been corrected for the extraction of chloride and acid under identical conditions except for the absence of thallium. The high values observed for the Cl^-/Tl ratios are due principally to the small amounts present. From these data, it was assumed that the empirical formula of the ethereal species was $HTlCl_4$.

The observed distribution ratio, K_T, decreased as the chloride concentration was increased. Data at an ionic strength of 3.0 are shown in Fig. 1. Similar results were obtained at an ionic strength of 2.0. A reasonable explanation of this effect is the formation of a non-extractable species, such as $TlCl_5^=$. Since it was not possible to obtain sufficient data at low chloride concentrations to evaluate the constants for the mono to tetra-chloro complexes independently, the values of Benoit[8] were used. His determinations of these constants, defined as in equation 2 are for K_1, 1.38 × 10⁸; K_2, 4 × 10¹³; K_3, 6 × 10¹⁵; and K_4, 10¹⁸. Equation 4 was used with these constants in successive approximations to determine a value of K_5 which would give the best evaluation of K'. This treatment gave 2.96 × 10¹⁷ for K_5. In the region of very high ionic strength, about 5, the formation of

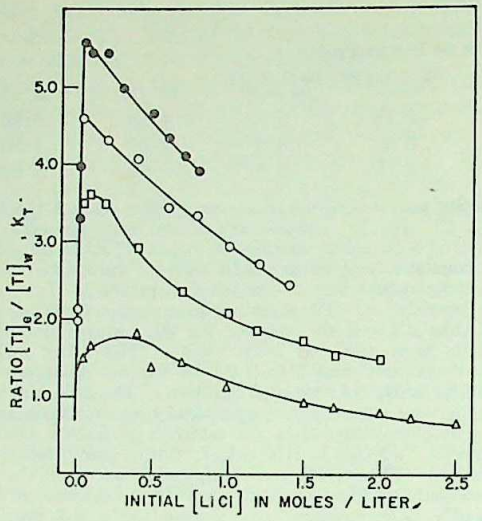

Fig. 1.—Extraction at total salt and acid concentration of 3.0 *M*: ●, 2.2 *M* $HClO_4$; ○, 1.6 *M* $HClO_4$; □, 1.0 *M* $HClO_4$; △, 0.4 *M* $HClO_4$.

three phases was observed which has been described in the cases of $FeCl_3$ and $GaCl_3$ extraction.[10-12] The three phases are a "light ether," a "heavy ether" and an aqueous phase with 90–96% of the thallium in the heavy ether phase. Repetition of these experiments in the absence of thallium gave rise to the same phenomenon so that under these conditions it is caused by the high salt and acid concentration and not by the heavy metal complexes. In the case of solutions 4 *M* in $HClO_4$ and 1 *M* in LiCl plus $LiClO_4$, large amounts of the acid were found in the heavy ether layer. The explanation by Nachtrieb and Fryxell for the similar phenomenon in $FeCl_3$ extraction was that the acid H_2FeCl_5 was forming ethereal polymers by multiple hydrogen bonds. In the present case $HClO_4$ may be replacing the H_2FeCl_5 in such a polymer with ether molecules.

The difficulties of interpretation which were brought about by the three phase behavior at very high ionic strength made it necessary to conduct the more detailed study of the extraction at lower ionic strength. The total salt plus acid concentrations were kept at 2.0 and 3.0 *M* while the chloride and acid concentrations were varied. Equation 4 was used to calculate K' using the Debye–Hückel equation[13] for the estimation of the activity co-

$$-\log \gamma_i = \frac{AZ_i^2\sqrt{\mu}}{1 + Ba_i\sqrt{\mu}}$$

efficients of the thallium species. As the various forms of thallium(III) are large ions, the product $B \times a_i$ was taken as 3 for all species. The activity coefficient of the chloride ion was assumed to be equal to the mean activity coefficient of HCl under the same conditions; values of 0.993 at 2.0 *M* HCl and 1.288 at 3.0 *M* HCl at 30° were used. The calculated values of K' are shown in Figs. 2 and 3.

The constant values of K' at all but the lowest chloride concentrations indicate that the description of the extraction in terms of extractable $HTlCl_4$ and non-extractable H_2TlCl_5 is valid. The sharp increase in the values of K' at low chloride

concentrations is attributed to one or both of two factors, the co-extraction of $TlCl_3$ or the ionization of $HTlCl_4$ in highly dilute ether solutions.

The directly measured extraction coefficient, K_T, showed a first-order dependence on the concentration of hydrogen ion. The quantity K', involving formation constants and activity coefficients, also showed such a relationship when plotted against the $HClO_4$ concentration as in Fig. 4. The linear acid dependence agrees with the idea that $HTlCl_4$ is the extracted species and in addition indicates that the activity coefficient of the hydrogen ion is constant at a given ionic strength.

The acid dependence is expressed in equations 1 and 4 and if these truly represent the data one would expect the curves of Fig. 4 to pass through the origin. The fact that they do not, indicates that at lower acid concentrations some other process is taking place which could be either the ionization of $HTlCl_4$ in ether or the co-extraction of $TlCl_3$.

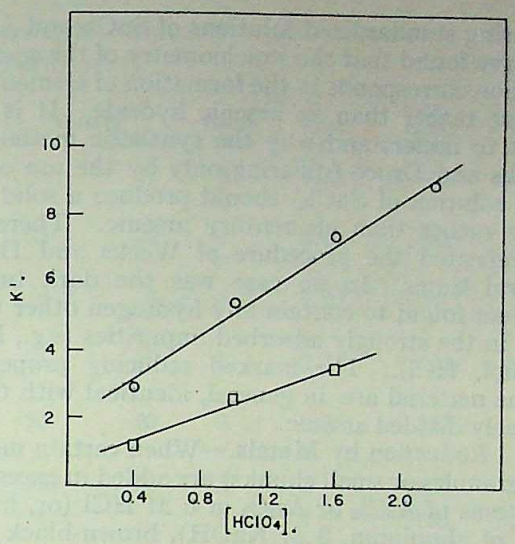

Fig. 4.—Dependence of K' upon $HClO_4$ concentration: O, 3.0 M total salt and acid concentration; □ 2.0 M total salt and acid concentration.

Conclusions

The following results and conclusions can be drawn from this study.

The extraction was found to have a negative temperature coefficient in the range of 20 to 30°. An average value of ΔH of 9.7 ± 0.5 kcal. per mole was found under the conditions of the experiments.

In order to explain the reduced extraction at high acidities a non-extractable species with formula H_2TlCl_5 was postulated. The data were used to calculate its formation constant as 3.0×10^{17}.

The empirical formula of the extracted species was found to be close to $HTlCl_4$.

At a given ionic strength and acid concentration the extraction equilibrium constant was found to be essentially constant, independent of the chloride concentration except when this was quite low. The lack of constancy was possibly due to ionization of $HTlCl_4$ in the ether phase or to coextraction of the $TlCl_3$ species.

The extraction was found to have a linear dependence on the hydrogen ion concentration in agreement with the supposition that $HTlCl_4$ was the species extracted. The fact that the extraction did not extrapolate to zero at low acidity agrees with the idea that $TlCl_3$ is extracting or that $HTlCl_4$ is ionizing in the ether phase. Values of the extraction coefficient at 30° are about 2.3 at an ionic strength of 2 and 4.3 at an ionic strength of 3 and relatively high acidities.

Solid Arsenic Hydrides

BY W. L. JOLLY, L. B. ANDERSON AND R. T. BELTRAMI

RECEIVED OCTOBER 3, 1956

Various methods for preparing solid arsenic hydrides have been evaluated as to yield and product composition. Atom ratios of hydrogen/arsenic as high as 0.52 have been observed for solid hydrides. A method has been developed for preparing an unstable, volatile arsenic hydride (probably biarsine, As_2H_4) from arsine by use of a silent electrical discharge.

I. Introduction

The literature contains many conflicting statements regarding the solid arsenic hydrides. Not only the compositions of these hydrides, but also their methods of preparation, have been the subject of dispute.[1] We have evaluated various preparative methods in terms of both yield and hydrogen content of the product. Several new preparative methods have been developed, including a method for the preparation of an unstable, volatile hydride (probably biarsine).

Some studies of the adsorption of arsine on arsenic have been made, in an attempt to elucidate the nature of the solid arsenic hydrides.

II. Results and Discussion

A. Reduction of Arsenic Solutions. 1. Reduction by $SnCl_2$.—Weeks and Druce[2] reported that a brown, amorphous arsenic hydride may be prepared by the action of an ether solution of stannous chloride on a solution of arsenic trichloride in aqueous hydrochloric acid

$$2AsCl_3 + 4SnCl_2 + 2H^+ + 2Cl^- = As_2H_2 + 4SnCl_4$$

By using standardized solutions of $SnCl_2$ and $AsCl_3$ we have found that the stoichiometry of the *aqueous* reaction corresponds to the formation of elementary arsenic rather than an arsenic hydride. It is difficult to understand why the synthetic method of Weeks and Druce (differing only by the use of an *ether* solution of $SnCl_2$) should produce a solid hydride rather than elementary arsenic. Therefore we repeated the procedure of Weeks and Druce several times. In no case was the dark brown product found to contain any hydrogen other than that in the strongly adsorbed impurities (*e.g.*, H_2O, alcohol, HCl). The marked reducing properties of the material are, in general, identical with those of finely divided arsenic.

2. Reduction by Metals.—When certain metals (as granules or small chunks) are added in excess, to solutions of $AsCl_3$ or As_2O_3 in 6 *M* HCl (or, in the case of aluminum, 3 *M* NaOH), brown-black precipitates form, along with large amounts of hydrogen (and some arsine). The results of such experiments are summarized in Table I. The empirical formulas are the average values from several experiments. The best products were consistently obtained by the use of powdered magnesium, although the yields were never as great as those obtained by the use of granulated zinc. It is interesting that practically no solid product was obtained when calcium was the reducing agent. This may be caused by the extremely rapid reaction of calcium with water and by the fact that the calcium chunks floated on the surface of the solution.

TABLE I

REDUCTION OF 0.24 *M* As(III) SOLUTIONS BY METALS

Metal	Soln.	Yield, %	Empirical formula of solid product
Mg	HCl	~25	$AsH_{0.19}$
Zn	HCl	~85	$AsH_{0.04}$
Al	HCl	~18	$AsH_{0.025}$
Al	NaOH	~85	$AsH_{0.025}$
Ca	HCl	0	.....

An important method of isolating trace amounts of arsenic for subsequent analysis involves the quantitative reduction to arsine by zinc in hydrochloric or sulfuric acid solution.[3] Apparently little or no solid product is obtained when the arsenic concentration is very low.

3. Reduction by Miscellaneous Reducing Agents.—The reduction of $AsCl_3$ in 6 *M* HCl by chromous chloride gave a product of composition $AsH_{0.02}$ when the chromous chloride was in excess, and a product of composition $AsH_{0.002}$ when the $AsCl_3$ was in excess.

The addition of lithium hydride chunks to a solution of sodium arsenite gave no solid product. In this respect lithium hydride resembles calcium. Perhaps some reduction to arsine took place in the case of these powerful reducing agents.

B. Electrolytic Reduction of Arsenic Solutions.—Davy[4] was the first to report the formation of a brown precipitate when a solution of potassium hydroxide was electrolyzed using an arsenic cathode. Weeks[5] stated that the brown material obtained from a similar experiment was a solid arsenic hydride, but he gave no analytical data. Olszewsky[6] obtained a similar product by electrolyzing a solution of arsenious acid, using platinum electrodes.

We chose mercury as a cathode principally because of its high overvoltage for hydrogen evolution. Since hydrogen overvoltage increases with both increasing current density and decreasing temperature, we usually cooled the electrolytic cell as much as possible without unduly increasing the resistance. It is well known that arsine is liberated when an arsenic solution is reduced at a mercury cathode,[7,8] and we suspected that the presence of arsine was necessary for the formation of "solid arsenic hydrides."

The results are summarized in Table II. It will be noted that the ratio of hydrogen to arsenic in the product was high for those runs in which the electrolyte was acidic and cold. On the other hand, yields (based on electrical efficiency) were low under these conditions. It was observed that when the electrolytic experiments were started, the brown precipitate did not form at the surface of the mercury cathode, rather it formed homogeneously throughout the catholyte. We suspected that this phenomenon was caused by the reaction of dissolved arsine with the As(III) in the solution. It has been reported that arsine and arsenious acid react to give arsenic.[9]

We did not vary the concentration of As(III) in the electrolyte. It is known, however, that, as the concentration of As(III) decreases, the ratio of solid product to liberated arsine also decreases. In fact, when the concentration of As(III) is sufficiently small, quantitative yields of arsine gas are obtained.[3,8] It is probably significant that, in the reduction of As(III) solutions by sodium amalgam, the proportion of arsenic appearing as the metal (or solid hydride?) decreases with decreasing As(III) concentration.[10]

C. Oxidation of Arsine. 1. Oxidation by As(III).—Since our observations of the electrolysis of As(III) solutions led us to suspect that at least part of the solid product was formed by the reaction between arsine and As(III), we performed some experiments in which arsine was passed through As(III) solutions. The reaction of arsine with arsenious acid in sulfuric acid solution at room temperature was found to be so slow as to be an impractical synthetic method. We were unable to collect enough product to analyze. However, arsine reacts more rapidly with $AsCl_3$ in 6 *M* HCl. The product from such an experiment was found to have the empirical formula $AsH_{0.021}$. It thus seems likely that only a minor fraction of the product from the electrolytic preparations was formed by the reaction of arsine with arsenious acid.

[a] Mole ratio AsH_3/H_2 in gas from vacuum thermal decomposition of vacuum heated product.

2. **Oxidation by $SnCl_4$.**—Moser and Brukl[11] reported the preparation of a hydride of the composition As_4H_2 by the oxidation of arsine by stannic chloride in aqueous hydrochloric acid. We repeated their experiments, but under conditions such that the $SnCl_4$ was always in excess. (Moser and Brukl kept the arsine in excess.) Our products had the average empirical formula $AsH_{0.18}$.

D. **Decomposition of Arsine by a Silent Electrical Discharge.**—Ogier[12] decomposed arsine in a discharge tube and obtained only 85.6% of the theoretical amount of hydrogen gas. This datum corresponds to a solid residue of the composition $AsH_{0.43}$. We repeated this experiment twice, using a closed discharge tube, and obtained solids with calculated compositions $AsH_{0.20}$ and $AsH_{0.23}$.

E. **Disproportionation of Biarsine (?).**—In preliminary experiments it was found that, when arsine was passed through a silent electrical discharge tube followed by a trap cooled to −196°, a yellow-brown solid formed in the trap.

Nast[13] has isolated small amounts of biarsine, As_2H_4, from the volatile products in the hydrolysis of magnesium aluminum arsenide. Pure biarsine was reported to be extremely unstable, decomposing to arsine and a solid red hydride of the approximate composition $AsH_{0.62}$. We suspected that, in our preliminary experiments with the discharge tube, the arsine had been decomposed to, among other things, hydrogen and biarsine. Presumably the biarsine, in turn, decomposed at the cold trap into arsine and the yellow-brown solid which we observed.

Further experiments indicated that we could, indeed, isolate a volatile material (not arsine) from the discharge tube products. This material (which may have been a mixture of biarsine and higher polymers such as As_3H_5 and As_3H_3) could be partially condensed in traps cooled to −80° and almost completely condensed in traps cooled to −120°. It partially decomposed to a bright yellow non-volatile hydride (and probably arsine and/or hydrogen) during the processes of condensation and vaporization. The yellow hydride, on warming to room temperature, turned red and finally brown. The volatile material was too unstable to analyze directly, but several samples of the solid hydride were analyzed. The average of several analyses corresponded to the empirical formula $AsH_{0.52 \pm 0.07}$.

F. **Ammonolysis of Sodium Arsenide.**—When ammonium chloride is added to a liquid ammonia solution of $NaAsH_2$, arsine is liberated and a finely divided brown precipitate of arsenic forms. This precipitated arsenic was found to contain only negligible amounts of hydrogen, in agreement with the findings of Johnson and Pechukas.[14]

G. **Adsorption of Arsine on Arsenic.**—The arsenic prepared by the method of Weeks and Druce ("As_2H_2") was found to be extremely finely divided. One sample had a surface area of 120 m.²/gram.

The adsorption of arsine on a similar sample of arsenic at −78.5° was found to show some hystere-

sis in an adsorption–desorption cycle, but there was no strong bonding between the arsine molecules and the arsenic.

III. Experimental[15]

A. Analysis.—The solid arsenic hydrides were analyzed by thermal decomposition in a vacuum manifold. Weighed samples were heated *in vacuo* until the arsenic sublimed vigorously. The evolved gases were Toepler-pumped through, successively, a tube of Ascarite (to absorb CO_2, HCl and H_2O), a trap cooled to −78° (to trap H_2O, alcohol, etc.), and a trap cooled to −196° (to trap AsH_3). The non-condensable gas was usually assumed to be hydrogen; occasionally this was checked by a molecular weight determination or by mass-spectrometric analysis. Arsine was identified by its vapor pressure at the melting point of CS_2: lit.[14] 35 mm., found 34–36 mm. Usually the molar ratio AsH_3/H_2 in the gaseous decomposition products was approximately 0.05. The hydrogen contents of the solid hydrides were calculated from the molecular hydrogen and arsine evolved in the thermal decompositions.

B. Electrolytic Reduction of Arsenic Solutions. 1. Apparatus.—The anode compartment was a cylindrical tube 100 mm. long with a 40-mm. fritted disc at the lower end. Two types of anodes were used. One was a graphite rod 12 mm. in diameter. The other was a 1 × 10 cm. strip of platinum sheet. The cathode compartment was a one-liter "tall form" beaker, equipped with a stirrer. A pool of mercury (1/2 inch deep) in the bottom of the cathode compartment served as the cathode. Electrical contact was made to the mercury by a platinum-tipped wire passing through a tube. In some experiments, the cell was cooled externally with ice-water.

2. General Procedure.—Fifteen grams of arsenious oxide was dissolved in 25 ml. of 5 *M* sodium hydroxide. The solution was diluted with water and the appropriate amount of sulfuric acid to a volume of one liter.

In run no. 12, phosphoric acid was used instead of sulfuric acid. The catholyte for run no. 9 was prepared by dissolving arsenious oxide in hot water. The catholyte of run no. 6 was half-molar sodium hydroxide. The anolytes were the same as the catholytes in acid or base composition, but lacking in arsenious oxide. In run no. 6 the platinum anode was immersed directly in the catholyte.

At the end of each run, the mercury was removed with a separatory funnel, and the product was collected in a fritted funnel by vacuum filtration. The product was washed with water and dried for at least eight hours *in vacuo* over magnesium perchlorate.

Table II summarizes the data for each experiment.

C. Decomposition of Arsine by a Silent Electrical Discharge.—The discharge tube was similar to the usual ozone generator. It consisted of a glass cylindrical "finger" within and concentric with another glass cylinder. The discharge tube could be closed by means of stopcocks located at either end. The capacity of the tube was 63 cc.; the inner and outer cylinders were separated by about 0.5 cm. When in operation, 20,000 volts (60 cycles) were applied across the gap (one electrical contact was made to a salt solution in the inner "finger"; the other contact was made to aluminum foil wrapped around the outer cylinder). The results of two static experiments with AsH_3 are given in Table III.

TABLE III

S.E.D. DECOMPOSITION OF AsH_3 TO $AsH_x + (3/2 - x/2)H_2$

Voltage	Time (min.)	Initial mmoles AsH_3	Mmoles AsH_3 dec.	Moles H_2 formed per mole AsH_3 dec.	x (calcd.)
20,000	11	0.254	0.253	1.400	0.20
20,000	10	.696	.279	1.385	.23

In the first experiment, the discharge tube was flamed after pumping out the hydrogen and unreacted arsine in an attempt to decompose the residual brown solid hydride. Only 0.0050 mmole of H_2 and 0.0035 mmole of AsH_3 were obtained (corresponding to 0.010 mmole of H_2 total). One calculates that 0.016 mmole of H_2 were combined in the solid hydride; the deficiency was probably caused by incomplete thermal decomposition. (The peculiar shape of the discharge tube prevented efficient flaming.)

D. Disproportionation of "Biarsine."—The experiments may be divided in two classes: (1) those in which arsine was pumped through the discharge tube at low pressure (<1 mm.), and (2) those in which the arsine was carried through the discharge tube by a large excess of hydrogen gas (*ca.* 1 atm.). The former experiments were characterized by the formation of brown solid deposits in the tubing leading from the discharge tube. This phenomenon was probably caused by the glow discharge, which extended beyond the discharge tube itself. In the latter experiments, the brown deposit was limited to the interior of the discharge tube. In general, both methods involved the decomposition of about 5% of the arsine.

The gases leaving the discharge tube were usually first passed through a −120° trap and then through a −196° trap. After complete passage of the arsine through the discharge, the system was pumped down to about 10 μ pressure. The −120° trap was then closed off and *slowly* warmed to room temperature, thereby decomposing the "biarsine."

The trap was then evacuated. The red-brown solid residue was gently heated with a flame until it was black and the evolved arsine and hydrogen were measured. The remaining arsenic metal was dissolved in warm nitric acid and the solution was analyzed for arsenic by the molybdenum-blue colorimetric method.[3] For every 100 cc. of arsine passed through the discharge with one atmosphere of hydrogen, about 0.01 mmole of arsenic was obtained in the form of the solid hydride in the first trap (0.014 mmole in the low pressure experiments).

In Table IV, the results of five experiments are summarized.

TABLE IV

ANALYSIS OF SOLID DECOMPOSITION PRODUCT OF "BIARSINE"

Mmoles H_2 evolved during thermal decn.	Mmoles AsH_3 evolved during thermal decn.	Mmoles As remaining after thermal decn.	Calcd. empirical formula
0.0024	0.00261	0.0270	$AsH_{0.43}$
.00294	.00357	.0244	$AsH_{0.49}$
.0140	.0162	.119	$AsH_{0.57}$
.00157	.00367	.0210	$AsH_{0.37}$
.00354	.00327	.0356	$AsH_{0.43}$

In several qualitative experiments, the material in the −120° trap was not allowed to decompose completely, but was distilled to various places in the vacuum line. It was noted that, after distilling the material from a glass receptacle, a film of yellow solid remained which, when warmed to room temperature, turned red-brown. The material seemed to be relatively stable in the gaseous state, even at room temperature.

IV. Conclusions

The experimental data indicate that whenever one attempts to form elementary arsenic in the presence of arsine, the solid product contains not only arsenic, but also varying amounts of firmly held hydrogen. If we conclude that the presence of arsine is essential to the formation of these solid arsenic hydrides, then it is explained why a weak reducing agent like stannous chloride will only reduce As(III) to elementary arsenic. (Stannous chloride is thermodynamically incapable of reducing As(III) to arsine.)

It is very unlikely that the hydrogen of these solid hydrides exists as molecular hydrogen or arsine adsorbed on arsenic. Perhaps the solid hy-

(15) For detailed experimental data, the reader is referred to University of California Radiation Laboratory Report UCRL-4707, "Solid Arsenic Hydrides," June 7, 1956. The data on the preparation of arsine, the chemical reduction of As(III) solutions, the oxidation of arsine, the ammonolysis of sodium arsenide and the adsorption studies are presented in that report.

drides prepared by certain methods consist of hydrogen and arsine occluded in cracks and holes in arsenic particles, but it is difficult to explain the very hydrogen-rich solids of composition $AsH_{0.5}$ in this manner. When macro amounts of these latter hydrides are available, various physical-chemical studies may elucidate their structure.

The Reaction of Silylamines with Boron Trifluoride. Methyl- and Silylaminoboron Difluorides

BY SEI SUJISHI AND SAMUEL WITZ

RECEIVED DECEMBER 17, 1956

N-Silyldimethylamine, N-methyldisilylamine and trisilylamine react with boron trifluoride to yield dimethylaminoboron difluoride, N-methylsilylaminoboron difluoride and disilylaminoboron difluoride, respectively, and silyl fluoride. The variation in the physical properties of the aminoboron difluorides is discussed. Silylaminoboron difluorides decompose to form borazole derivatives and silyl fluoride. New vapor pressure data for silyl fluoride and N,N′,N″-trimethyl-B,B′,B″-trifluoroborazole were obtained.

With trimethylboron as the reference acid, the base strengths of silylamines show the following order: $(CH_3)_3N > (SiH_3)(CH_3)_2N > (CH_3)(SiH_3)_2N \sim (SiH_3)_3N$.[1] Neither methyldisilylamine nor trisilylamine forms an addition compound with trimethylboron and, therefore, their relative base strengths are not known.

With the object of completing this order, the reactions of the silylamines with boron trifluoride were investigated. Boron trifluoride appeared to be a suitable reference acid since Burg and Kuljian had reported that trisilylamine–boron trifluoride forms reversibly in the range −78 to −40° with a solid–gas equilibrium pressure of 3.7 mm. at −55°.[2] Although we found evidence for the formation of amine–boron trifluoride addition compounds, we could not measure the equilibrium pressures. This difficulty arose because secondary reactions, which yield aminoboron difluorides and silyl fluoride, occurred too rapidly. The nature of this secondary reaction is similar to that reported for the silylamine–boron trichloride system[2] and is the subject of the present paper.

Results and Discussion

Reaction of Silylamines with Boron Trifluoride.—Silyldimethylamine, methyldisilylamine and trisilylamine all absorbed an equimolar quantity of boron trifluoride at −80° to form white solids. Silyl fluoride was liberated slowly and at −80° less than an equivalent of it was formed in 16 hours.

When the amine–boron trifluoride mixtures were warmed to 25° about an equivalent of silyl fluoride was obtained. The formation of silyl fluoride was rapid in the methyldisilylamine and silyldimethylamine systems but was slow in the trisilylamine system. In the trisilylamine–boron trifluoride system, the total pressure indicated that trisilylamine–boron trifluoride was completely dissociated at partial pressures of 27 mm. of the components. After several days, however, almost an equivalent of silyl fluoride was obtained.

Along with silyl fluoride, substituted aminoboron difluorides were obtained. Dimethylaminoboron difluoride,[3] N-methylsilylaminoboron difluoride and disilylaminoboron difluoride were isolated from the silyldimethylamine, methyldisilylamine and trisilylamine systems, respectively. The silylaminoboron difluorides have not previously been reported in the literature.

The results suggest that the reactions of the silylamines with boron trifluoride proceed in two steps: (1) absorption of boron trifluoride to form an addition compound and (2) the elimination of silyl fluoride from the addition compound to form aminoboron difluoride.

$$(SiH_3)_2N: + BF_3 = (SiH_3)_3N:BF_3 \qquad (1)$$

$$(SiH_3)_3N:BF_3 = SiH_3F + (SiH_3)_2N{=}BF_2 \qquad (2)$$

The heats of formation of the addition compounds in the gas phase, from the amine and boron trifluoride, can be estimated and correlated with the results. According to Brown and Johannesen, the heat of formation of trimethylamine-boron trifluoride is −28 kcal./mole.[4] We have suggested that the substitution of a silyl group for a methyl group increases the heat of formation by about 9 kcal. for each successive substitution.[1] Hence, the approximate heat of formation of silyldimethylamine–boron trifluoride is −19 kcal., for methyldisilylamine–boron trifluoride −10 kcal., and for trisilylamine–boron trifluoride −1 kcal.

The last value is compatible with the observed gas phase non-association in the trisilylamine–boron trifluoride system.[5] The rapid formation of silyl fluoride in the methyldisilylamine–boron trifluoride and silyldimethylamine–boron trifluoride systems at 25° is compatible with heats of for-

(4) H. C. Brown and R. B. Johannesen, *ibid.*, **75**, 16 (1953).

(5) The value of −1 kcal. for the heat of formation of trisilylamine–boron trifluoride appears on first consideration to be too small to account for the formation of the solid adduct at −80°. However, A. B. Burg and Sr. A. A. Green (*ibid.*, **65**, 1838 (1943)) report that trimethylamine–boron trifluoride molecules form associated aggregates even in the gas phase. In the solid state, therefore, strong dipole forces between the addition compound molecules could stabilize the adduct.

mation of the addition compounds. Steps 1[6] and 2 both occur rapidly in these systems. The elimination of silyl fluoride may be comparably rapid from trisilylamine–boron trifluoride, but because of the low concentration of the addition compound the over-all rate is slow.

We conclude that, with boron trifluoride as the reference acid, methyldisilylamine is a stronger base than trisilylamine.

Aminoboron Difluorides.—The volatility of the substituted aminoboron difluorides increases in a striking manner with successive replacement of methyl groups by silyl groups. Thus, at 0° the vapor pressures are 0.2 mm. for solid dimethylaminoboron difluoride, 23 mm. for solid methylsilylaminoboron difluoride and 230 mm. for liquid disilylaminoboron difluoride. The high vapor pressure of disilylaminoboron difluoride is especially noteworthy. It is greater than that of either trisilylamine (110 mm.) or of methyldisilylamine (193 mm.) at 0°.[1]

The heats of vaporization and the melting points of dimethylaminoboron difluoride (19.1 kcal. and 160–164°) and disilylaminoboron difluoride (7.2 kcal. and $< -120°$) also show marked difference. Unfortunately corresponding values could not be determined for methylsilylaminoboron difluoride because of its instability toward decomposition. However, it was noted that methylsilylaminoboron difluoride was a solid at 25°.

The physical properties suggest that in the condensed state, dimethylaminoboron difluoride molecules are associated by strong intermolecular forces, while disilylaminoboron difluoride molecules are unassociated and held together by ordinary van der Waals forces. The interaction between methylsilylaminoboron difluoride molecules appears to be intermediate between these two extremes.

Previous workers have not agreed on the state of aggregation of dimethylaminoboron difluoride in the solid. Brown[3a] has assumed that dimethylaminoboron difluoride is dimeric while Burg and Banus[3b] have assumed that it is monomeric. Both of these conclusions were extrapolated from vapor density results. Brown's data were obtained at 155° and 747 mm. while Burg and Banus do not state the conditions of their experiments. Our data show that at low pressures (35 mm. at 96°), monomers are the chief species in the gas phase, while at moderate pressures (141 mm. at 136°) dimers occur to the extent of about 30%.

Convincing evidence for the association of dimethylaminoboron difluoride in the solid may be obtained by examination of the properties of aminoboron dichlorides. There is very little difference in the physical properties of monomeric dimethylaminoboron dichloride (m.p. −43°, v.p. 26 mm. at 25°)[7] and disilylaminoboron dichloride (m.p. $< -78°$, v.p. 22 mm. at 25°).[2] In contrast, dimeric dimethylaminoboron dichloride is much less volatile (v.p. 1 mm. at 90°)[7] and higher melting (m.p. 142°).[7] On the basis of these facts, it would be expected that the properties of monomeric dimethylaminoboron difluoride and disilylaminoboron difluoride should be similar. The enormous difference actually observed, therefore, indicates that dimethylaminoboron difluoride is associated in the solid state.

Wiberg and Schuster[8] and Brown and Osthoff[7] have suggested that the dimerization of dimethylaminoboron dichloride occurs through nitrogen–boron coördinate bond formation. We assume that the association of dimethylaminoboron difluoride also occurs through nitrogen–boron coördinate bonds. Without specifying the nature of the molecular unit in the solid, but assuming only that all possible coördinate bonds are formed, as for example in cyclic polymers or linear polymers, it is possible to estimate the heat of dissociation of such bonds between dimethylaminoboron difluoride molecules. The estimation is made in the same way as the value for the proposed nitrogen–silicon coördinate bond in silyldimethylamine was obtained.[1] For dimethylaminoboron difluoride, the heat of dissociation thus obtained is 10.5 kcal./mole of nitrogen–boron bond.

The estimated value of 10.5 kcal. for dimethylaminoboron difluoride can now be used to explain the variation in the physical properties of the silylaminoboron difluorides. In methylsilylaminoboron difluoride, the silyl group stabilizes the monomer by 9 kcal./mole and the nitrogen–boron coördinate bond energy decreases to 1.5 kcal. Similarly in disilylaminoboron difluoride, the two silyl groups reduce the heat of dissociation to −7.5 kcal. and, hence, disilylaminoboron difluoride shows no association.

Decomposition of Aminoboron Difluorides.—The silylaminoboron difluorides decomposed to form borazole derivatives and silyl fluoride. This reaction is similar to the decomposition of silylaminoboron dichlorides.[2] Thus, methylsilylaminoboron difluoride yielded N,N′,N″-trimethyl-B,B′,B″-trifluoroborazole, a compound previously reported by Wiberg and Horeld,[9] and disilylaminoboron difluoride yielded N,N′,N″-trisilyl-B,B′,B″-trifluoroborazole. The quantity of the last compound was too small to characterize the compound.

The rate of formation of silyl fluoride was rapid from methylsilylaminoboron difluoride and slow from disilylaminoboron difluoride. Burg and Kuljian[2] found that methylsilylaminoboron dichloride decomposed more rapidly than disilylaminoboron dichloride. These differences in rate may be rationalized by the mechanism suggested below.

Mechanism of Elimination of Silyl Fluoride.—When silylamines form addition compounds with boron trifluoride, the electron density on the fluorine atom should be relatively large and the electron density on the silicon atom relatively small. The fluorine atoms have three pairs of unshared electrons and, hence, may form coördinate bonds in the transition state with the silicon atom, using its 3d orbitals,[10] either in the same molecule or in a different molecule. The elimination of silyl fluoride is facilitated in this

(6) The rate of formation of trimethylamine–boron trifluoride has been found to be very rapid with only a small activation energy; G. B. Kistiakowsky and R. Williams, *J. Chem. Phys.*, **23**, 334 (1955).

[a] Methylsilylaminoboron difluoride was purified by distillation through a trap at −80° and condensation in a trap at −126°.

way. As indicated earlier the rate-determining step in the over-all reaction, of silylamines with boron trifluoride, is the formation of the addition compound.

The decomposition of silylaminoboron difluorides may be interpreted similarly. Silyl fluoride is eliminated from the dimer. This is followed by the association of the resultant boron–nitrogen derivative with another mole of silylaminoboron difluoride and the elimination of silyl fluoride from the adduct. The rate-determining step is the formation of the dimer. Since silylmethylaminoboron difluoride dimerizes more readily than disilylaminoboron difluoride, the rate of elimination of silyl fluoride from the former is greater than from the latter.

Experimental Part

A Stock type high vacuum line was employed. The silylamines were prepared and purified by methods described previously.[1] Boron trifluoride (Matheson Co., Inc.) was purified in the vacuum line and a tensiometrically homogeneous sample (v.p. obsvd. 300 mm. at −111.8°, lit.[11] 300 mm.) obtained.

The various products of the reactions were separated and purified by fractional distillation and condensation. Silyl fluoride, which was obtained in all of the reactions, was isolated by distillation at either −126 or −117°. The pertinent data for the separation of the other compounds are summarized in Table I.

Silyl fluoride was purified by the method described in the section on the vapor pressure of silyl fluoride. When the presence of boron trifluoride was suspected, the silyl fluoride fraction was treated with a measured quantity of ethyl ether. The ethyl ether combined with the boron trifluoride to form ethyl ether–boron trifluoride. The silyl fluoride, ethyl ether and ethyl ether–boron trifluoride were separated by distillation and the quantity of boron trifluoride originally present was calculated from the results of the separation. This method will be referred to as the ethyl ether test for boron trifluoride.

All quantities expressed in cc. are those for the gas at S.T.P. These volumes are accurate to ±0.2 cc.

Silyldimethylamine–Boron Trifluoride System.—Silyldimethylamine, 10.6 cc., and 10.6 cc. of boron trifluoride were combined and kept at −80°. A white solid was observed and the pressure remained constant at 98 mm. (6 cc.) for 15 hours. The pressure did not change significantly as the temperature was raised. Thus, at −55° it was 97 mm. and at −30° it was 109 mm. The mixture was warmed to 22°. The pressure rose to 198 mm. (11.9 cc.) and a white crystalline solid was observed.

The mixture was fractionated and 11.0 cc. of crude silyl fluoride and an unmeasured quantity of dimethylaminoboron difluoride were obtained. The crude silyl fluoride was found to contain 0.3 cc. of silane, 6.0 cc. of boron trifluoride (ethyl ether test), 1.3 cc. of pure silyl fluoride (v.p. 29 mm. at −126°) and 3.4 cc. of a mixture of silyl fluoride and polyfluorosilane (v.p. 23 mm. at −126.3°).

Dimethylaminoboron Difluoride.—The dimethylaminoboron difluoride was identified by its v.p. (obsd. 4.2 mm. at 55° and 20.0 mm. at 70° lit.[3b] 3.8 and 19.1 mm., respectively) and its m.p. (obsd. 146–149°, 160–165°, 164–165°, lit. 155° (Burg)[3b] and 167–169° (Brown)[3a]). The heat of sublimation may be calculated to be about 19 kcal./mole of monomer gas.

In a similar expt., 24.4 cc. of boron trifluoride and 24.4 cc. of silyldimethylamine reacted at 25° in 5 minutes to yield 0.9 cc. of silane, 23.3 cc. of silyl fluoride, 0.3 cc. of polyfluorosilane, and dimethylaminoboron difluoride. The dimethylaminoboron difluoride was tensiometrically homogeneous with a v.p. of 8.3 mm. at 65.1°. The vol. of the gas was 20.8 cc. at 136° and 141 mm. and 21.3 cc. at 161° and 154 mm. Using the initial quantities of boron trifluoride and silyldimethylamine as the base, it may be calculated that the dimethylaminoboron difluoride was about 30% dimerized.

Methyldisilylamine–Boron Trifluoride System.—Methyldisilylamine, 17.8 cc., and 17.8 cc. of boron trifluoride were kept at −80°. The pressure slowly rose to 32 mm. in 2 hours and to 49 mm. (10 cc.) in 16 hours. A white solid was observed. The mixture was distilled at −126° and 10.1 cc. of distillate which contained 0.3 cc. of silane, 9.7 cc. of silyl fluoride and 0.1 cc. of polyfluorosilane was obtained. All of the fractions were recombined and the mixture warmed to 27°. After 10 min., the pressure became constant at 174 mm. (35.2 cc.). A very small quantity of white solid failed to vaporize. After 45 min. at 27°, the mixture was fractionated. Silane, 0.2 cc., silyl fluoride, 23.8 cc., polyfluorosilane, 0.5 cc., and crude methylsilylaminoboron difluoride, 10.9 cc., were obtained.

Methylsilylaminoboron Difluoride.—The crude methylsilylaminoboron difluoride was purified by distillation at −80°. In 15 minutes, 1.7 cc. of distillate was obtained and in the next ½ hour no further quantity of volatile fraction was obtained. The residue, 7.8 cc., was pure methylsilylaminoboron difluoride. It was a white solid at 0° and was tensiometrically homogeneous with a v.p. of 23.0 mm. The mol. wt. by vapor density measurement at 27° and 106 mm., was 108 (calcd. for $(CH_3)(SiH_3)NBF_2$ 109.0).

Methylsilylaminoboron difluoride decomposed slowly even at 0°. All of the material present in the crude methylsilylaminoboron difluoride fraction were combined and the mixture allowed to stand at 27°. After 20 hours, white crystals were observed and by fractionation, 4.1 cc. of silyl fluoride was isolated. After 5 days a total of 10.7 cc. of silyl fluoride, 0.2 cc. of methylsilylaminoboron difluoride and 3.2 cc. of crude N,N′,N″-trimethyl-B,B′,B″-trifluoroborazole were obtained.

N,N′,N″-Trimethyl-B,B′,B″-trifluoroborazole.—The crude trimethyltrifluoroborazole, 3.2 cc., was purified by distillation at −23°. A tensiometrically homogeneous sample (v.p. 0.25 mm. at 0°) was obtained. The v.p. were measured at various temperatures. The results may be expressed by the equation $\log P_{mm} = -3165.2/T°_K + 10.8256$. The results are summarized in Table II. The

TABLE II

VAPOR PRESSURE OF $(CH_3NBF)_3$

T, °C.	0.0	25.1	34.8	44.6	54.7

mol. wt., by vapor density measurement at 64° and 15.6 mm., was 176 (calcd. for $(CH_3NBF)_3$, 176.6). The heat of vaporization is calculated to be 14.5 kcal. The m.p. in an evacuated and sealed capillary tube was 88–89° (lit. 85°).[12]

In a duplicate experiment, 12.5 cc. of methyldisilylamine and 12.5 cc. of boron trifluoride reacted to yield as the final products 22.8 cc. of silyl fluoride, 1.8 cc. of silylmethylaminoboron difluoride and 3.4 cc. of trimethyltrifluoroborazole.

(11) E. Pohland and W. Harlos, *Z. anorg. allgem. Chem.*, **207**, 242 (1932).

(12) The physical constants reported for N,N′,N″-trimethyl-B,B′,B″-trifluoroborazole (ref. 9) are m.p. 85°, v.p. 6 mm. at 69° and 320 mm. at 186°. Although the m.p. observed by us is in fair agreement with the value reported, the v.p. show very poor agreement.

Trisilylamine–Boron Trifluoride System.—Boron trifluoride, 14.4 cc., and trisilylamine, 14.4 cc., were combined and kept at −80°. After 0.6 hour the pressure reached a minimum value of 22 mm. and a white solid formed. The pressure slowly increased and in 1.6 hours was 26 mm. (5 cc.). The mixture was distilled at −126° and 5.9 cc. of silyl fluoride was obtained (v.p. at −123.2°, obsd. 42.5 mm., SiH_3F 43.1 mm.). The absence of boron trifluoride was confirmed by the ethyl ether test.

The residue was a solid at −80° and exerted a pressure of 1.9 mm. This was examined for homogeneity by distilling small quantities away at −80° and measuring the pressure over the solid after each distillation at −53.7°. The pressure varied from 12.8 to 2.2 mm. and, hence, the solid was not homogeneous. All of the fractions were combined and the total gas volume was measured. At 27° and 113.5 mm. the volume was 22.8 cc. (This value combined with the volume of silyl fluoride recovered initially, 5.9 cc., yields a total of 28.7 cc. The sum indicates that there was no net change in the number of moles of gas in the system. As it will be shown below, silyl fluoride is produced by reaction 2. Since all of the components of reaction 1 are volatile at 27°, the fact that only a portion of the silyl fluoride expected for complete reaction was obtained shows that trisilylamine and boron trifluoride must coexist as gases without association. The partial pressure of the components may be calculated to be 27 mm.)

The mixture, 22.8 cc., was kept at 27° and periodically analyzed for silyl fluoride. The additional quantity of silyl fluoride obtained was 4.5 cc. after one hour and 7.2 cc. after 5 days. (The total quantity of silyl fluoride obtained thus far was 13.1 cc. or 0.93 equivalent of the starting components.)

Heating the residue after the separation of silyl fluoride did not appreciably effect the rate of formation of silyl fluoride. Thus, 4 hours at 55° gave 0.8 cc., 24 hours at 75° gave 2.2 cc., 24 hours at 85° gave 0.1 cc. and 18 hours, at 115° gave 0.5 cc. of silyl fluoride, respectively.

A total of 16.7 cc. of silyl fluoride and 12.5 cc. of other products was obtained. The 12.5-cc. fraction was separated into 11.9 cc. of disilylaminoboron difluoride and 0.6 cc. of borazole derivative.

Disilylaminoboron Difluoride.—The 11.9-cc. fraction was identified as disilylaminoboron difluoride by vapor density measurement. The mol. wt. was 124 at 23° and 144 mm. (calcd. for $(SiH_3)_2NBF_2$, 125.0). The vapor pressures of the compound, a liquid down to −120°, were measured. The results can be represented by the equation $\log P_{mm} = -1563/T°_K + 8.102$ and are given in Table III. The heat of vaporization is 7.2 kcal.

TABLE III

VAPOR PRESSURE OF $(SiH_3)_2NBF_2$ (LIQUID)

T, °C.	−52.5	−49.3	−30.9	−23.4
P_{mm}, obsd.	11.1	13.2	45.8	69.9
P_{mm}, calcd.	10.5	13.2	44.8	70.0

Disilylaminoboron difluoride decomposed very slowly when it was stored as a gas at room temperature. One of the products of the decomposition was silyl fluoride. The other product was undoubtedly N,N′,N″-trisilyl-B,B′,B″-trifluoroborazole, although the quantity obtained was too small to permit positive identification. The decomposition reaction may be written as

$$3(SiH_3)_2NBF_2 = 3SiH_3F + (SiH_3NBF)_3 \quad (3)$$

The quantities of products isolated may be accounted for by equations 2 and 3. Thus, assuming that reaction 2 proceeded to completion, the quantity of disilylaminoboron difluoride which decomposed according to equation 3 should be 14.4 − 11.9 = 2.5 cc. The total quantity of silyl fluoride recovered then should be 14.4 + 2.5 = 16.9 cc. (obsd., 16.7 cc.) and that of the borazole derivative 0.8 cc. (obsd., 0.5 cc. in the trap at −80°).

In a duplicate expt., 13.6 cc. of trisilylamine and 13.6 cc. of boron trifluoride reacted to yield 18.0 cc. of silyl fluoride, 9.8 cc. of disilylaminoboron difluoride and a small quantity of the borazole derivative (v.p. 2.5 mm. at 24°). The borazole derivative was hydrolyzed with aqueous ammonium hydroxide and 10.8 cc. of hydrogen was obtained. Using the quantity of disilylaminoboron difluoride isolated as the base, it may be calculated that 17.4 cc. of silyl fluoride (obsd., 18.0 cc.) and 1.27 cc. of the trisilyltrifluoroborazole should have been obtained. The last compound on hydrolysis should yield 11.4 cc. of hydrogen (obsd., 10.8 cc.).

Disilylaminoboron Difluoride–Boron Trifluoride System.—Disilylaminoboron difluoride did not react with boron trifluoride at moderate pressure at either 26 or −80°. Thus, when 9.8 cc. of disilylaminoboron difluoride and 9.8 cc. of boron trifluoride were combined at 26° the total pressure remained constant at 169 mm. (19.6 cc.) for 18 hours. By fractional condensation, 9.2 cc. of boron trifluoride was isolated from the mixture.

Similarly, when 9.8 cc. of disilylaminoboron difluoride and 9.5 cc. of boron trifluoride were kept at −80°, the total pressure of 48 mm. (9.8 cc.) indicated that the boron trifluoride was not soluble in liquid disilylaminoboron difluoride. After three days at −80°, 9.8 cc. of boron trifluoride was isolated from the mixture.

Disilylaminoboron difluoride and boron trifluoride did react, however, at −80° when the partial pressure of boron trifluoride was high. Disilylaminoboron difluoride, 9.8 cc., and 64.4 cc. of boron trifluoride were sealed in an ampoule of 6-cc. volume and kept at −80° for five days. (The v.p. of boron trifluoride is roughly 4.5 atm. at this temp.) After the first day white crystals and a colorless liquid phase were observed. On distillation at room temperature 73.2 cc. of gas was recovered from the ampoule. A small quantity of grayish white residue was left in the ampoule. Fractionation yielded 0.5 cc. of unidentified product (volatile at 25°, non-volatile at −80°), 3.4 cc. of disilylaminoboron difluoride (v.p. obsd. 15.5 mm. at −45.4°, calcd. 17 mm.), 57.4 cc. of boron trifluoride (ethyl ether test), 1.5 cc. of silane, 7.5 cc. of silyl fluoride (v.p. obsd., 28.9 mm. at −127.5°, calcd. 28 mm.), and 1.6 cc. of polyfluorosilane (v.p. obsd., 15 mm. at −127.2°).

The results of the experiment indicate that 7.0 cc. of boron trifluoride reacted with 6.4 cc. of disilylaminoboron difluoride to yield 7.5 cc. of silyl fluoride, and 3.1 cc. of silane and polyfluorosilane and other products.

Vapor Pressure of Silyl Fluoride.—The vapor pressures of silyl fluoride obtained in the present work differed considerably from those reported by Emeleus and Maddock.[13] Emeleus and Maddock obtained silyl fluoride from the reaction of silyl chloride with antimony trifluoride and state that the purity of the product did not exceed 98%.

The different fractions of silyl fluoride isolated from the experiments were combined and purified by distillation through a series of traps kept at −126, −160 and −196°. The major portion of the silyl fluoride condensed in the −160° trap along with some less volatile material. The silyl fluoride was recovered from this by slow distillation at −160°. A tensiometrically homogeneous sample was thus obtained. The purity was further established by mol. wt. determination and by hydrolysis. The mol. wt. at 24° and 80.6 mm. was 50.0 (calcd. for SiH_3F, 50.08). Hydrolysis with saturated aqueous sodium hydroxide at 30–40° for 45 min. of 8.84 cc. and 11.57 cc. samples gave 26.5 cc. (calcd., 26.5 cc.) and 34.4 cc. (calcd., 34.7 cc.) of hydrogen, respectively.

The vapor pressures of the liquid were measured and the results can be expressed by the equation $\log P_{mm} = -984.86/T°_K + 8.2001$. The results are summarized in Table IV. The extpd. b.p. is −88.1° and the heat of vaporization is 4.5 kcal./mole. Emeleus and Maddock reported −98.6° and 4.5 kcal., respectively, for these two values.[13]

Inorganic Chemistry in Trifluoroacetic Acid[1]

BY GEORGE S. FUJIOKA AND GEORGE H. CADY

RECEIVED OCTOBER 30, 1956

In the investigation of inorganic reactions in anhydrous trifluoroacetic acid, the effects of anhydrous HCl, H_2S, $HClO_4$, H_2SO_4, SO_3, H_3PO_4, HPO_3, Cl_2, CrO_3, $KMnO_4$ and SO_2 upon 25 dissolved trifluoroacetates of metals were studied. The reactions obtained from H_2S closely paralleled those obtained in acidic aqueous systems. More chlorides, perchlorates and bisulfates were precipitated from trifluoroacetic acid than from water. The reactions with H_2SO_4 were in most cases rapid and complete. By contrast, the reactions with SO_3 were slow and only partially complete. Orthophosphoric acid produced precipitates slowly. Many of these precipitates were in the form of gels, suggesting polymer formation. The reagents CrO_3, Cl_2 and $KMnO_4$ acted as oxidizing agents, but more slowly than in water. Hydrogen peroxide decomposed in the presence of dissolved trifluoroacetates of metals to form water and oxygen. It also reduced Mn(VII) to Mn(II), and reacted with CrO_3 forming a blue-green solution of a peroxy–chromium compound. The slow reaction of $KMnO_4$ with trifluoroacetic acid produced the gases: CO_2, CF_3COF and COF_2, while Mn(VII) was reduced to Mn(III).

Trifluoroacetic acid is a good solvent for a wide variety of organic compounds, both aliphatic and aromatic.[2,3] Inorganic compounds also dissolve in trifluoroacetic acid[4] but in general to a lesser degree than in water. The solubility of inorganic salts in trifluoroacetic acid must be considered high, particularly when the low dielectric constant, 8.22 at 30°,[5] is taken into account. The low electrical conductivities[6] of salts when dissolved in trifluoroacetic acid illustrate that the acid is not a good ionizing solvent. Ionic type reactions do occur, however, and this study deals largely with such reactions.

Experimental

(I) Reactions Occurring in the Solvent Trifluoroacetic Acid.—The solvent, trifluoroacetic acid, as supplied by the manufacturer (Minnesota Mining and Manufacturing Co.) was used without further purification. The metal trifluoroacetate solutions were prepared from salts synthesized by Hara and Cady in their solubility studies.[4] Solutions of $AsOCF_3CO_2$ and the trifluoroacetates of NH_4^+, Sb(III), Bi(III), Cr(III), Fe(III), Pb(II), Li, Mn(II) and Hg(I) were prepared by the authors. Either the carbonates or oxides of the metals were caused to react with trifluoroacetic acid containing enough trifluoroacetic anhydride to combine with water formed by the reaction. The trifluoroacetates were then obtained as solids by evaporating away the solvent. With the exception of $AsOCF_3CO_2$ the products were crystalline solids. The arsenic compound formed a clear, colorless gel which took on a milky white appearance after standing for several weeks. When the temperature of the milky solid was raised to a few degrees above that of the room it again became colorless. No definite melting point could be observed. When possible, 0.1 *m* solutions were used. Saturated solutions were employed for substances of lower solubility than 0.1 *m*.

The reactants were either gases or compounds dissolved in trifluoroacetic acid. The gaseous reactants were HCl, H_2S, SO_2, Cl_2 and SO_2. Except for SO_2 the gases were dried by passage through concentrated sulfuric acid or by passage through a trap cooled with a Dry Ice–acetone bath. Sulfur trioxide was carried from a storage bulb to the reaction solution by dry N_2. The reactants which were dissolved in trifluoroacetic acid were reagent grade $HClO_4$, H_2SO_4, H_3PO_4, HPO_3, CrO_3, H_2O_2 and $KMnO_4$.

With H_2SO_4, H_3PO_4 or H_2O_2 an anhydrous solution was prepared by first dissolving an aqueous solution of known concentration in trifluoroacetic acid. A calculated amount of trifluoroacetic anhydride was then added to just react with the water present. A slight excess of trifluoroacetic anhydride was added to all solutions to maintain the anhydrous state. No anhydride was added to the perchloric acid solution. The anhydride was added, however, to the reaction mixtures either just before the addition of the perchloric acid solution or just after. The order of addition produced no observed effect upon the final results.

Table I lists the concentrations of the stock solutions of trifluoroacetates used for these studies. Table II lists the concentrations of solutions of the reactants. In the cases of HCl, H_2S, Cl_2 and SO_2 the concentrations were those reached by saturating trifluoroacetic acid with the gases at 26° under a total pressure of one atmosphere.

TABLE I

CONCENTRATIONS OF TRIFLUOROACETATES

Solute[a]	Molal concn. (mole/1000 g.)	Solute	Molal concn. (mole/1000 g.)
NH_4[a]	0.1	Mg	0.1
As(III)[a]	.015	Mn(II)	.025
Sb(III)	.015	Hg(II)	.1
Ba	.1	Hg(I)	.1
Bi(III)	.04	Ni(II)	.1
Cd	.1	K	.1
Ca	.09	Ag(I)	.1
Cr(III)	.06	Na	.1
Co(II)	.1	Sr	.1
Cu(II)	.1	Sn(IV)[a]	.1
Fe(III)	.03	Sn(II)	.06
Pb(II)	.1	Zn	.03
Li	.1		

[a] All the solutes are trifluoroacetates except As(III) and Sn(IV) which are $AsOCF_3CO_2$ and $SnCl_4$.

TABLE II

APPROXIMATE CONCENTRATION OF REACTANTS IN TRIFLUOROACETIC ACID

Reactants	Molal concn.	Reactants	Molal concn.
HCl	0.1	HPO_3	0.5
H_2S	0.2	Cl_2	.2
$HClO_4$	2	CrO_3	.008
H_2SO_4	15	H_2O_2	1.3
SO_3	?	$KMnO_4$	0.04
H_3PO_4	0.3	SO_2	0.6

The reactions were carried out at 25 to 26° in 10 × 75 mm. test-tubes using in each case between 0.5 to 1.5 ml. of a solution of a metal trifluoroacetate. The reactant solutions were added to the trifluoroacetate solutions dropwise until about a two-fold excess was present or until further addition ceased to yield an observable reaction. Gaseous reactants were bubbled through the trifluoroacetate solution until all observable reaction ceased. The reactions were carried out with solutions of trifluoroacetic anhydride

(*ca.* 0.05 g.) added to the reaction vessel to ensure anhydrous conditions at all times.

Precipitates formed by the reactions were concentrated by centrifugation, washed with trifluoroacetic acid by decantation, and dried in an oven at 105°. The remaining solid was analyzed in most cases. The supernatant liquid was evaporated, and the residue, if any, was dissolved in water and qualitatively analyzed for both the anion and cation. A designation of "Complete," "Nearly Complete" or "Partial" was placed on the extent of a particular precipitation reaction depending upon whether the qualitative tests showed the metallic ion in question to be (a) absent, (b) present in trace quantity, (c) present in appreciable amount.

Table III lists the precipitates obtained in the reactions of hydrogen chloride, hydrogen sulfide and perchloric acid and the solutes listed in Table I. It is possible that some of the precipitates may have contained trifluoroacetic acid of solvation.

Many analyses of the precipitates resulting from reactions with anhydrous sulfuric acid indicated the presence of both acid and normal sulfates. It appears unlikely that two sulfate species were precipitated from the reaction mixture. It is more probable that some of the precipitated acid sulfates were partially converted to normal sulfates while being washed with pure trifluoroacetic acid. Table IV lists the solutes that gave a sulfate precipitate. The table also gives the mole percentages of acid and normal sulfate found by analysis.

TABLE III

REACTIONS OF TRIFLUOROACETATES IN TRIFLUOROACETIC ACID

Reactant	Product
HCl	Chloride ppt.:
	Reaction, complete: Cd(II), Cu(II), Pb(II), Hg(II), Hg(I), Ni(II), Zn(II). All the ppt. colors were white except for Ni(II) which was amber
	Reaction, nearly complete: Bi(III), Co(II), Mn(II), Sn(II). The Co(II) ppt. was light blue, but the others were white
	Reaction, partial: Fe(II), olive color
	Colloidal ppt.: Ag(I), white, orange CrO_2 soln. was converted to a red soln. probably CrO_2Cl_2
H_2S	Sulfide ppt.:
	Reaction, complete: Sb(III), Cd(II), Cu(II), Hg(II), Hg(II) and Hg from Hg(I), Ag(I)
	Reaction, nearly complete: Fe(II) soln. and S from Fe(III), Sn(II), Zn(II)
	Reaction, partial: Bi(III)
	Colloidal ppt.: As(III), orange CrO_3 soln. was converted to a green soln. of Cr(III) and H_2SO_4
	The colors of the sulfides were the same as the colors obtained from pptn. from aqueous media
$HClO_4$	Perchlorate ppt.:
	Reaction, complete: K(I)
	Reaction, nearly complete: NH_4^+, Cd(II), Hg(I), Ag(I), Na(I), Sr(II), Sn(II), Zn(II)
	Reaction, partial: Sb(III), Ba(II), Bi(III), Cr(III), Co(II), Cu(II), Fe(III), Pb(II), Mg(II), Mn(II), Hg(II), Ni(II)
	Colloidal ppt.: As(III) (solid not identified)
	Cobalt perchlorate was pink, copper perchlorate was light blue, nickel perchlorate was light green. All the other perchlorates were white

Sulfur trioxide precipitated most of the metals which reacted with dissolved sulfuric acid. A few sulfates were precipitated which were not brought down by sulfuric acid. Sulfur trioxide is very soluble in trifluoroacetic acid and is known to react with the acid to produce trifluoroacetic anhydride and sulfuric acid. With a high concentration of SO_3 some of the sulfuric acid may be converted to pyrosulfuric acid. Some of the precipitates were normal sulfates. Others were either acid sulfates or pyrosulfates or mixtures. As a sample was dried in the oven before analysis it had a chance to absorb water which would convert a pyrosulfate to an acid sulfate. On this account the analyses did not clearly characterize all of the precipitates. On the basis of the metal to sulfate ratio and on this alone the compositions of the precipitates are given in Table V in terms of the % of normal sulfate and the % of pyrosulfate. Table V lists: (1) the trifluoroacetates that gave precipitates with SO_3, (2) the weight per cent. of the cation and of the sulfate ion found in the precipitate, (3) the molar ratio of the cation to the sulfate, (4) the possible formula or formulas that could fit this molar ratio (assuming pyrosulfate and not acid sulfates to be present).

Table VI lists the reactions obtained with orthophosphoric acid and Table VII gives the reactions obtained with metaphosphoric acid. The high phosphate content of many of the precipitates suggests that in those cases polyphosphates were formed. The precipitates produced by orthophosphoric acid were generally slow in forming and often they were in the form of gels. The precipitate obtained from stannic chloride and orthophosphoric acid formed a foam and expanded to about 50 times its original volume when it was dried at 105°.

[a] Based on analysis of the precipitate after washing in trifluoroacetic acid and drying at 105°.

Chromium trioxide and potassium permanganate failed to precipitate dichromates or permanganates with the dissolved metal trifluoroacetates. They still retained their oxidizing activities but to somewhat lesser degree than in water. In the reactions with potassium permanganate, the manganese was reduced to the +3 state rather than the +4 or +2 state. The reactions of these substances are summarized in Tables VIII and IX. The oxidation reactions of chlorine are listed in Table X.

Besides the oxidation reactions with some trifluoroacetates, potassium permanganate also reacted slowly with the pure anhydrous solvent. After three hours, a solution of the salt had lost about 3% of its oxidizing power. Mass spectrum analyses of the gaseous products showed the presence of CO_2, CF_3COF and COF_2. In these analyses the major constituent found was carbon dioxide. The presence of some silicon tetrafluoride in the product indicated that part of the carbonyl fluoride reacted with the glass container. A solution of potassium permanganate in trifluoroacetic acid had a green color similar to that of a solution of potassium permanganate in concentrated sulfuric acid. The Mn(VII) was present as a volatile substance, probably Mn_2O_7, which distilled under vacuum with the trifluoroacetic acid. To avoid danger from possible explosions only small amounts of potassium permanganate were used.

(II) Solubilities of Gases in Trifluoroacetic Acid.—The concentrations given in Table II for gaseous reactants are those for saturated solutions at 26°. These quantities were

determined by using a gas measuring tube in such a way that the materials were confined over mercury. First, a sample of gas was placed in the tube and measured. Second, a measured sample of trifluoroacetic acid was added from a hypodermic syringe. The apparatus was then shaken mechanically for several hours until repeated measurements of the volume of gas in the tube indicated that the solution had become saturated. By using the measured changes in the volume of gas and by applying a correction for the partial pressure of trifluoroacetic acid vapor, it was possible to calculate the solubility coefficients given in Table XI. The coefficient given is that of Ostwald. It is the volume of gas (ml.) absorbed in unit volume of solvent (1 ml.), the pressure of the gas being that existing over the solution. The pressure given in the table is the difference between atmospheric pressure and the partial pressure of trifluoroacetic acid. To permit a comparison, the table also gives the corresponding solubility coefficients for aqueous solutions of the same gases as found in the literature[8,9] for a temperature of 25°, and partial pressures of 74 to 76 cm.

TABLE XI

SOLUBILITIES OF GASES IN TRIFLUOROACETIC ACID

Gas	Temp., °C.	Partial pressure of gas, cm.	Ml. of gas dissolved in one ml. of solvent In CF_3COOH	In H_2O[8,9]

SO_2	26	66.7	23.4	35.7

Discussion

Although trifluoroacetic acid is not a good ionizing solvent, rapid reactions resembling ionic reactions in water do occur. Many of these changes proceed to completion. The ease with which they occur suggests that the reactants exist as ion pairs. Many precipitation reactions which do not occur in water proceed in trifluoroacetic acid. Generally speaking, precipitation reactions of hydrogen sulfide which take place in acidic aqueous solutions also occur in anhydrous trifluoroacetic acid. An exception to this is the failure of lead sulfide to precipitate in trifluoroacetic acid. A large number of precipitates were obtained in trifluoroacetic acid which are not produced in water. This is especially true for the precipitation of the perchlorates.

The observed high solubilities of gases confirm other studies[2,4] which have indicated the excellence of trifluoroacetic acid as a solvent. Most of the gases tested are considerably more soluble in the acid than in water. The exceptions to this are the hydrogen halides and sulfur dioxide which are highly soluble in water, because they react with the solvent.

Acknowledgment.—A part of this work was done under contract with the Office of Naval Research. The study also received support for one year in the form of a fellowship granted to one of the authors (G. S. F.) by the National Science Foundation.

Inorganic Complex Compounds Containing Polydentate Groups. XII. Cobalt(II) Complexes of Tetraethylenepentamine

BY HANS B. JONASSEN AND FRED W. FREY[1]

RECEIVED OCTOBER 12, 1956

The complexing tendency of tetraethylenepentamine (abbrev. tetren) with the cobalt(II) ion has been determined. The data indicates that all five amino groups of tetren coördinate. The sixth coördinating position can be occupied by H_2O, CH_3OH or the OH^- ion. The complexity constants of $[CotetrenH_2O]^{2+}$ have been determined at 25, 35 and 45°. The complex ion $[CoTetrenOH]^{1+}$ has been shown to oxygenate reversibly with only a slight amount of oxidation.

Introduction

The metal complexes of polyamines containing up to four amino groups have been investigated extensively.[2,3]

The purification of tetraethylenepentamine (abbrev. tetren) the next higher polyamine has only recently been accomplished.[4]

The present study was undertaken to investigate the type of complexes formed between the cobalt(II) ion and tetren.

Experimental

A. Materials.—The tetren was obtained from the Carbide and Carbon Corporation and purified as described previously.[4] All other chemicals were C.P. materials.

B. Instruments.—The *p*H measurements were made with a Model G *p*H meter standardized with Beckman buffer solutions of *p*H 4, 7 and 10. The solutions were measured in constant temperature baths at 25 ± 0.2°, 35 ± 0.2°, and 45 ± 0.2°. The spectrophotometric measurements were made on a Beckman Model B spectrophotometer with matched Corex cells. The conductometric titrations were performed as described earlier.[5]

C. Determination of Log *K* Values of $[CotetrenH_2O](ClO_4)_2$.—The complexity constants of the cobalt tetren complex were determined by the method of Bjerrum[6] at 25,

35 and 45°; 100 ml. of a solution 0.001 *M* in tetren 0.5 *M* in HNO_3 and 0.0005 *M* in $Co(ClO_4)_2$ were titrated with 0.01 *M* NaOH. The values of log *K* are 15.07 at 25°, 14.97 at 35° and 14.87 at 45°.

D. **Conductometric Titrations. 1. Titration of Tetren with $CoCl_2$.**—In the titration of 2 ml. of 0.2134 *M* tetren in acetone with 0.051 *M* $CoCl_2$ in acetone breaks occur at mole ratios of about 0.98 cobalt to 1 tetren and 1.98 cobalt to 1 tetren (Fig. 1). A precipitate forms which initially is brown but becomes green as excess of $CoCl_2$ is added.

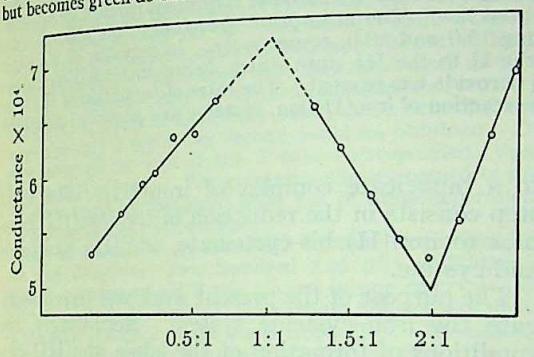

Fig. 1.—Ratio Co/amine.

2. **Titration of $CoCl_2$ with Tetren.**—Ten ml. of 0.051 *M* $CoCl_2$ in acetone was titrated with 0.2134 *M* tetren in acetone. A break occurs at a ratio of 2 moles Co to 1 of amine. The precipitate is initially green but turns brown as more tetren is added.

3. **Titration of Tetren with $Co(ClO_4)_2$.**—A methanol solution of tetren was titrated with $Co(ClO_4)_2$ in methanol, since the complex is insoluble in methanol. Two ml. of 0.599 *M* tetren was titrated with 0.559 *M* $Co(ClO_4)_2$ at 1 and 30°. A break in the curve occurs at a mole ratio of 1.08 moles tetren to 1 mole cobalt.

E. **Preparation of the Solid Complexes. 1. [Cotetren-CH_3OH]Cl_2.**—Since the conductometric titration curves indicated the brown species formed in excess tetren, this complex was precipitated from a solution containing an excess of tetren. Three hundred ml. of 0.041 *M* $CoCl_2$ in acetone was added to 100 ml. of 0.2134 *M* tetren in acetone. Acetone was added to complete precipitation. The precipitate was filtered by suction, recrystallized from methanol and acetone.

Anal. Calcd. for [CotetrenCH_3OH]Cl_2: Cl, 20.2; N, 19.9. Found: Cl, 19.76; N, 19.29.

2. [CotetrenCH_3OH]$CoCl_4$.—Seventy-five ml. of 0.234 *M* tetren in acetone was added to 400 ml. of 0.051 *M* $CoCl_2$ in acetone. The precipitate was filtered and recrystallized from methanol and acetone.

Anal. Calcd. for [CotetrenCH_3OH]$CoCl_4$: N, 14.5; Cl, 29.5. Found: N, 14.04; Cl, 29.90.

In order to establish the existence of the $CoCl_4^{2-}$ ion the precipitate was allowed to come to equilibrium with acetone at 25° and the spectra observed. A maximum is observed at about 695 mμ which has been described by Katzin[7] to the $CoCl_4^{2-}$ ion.

3. [CotetrenCH_3OH]$(ClO_4)_2$.—Twenty-two ml. of 0.56 *M* $Co(ClO_4)_2$ was added to 20 ml. of 0.6015 *M* tetren in methanol and precipitation completed by addition of 25 ml. of ether. The brown precipitate was filtered and washed with methanol and dried in an oven at 90°.

Anal. Calcd. for [CotetrenCH_3OH]$(ClO_4)_2$: Co, 12.2; N, 14.7. Found: Co, 12.2; N, 14.35.

4. [Cotetren$OH]_2PtCl_6$.—Although the perchlorate complex is only slightly soluble in CH_3OH, it dissolves very rapidly in methanolic NaOH or KOH. From this it was concluded that the methanol molecule was replaced by hydroxide ions. Chloroplatinic acid in methanol was added and a brown precipitate was formed.

Anal. Calcd. for [Cotetren$OH]_2[PtCl_6]$: Pt, 20.6; Co, 12.4. Found: Pt, 20.6; Co, 12.1.

F. **Oxygenation and Deoxygenation of** [CotetrenOH]ClO_4. **1. Oxygenation.**—Attempts to oxygenate [Cotetren$H_2O]^{2+}$ in water solution were unsuccessful in neutral or basic solution, oxidation to cobalt(III) occurs.

However, when 10 ml. of methanolic NaOH solution containing 0.0913 g. of the complex was placed in an oxygen atmosphere at 32° a rapid pickup of oxygen occurred during the first 10 minutes, as determined in a vapor pressure apparatus. After 15 minutes, further volume changes were very slight indicating that only extremely slow oxidation occurs.

Figure 2 shows the curve obtained when volume is plotted against time in minutes. A blank of 10 ml. of methanolic NaOH in the system produced a negligible volume decrease of 0.1 ml.

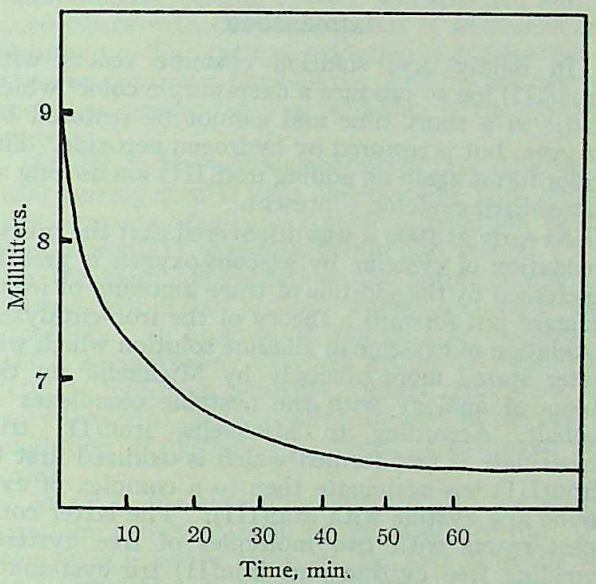

Fig. 2.—Rate of oxygenation.

2. **Deoxygenation of the Complex.**—Eighteen ml. of a methanolic NaOH solution containing 0.15 g. of the oxygenated complex were placed in a vapor pressure apparatus until equilibrium vapor pressure was obtained. Similarly the vapor pressure of a blank 18 ml. of methanolic NaOH solution was measured. The corrected volume of oxygen released by the oxygenated complex was 4.09 ml.

Discussion of Results

As expected, the log *K* values for the 1:1 complexes are greater for $[Cotetren]^{2+}$ (log *K* formation = 15.1) than for $[Cotrien]^{2+}$ (log *K* formation = 11.1). Analysis of the precipitates indicate that methanol and hydroxide ions seemingly can occupy the sixth position in this complex.

As the oxygenation and deoxygenation data show only in a methanolic NaOH solution can the complex become oxygenated; in water solution *oxidation* occurs immediately. If it is assumed that oxygenation occurs through an oxygen–oxygen bridge between two cobalt complexes the theoretical volume of oxygen recovered from the sample should have been 4.43 ml. whereas experimentally only 4.09 ml. was recovered, a decrease of about 8%. This seems to indicate some oxidation occurred for these complexes in line with the observation of the slight decrease in volume during the oxygenation studies.

The Oxidation of Cysteine by Iron and Hydrogen Peroxide

BY ROY G. NEVILLE[1,2]

RECEIVED DECEMBER 13, 1956

The conditions of formation of the labile purple iron(III) cysteine complex in oxygen-free acid and basic solution have been studied. In acid solution the complex decomposes in less than 0.5 sec., but under basic conditions persists for approximately 40 min., the color fading according to a roughly exponential law. The absorption spectrum of the residual color possesses maxima at 445 and 570 mμ, the extinction values being 15.0 and 19.0, respectively. In presence of hydrogen peroxide the cysteine complex of iron is rapidly oxidized from the II to the III state which, being unstable, decomposes yielding cystine and iron(II) ion, the process continuing until all peroxide has reacted. The rates of formation of the iron-(III) cysteine complex, its oxidation by peroxide at *p*H 8, and the reaction of iron(II) ion, cysteine and peroxide, have been studied using a rapid-flow technique.

Introduction

In mildly acid solution cysteine reacts with iron(III) ion to produce a deep-purple color[3] which fades in a short time and cannot be restored by oxygen, but is restored by hydrogen peroxide. The color forms again on adding iron(III) ion as long as unoxidized cysteine is present.

As early as 1909 it was discovered that the rate of oxidation of cysteine by gaseous oxygen is greatly increased by the addition of trace amounts of iron.[4] Harris[5] put forward a theory of the iron-catalyzed oxidation of cysteine in alkaline solution which was later stated more precisely by Michaelis[6] on the basis of analogy with the cysteine complexes of cobalt. According to Michaelis, iron(II) tris-cysteinate is first formed which is oxidized first to iron(III) tris-cysteinate then to a complex of cysteine and cystine with iron(III). The latter complex reacts with two molecules of free cysteine yielding free cystine and iron(II) tris-cysteinate. This cyclic process results in the oxidation of all cysteine present to cystine.

When gaseous oxygen is the oxidant it is reduced to water, hydrogen peroxide being an intermediate. Pirie[7] showed that addition of peroxide to an iron-containing cysteine solution increased the rate of oxidation, but no direct evidence for the existence of hydrogen peroxide in this reaction was available until Schales[8] carried out the reaction in presence of luminol (5-amino-2,3-dihydro-1,4-phthalazinedione), when a very pronounced chemiluminescence resulted. This luminescent reaction is known to occur only in presence of peroxide ion which may thus be detected in concentrations down to 1 part in 10^7.

Working in absence of oxygen, Schubert[9] isolated a number of complexes of iron with cysteine, and presented a theory similar to that of Michaelis but differing in the constitution of the complexes assumed as intermediates. According to Schubert, at *p*H 8–10, the first formed complex is iron (II) bis-cysteinate which is oxidized by oxygen to a binucleate complex of iron(III). The third step consists in the reduction of the iron(III) complex to iron(II) bis-cysteinate, iron(II) hydroxide and cystine.

The purpose of the present work was to reinvestigate the iron–cysteine system. Accordingly, the conditions of formation of the labile iron(III) cysteine complex have been studied in the presence and absence of peroxide ion, and the views of Michaelis and Schubert have been substantiated.

Experimental

Chemicals.—All reagents were of C.P. grade. Cysteine hydrochloride was supplied by Eastman Organic Chemicals, Rochester, New York, and was used without further purification. Assay of fresh samples by three independent methods showed it to contain about 94% –SH group.[10] A portion of cysteine oxidized with iron-free nitric acid gave no color with thiocyanate and thus may be considered free from iron.

Equipment.—Spectral determinations were carried out using a Beckman spectrophotometer, model DU, and 1 cm. quartz cells fitted with ground-glass stoppers.

Cysteine Complex of Iron(III). Formation in Acid Solution.—Experiments were conducted under nitrogen in which 0.1 ml. of 0.01 *M* iron(III) ammonium sulfate was added to eight oxygen-free solutions of 0.01 *M* hydrochloric acid (10 ml. each) containing cysteine ranging in concentration from 10^{-1} to 5×10^{-5} *M*. Water used to prepare solutions was freed from dissolved oxygen by boiling, sweeping out with oxygen-free nitrogen and storing under nitrogen. In all cases a transient purple coloration was produced which persisted for approximately 0.5 sec.

Cysteine Complex of Iron(III). Formation in Alkaline Solution.—Repeating the above experiments in 0.01 *M* ammonia solution the same purple color formed. This faded gradually on standing, usually persisting for about 20 to 40 minutes depending on the concentration of cysteine.

Cysteine Complex of Iron(III). From Iron(II) Cysteine and Hydrogen Peroxide.—To six oxygen-free solutions of 0.01 *M* hydrochloric acid, containing cysteine ranging in concentration from 10^{-1} to 5×10^{-4} *M*, was added 0.1 ml. of 0.01 *M* iron(II) ammonium sulfate, free from iron(III) ion. Reactions were conducted under nitrogen. To each solution 3.0 ml. of 3% hydrogen peroxide was added. No color was produced, but positive reaction with thiocyanate ion indicated the presence of iron(III). On standing cysteic acid precipitated.

A similar series of experiments at *p*H 8 likewise gave no coloration with peroxide, but within a few seconds cysteic acid precipitated. That all cysteine had reacted was shown by a negative reaction with sodium nitroprusside.

Spectrum of Iron(III) Cysteine Complex.—Absorption spectra of 9×10^{-3} *M* solutions of complex were determined between 400 and 600 mμ. Solutions were prepared by mixing 10.0 ml. of 0.01 *M* cysteine in ammonia at *p*H 9 with 1.0 ml. aliquots of either 0.01 *M* iron(II) ammonium sulfate or iron(III) ammonium sulfate. The initially intense purple of the iron(III) cysteine was allowed to fade until the intensity of color remained sensibly constant, as deter-

mined by plotting the optical density at a given wave length (445 mμ) *versus* time. The spectrum was then determined. Absorption maxima occur at 445 and 570 mμ, the extinction values being 15.0 and 19.0, respectively. The spectra obtained from either iron(II) or iron(III) ion were identical.

Apparatus for Determining Rates of Fast Reactions.—A simplified apparatus, based on the principle used by Roughton and Millikan,[11] was employed to obtain semi-quantitative measurements on the rates of reaction of cysteine with iron.

The apparatus consisted of two 250-ml. tap-funnels (serving as reservoirs for the reactants) which were connected to a T-tube, one arm of which was 150 cm. in length (internal diameter, 0.36 cm.) and was graduated in centimeters. Pressure could be applied simultaneously to both solutions by means of a mercury head, and a rate of flow of approximately 1 meter per second could be obtained. One centimeter on the arm of the T-tube corresponded, therefore, to 0.01 second. For greatest accuracy complete mixing must occur by turbulent flow, but in these experiments the flow was largely streamline.

Rate of Formation of Iron(III) Cysteine from Iron(III) Ion and Cysteine.—Two hundred and fifty milliliters of 0.01 *M* cysteine at *p*H 8 was placed in one reservoir, and 250 ml. of 0.01 *M* iron(III) ammonium sulfate was placed in the other reservoir of the above apparatus. By means of stopcocks, the iron solution was allowed to flow, then the cysteine was run in. The deep-purple iron(III) complex formed immediately, the maximum intensity of color being within 1 cm. of the mixing chamber.

Rate of Formation of Iron(III) Cysteine from Iron(II) Ion, Cysteine and Hydrogen Peroxide.—Two hundred and fifty milliliters of 0.01 *M* cysteine in dilute ammonia at *p*H 8 (containing 1.0 ml. of 0.01 *M* iron(II) ion per 100 ml. of cysteine solution) were allowed to react with 0.01 *M* hydrogen peroxide (iron-free) in the mixing chamber of the apparatus. The rates of flow of the two solutions were equal. The cysteine solution was purple due to iron(III) complex formed by oxidation of iron(II) ion by the oxygen in solution. This color served to show the course of the reaction. On mixing the two solutions the color faded within 1 cm. of the mixing chamber.

Rate of Oxidation of Cysteine by Hydrogen Peroxide.—Two hundred and fifty milliliters of 0.01 *M* cysteine (iron-free) in dilute ammonia at *p*H 8, containing a trace of nitroprusside ion, was allowed to react with 0.01 *M* hydrogen peroxide in the mixing chamber of the apparatus. Most of the sulfhydryl-nitroprusside color faded within 1 cm. of the mixing chamber, but a faint color persisted to a length of 60 cm.

Results and Discussion

Under oxygen-free conditions, addition of small amounts of iron(III) ion to acid solutions 10^{-1} to 5×10^{-5} *M* in cysteine produces a transient purple complex which persists for about 0.5 second or less. Similar experiments at *p*H 8–9 result in a purple complex which fades gradually but persists for 20–40 minutes depending on the cysteine concentration. Decomposition of this complex is thus strongly catalyzed by hydrogen ions. Addition of hydrogen peroxide to oxygen-free dilute acid or alkaline solutions of cysteine containing iron(II) ion produces no colored complex. That a very rapid oxidation occurs is demonstrated by the precipitation of crystalline cysteic acid a few seconds after peroxide addition.

These oxidation phenomena may be interpreted in the following manner. Hydrogen peroxide oxidizes the iron(II) cysteine complex to the iron(III) state which, being unstable, decomposes immediately yielding cystine and iron(II) ion, in accordance with the observations of Michaelis and Schubert. The cycle of oxidation and reduction of the iron continues until all the peroxide has reacted and then ceases, the iron returning to the divalent state.

At *p*H 8, the semi-quantitative rate data show that mixing iron(II) ion and cysteine with hydrogen peroxide results in complete oxidation of the purple iron(III) complex within 0.01 second. Under the same *p*H conditions the purple complex is formed within 0.01 second on mixing cysteine with iron(III). In absence of iron 0.01 *M* cysteine at *p*H 8 is completely oxidized within 0.6 second by 0.01 *M* hydrogen peroxide. These data show the very powerful catalytic effect of iron on the rate of oxidation of cysteine by oxygen or hydrogen peroxide.

At *p*H 9, the absorption spectrum of the purple complex shows maxima at 445 and 570 mμ. By comparison, at the same *p*H, the spectra of the bis- and green tris-complexes of cobalt(III) with cysteine and 2-mercaptoethylamine (in which amino and sulfhydryl coördination occur) possess maxima at 440 and 570–580 mμ.[12] Coördination in the iron(III) complex may also occur *via* the amino and sulfhydryl groups of cysteine, but at the present time there is no evidence to substantiate this hypothesis.

The Association of SCN^- with $Cr(H_2O)_6^{+3}$, $Cr(NH_3)_6^{+3}$, and $Cr(NH_3)_5Cl^{++}$ in Aqueous Solution[1]

BY ARTHUR L. PHIPPS[2] AND ROBERT A. PLANE

RECEIVED DECEMBER 3, 1956

Measurements of ultraviolet absorption spectra were made which indicate that there is slight association of SCN^- with $Cr(H_2O)_6^{+3}$, $Cr(NH_3)_6^{+3}$ and $Cr(NH_3)_5Cl^{+2}$ in aqueous solutions. Limits were assigned to equilibrium constants for the associations and for all three cases the constant lay between 10^{-1} and 10^{-3}. For the $Cr(H_2O)_6^{+3}$ and $Cr(NH_3)_6^{+3}$ measurements were made over the temperature range 3 to 26°. From such measurements the enthalpy change on association was found to be 0 ± 1 kcal. mole^{-1} and the entropy change at 25° was limited to the range -1.2 to -17 cal. deg.$^{-1}$ mole^{-1} for $Cr(H_2O)_6^{+3}$ and -1.2 to -14 cal. deg.$^{-1}$ mole^{-1} for $Cr(NH_3)_6^{+3}$. This entropy decrease is primarily responsible for the fact that SCN^- shows less tendency to associate with complex cations than do other anions (such as halides) which have previously been studied. The entropy decrease could arise from the loss of rotational entropy of SCN^- on association.

The association in solution of complex cations of the type $Co(NH_3)_6^{+3}$, $Cr(NH_3)_6^{+3}$, etc., with various anions has in recent years received considerable investigation.[3-13] For practically all of the systems studied association constants were found to lie between about ten and a thousand. Yet in most studies the total ionic strength was maintained constant by addition of sodium perchlorate, and it was assumed that there was no association of ClO_4^- with the highly charged cation. From the consistencies of the individual investigations this was apparently a valid conclusion, however a possibly surprising one in view of results that all other anions showed a marked tendency toward association. It seemed of interest to establish more directly the specificity of "outer sphere" association and if possible to determine factors which are responsible for specificity.

Of the methods used for detection and study of outer sphere complexes probably the most direct involves measurement of ultraviolet absorption spectra. It is generally found that in the ultraviolet region, ionic association is usually accompanied either by the appearance of a new absorption band, or by a shift of an existing band. These spectral changes can be attributed either to the introduction of a new electronic transition (for example the transfer of an electron from anion to cation), or to the perturbation of an existing electronic transition. The present authors found no spectral changes with changing concentration in solutions of $Cr(H_2O)_6^{+3}$ and ClO_4^-, even when ClO_4^- concentration was greater than 4 *M*. (The cation $Cr(H_2O)_6^{+3}$ was picked on solubility considerations and is suitable since it undergoes substitution reactions quite slowly.[14]) Such results do not necessarily indicate lack of association between these ions since the spectrum might remain unchanged by association, or accompanying changes might occur in the far ultraviolet. It was necessary therefore to pick a system in which a spectral change could be noted, but one in which association might be expected to be slight. From earlier work,[10,12] thiocyanate ion seemed to be suitable on both counts.

Experimental

The general experimental procedure involved rapidly mixing temperature equilibrated solutions to give a final solution of known composition. This solution was immediately placed in a thermostated cell of a Beckman DU quartz spectrophotometer and absorption measurements begun. The entire process, from mixing to measurement, required but 45 seconds. The time was kept short in order to minimize substitution reaction and other side reactions. The most serious such side reaction is a decomposition of thiocyanate in acidic solution to give an unknown species which is highly absorbing in the ultraviolet region. (Solutions containing $Cr(H_2O)_6^{+3}$ were made acidic, 0.05 or 0.10 *M* in order to suppress hydrolysis). At the wave lengths and temperatures used, the rate of change of the spectra amounted to several per cent. per minute, so that readings were taken periodically and extrapolated to time of mixing.

Absorption spectra of solutions of $Cr(H_2O)_6(ClO_4)_3$ plus $HClO_4$, of $Cr(NH_3)_6(ClO_4)_3$, and of $Cr(NH_3)_5Cl(ClO_4)_2$ were measured, individually and after being mixed with solutions containing NaSCN in the wave length region 2,600 to 2,900 Å. Every solution containing thiocyanate was also checked at 4750 Å., the wave length of maximum absorption of $FeSCN^{++}$, to ensure absence of ferric ion.

Materials.—Chromic perchlorate was made by reducing CrO_3 in $HClO_4$ with 30% H_2O_2. Excess H_2O_2 was destroyed by heating in the presence of platinized Pt. The solution was evaporated to crystals and these were recrystallized from 0.5 *M* $HClO_4$. Chromic analyses were performed spectrophotometrically following oxidation to chromate. Mallinckrodt AR 70% $HClO_4$ was used without purification. Reagent grade NaSCN was twice recrystallized from redistilled water. $NaClO_4$ was made by exactly neutralizing analytical reagent NaOH with analytical reagent $HClO_4$ and crystallizing. $Cr(NH_3)_6(ClO_4)_3$ was prepared by dissolving anhydrous $CrCl_3$ in liquid NH_3 in the presence of a bit of dissolved sodium.[15] The residue was dissolved in water, filtered, and $Cr(NH_3)_6(ClO_4)_3$ precipitated from the filtrate by addition of concentrated $HClO_4$. The product was washed with alcohol and ether and dried under vacuum in the dark. Chloropentamminechromium(III) chloride was obtained as a by-product and was purified by dissolving it in warm water, filtering and precipitating with concen-

trated HCl. The salt was filtered, washed with alcohol and ether, and dried under vacuum. The water used in all experiments was redistilled in a Barnstead block tin still.

Results

$Cr(H_2O)_6^{+3}$ + SCN^-.—The results of a typical series of experiments are shown in Fig. 1, which gives the optical density ($\log I_0/I$) for one cm. light path lengths of 0.040 *M* $Cr(H_2O)_6(ClO_4)_3$, 0.40 *M*

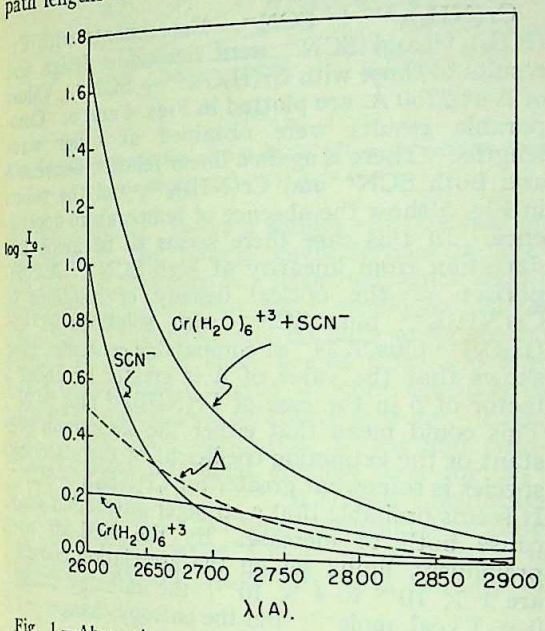

Fig. 1.—Absorption spectra of various ions in acidic solution at 3° for 0.04 *M* $Cr(H_2O)_6(ClO_4)_3$ and 1 *M* NaSCN in 0.1 *M* $HClO_4$.

though the chromic spectrum is *not* affected by change of acidity or temperature in the ranges covered by these experiments, the SCN^- spectrum was somewhat affected—increasing both with increasing acidity and with increasing temperature. In every case the Δs were obtained by subtracting the contribution of the $Cr(H_2O)_6^{+3}$ and that of a NaSCN solution identical with the final mixture except that $Cr(H_2O)_6(ClO_4)_3$ was absent.

Because of the decrease of Δ and of the optical density of SCN^- with increasing wave length, measurements at low SCN^- concentration were most precise at shorter wave length, and those at high SCN^-, at longer wave length. The shortest wave length at which the entire range of SCN^- concentration from 0.02 to 2.0 *M* could be precisely studied was 2750 Å. The results of experiments at this wave length are given in Fig. 2. Values of Δ are plotted *versus* formal concentration of SCN^-, and the plot shows that experiments at two acidities, three temperatures, with and without added $NaClO_4$ (to make total ionic strength 2 *M*) form a single curve, which is essentially a straight line. Experiments at other wave lengths give similar results.

If the association between SCN^- and $Cr(H_2O)_6^{+3}$ is governed by the equilibrium

$$Cr(H_2O)_6^{+3} + SCN^- \longrightarrow Cr(H_2O)_6SCN^{+2}$$

as seems to be true of all other cases studied,[3-13] then within the accessible range of SCN^- concentrations a significant fraction of the chromic ion is never converted to the associated species. Significant conversion would cause the plot of Δ *vs.* SCN^- concentration to approach zero slope; on the other hand only slight association requires the plot to approach a straight line of finite slope. From an assessment of errors and precision of the present experiments, it is found that an association equilibrium constant greater than 0.1 would cause detectable de-

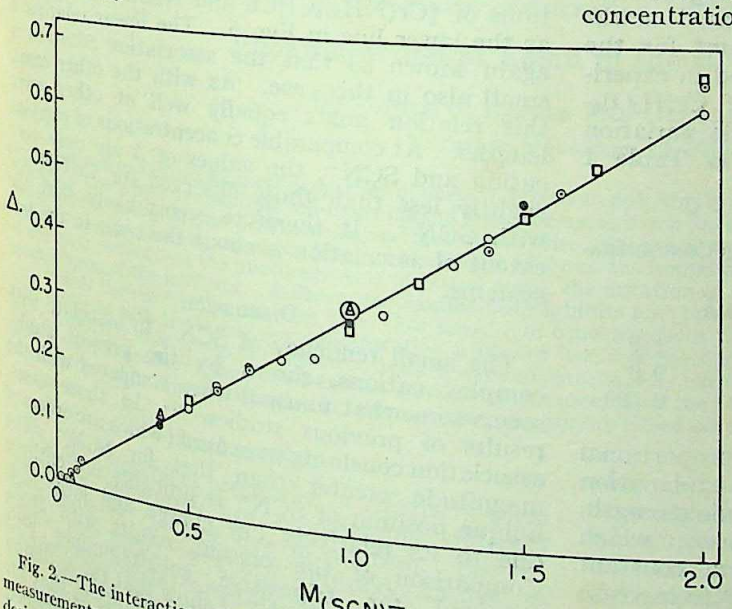

Fig. 2.—The interaction of 0.04 *M* $Cr(H_2O)_6^{+3}$ and various concentrations of SCN^-. Data obtained from optical density measurements at 2750 A. Circles represent points obtained at 3°; squares, at 15°; triangles, at 26°. Open symbols designate solutions containing 0.05 *M* $HClO_4$; symbols with dots, solutions containing 0.1 *M* $HClO_4$; blackened symbols, solutions containing sufficient $NaClO_4$ to make total ionic strength 2 *M*.

viation from the straight line described by the points in Fig. 2. In addition to this upper limit placed on the value of K, a lower limit can be assigned by assuming a maximum value for the extinction coefficient of the associated species. If this coefficient is assumed to be 10^4 at 2750 Å., it follows from the data plotted in Fig. 2 that at 1.0 M SCN^-, the concentration of the ion pair would be 3.2×10^{-5} and K would be 8×10^{-4}.

It might seem somewhat curious that even if the association constant for this system is small, points at various ionic strengths (both those in which the total ionic strength was allowed to vary from 0.36 to 2.34 and those in which the total ionic strength was maintained constant at 2.00 by addition of $NaClO_4$) describe a straight line. This would seem to indicate that over the concentration range investigated, the pertinent activity coefficients ratios of individual species are nearly constant. It is perhaps significant that the activity coefficients ($\gamma_\pm$) for NaSCN which comprises the bulk concentration in most experiments vary by less than $\pm 5\%$ in the ionic strength range of these experiments, and those of $NaClO_4$, which comprises the bulk concentration in the remaining experiments are almost equally constant and differ from the NaSCN coefficients by about 10%.[16]

At higher SCN^- concentrations, a plot of Δ *vs.* concentration of SCN^- does not give a straight line. Data obtained at 2900 Å. are plotted in Fig. 3. The curvature is in the opposite direction demanded by that for the "saturation" of an association. In this concentration region the activity coefficients of NaSCN increased markedly,[16] and may quite possibly account for the deviation. Similar deviations are noted in experiments in which the concentration of $Cr(H_2O)_6(ClO_4)_3$ is varied with consequent wide variation in total ionic strength. The data in Table I

VARIATION OF Δ AT 0.5 M SCN^- AND VARIOUS CONCENTRATIONS OF $Cr(H_2O)_6^{+3}$

Temperature 3°; wave length 3090 Å.

$Cr(H_2O)_6^{+3}$, M	0.5	1.0	1.5
Ionic strength, M	3.6	6.6	9.6
Δ	0.054	0.196	0.509

show that in this case, Δ is not directly proportional to chromic concentration. Again the explanation could well lie in the fact that at high ionic strength, activity coefficients of SCN^- increase, which should cause the apparent association constant (based on concentrations not activities) to increase with increasing ionic strength.

It was noted earlier that the effect of temperature on observed values of Δ is quite small. If the assumption is made that the absorption process (*i.e.*, extinction coefficient of the associated species) is not affected by temperature, then any change in Δ with temperature is due to a change in the extent of association. From a comparison of duplicate points at the temperatures 3, 15 and 26° of Fig. 2, it is found that the change in equilibrium constant within this temperature range is less than 10% so that the enthalpy change for the association is within 1 kcal. $mole^{-1}$ of 0. With this value for ΔH and the two limits previously placed on the equilibrium constant, it is possible to place limits on the entropy change for the association. At 25°, the entropy change lies in the range -1.2 to -17 cal. deg^{-1} $mole^{-1}$.

$Cr(NH_3)_6^{+3}$ + SCN^-.—Experiments with $Cr(NH_3)_6^{+3}$ and SCN^- were similar in design and results to those with $Cr(H_2O)_6^{+3}$ + SCN^-. Values of Δ at 2750 Å. are plotted in Figs. 4 and 5. Comparable results were obtained at other wave lengths. There is again a linear relation between Δ and both SCN^- and $Cr(NH_3)_6^{+3}$, and the points in Fig. 5 show the absence of temperature dependence. In this case there seems to be much less deviation from linearity at high SCN^-. A comparison of the optical density of solutions of $Cr(NH_3)_6^{+3}$ plus SCN^- with solutions of $Cr(H_2O)_6^{+3}$ plus SCN^- at comparable concentrations, shows that the value of Δ is greater by about a factor of 5 in the case of $Cr(NH_3)_6^{+3}$ plus SCN^-. This could mean that either the association constant or the extinction coefficient of the associated species is somewhat greater for $Cr(NH_3)_6^{+3}$–SCN^-. It seems probable that a stronger interaction would cause both to increase. By the methods used previously, limits set on the association constant are 1×10^{-1} to 4×10^{-3}; the enthalpy change, 0 ± 1 kcal. $mole^{-1}$; and the entropy change, -1.2 to -14 cal. $deg.^{-1}$ $mole^{-1}$.

$Cr(NH_3)_5Cl^{++}$–SCN^-.—Experiments with solutions of $[Cr(NH_3)_5Cl]Cl_2$ and NaSCN are plotted as the lower line in Fig. 5. The linear relation is again shown so that the association constant is small also in this case. As with the other cases, this relation holds equally well at other wave lengths. At comparable concentrations of complex cation and SCN^-, the values of Δ are only very slightly less than those observed for $Cr(NH_3)_6^{+3}$ with SCN^-. It therefore seems likely that the extent of association is about the same in the two systems.

Discussion

The small tendency of SCN^- to associate with complex cations, shown by the present study, seems somewhat unusual when compared with the results of previous studies.[3-13] In those cases, association constants were found which are orders of magnitude greater than that for SCN^-. The unique position of SCN^- is probably not entirely due to its relatively low charge and large size. Comparison of the present results with those obtained for tripositive cobaltammines plus SO_4^{--},[13] Cl^-, Br^- and I^-,[8] show that the enthalpy of association for SCN^- is as favorable as that for any of the other cases. (The values of ΔH obtained in the previous studies range from 0 to +3.7 kcal./mole). The significant difference between SCN^- and other anions is the entropy change which accompanies association. Whereas the entropy term for the associations noted above are all positive by 10 or more calorie $mole^{-1}$ $degree^{-1}$, that for SCN^- is negative. Of the anions previously

studied, only N_3^- shows a similar entropy loss on association.[8] The unique characteristic of N_3^- and SCN^- is that each is a linear ion which might possess rotational entropy which would be lost on association. Unfortunately, no data exist on the entropy of either of these anions from which it would be possible to decide whether the ions in aqueous solution possess rotational entropy. However, for gas phase association, Evans and Nancollas estimate rotational entropy loss for N_3^- of 11 cal. degree^{-1} mole^{-1}.[8] A similar calculation for SCN^- shows its gas phase rotational entropy loss to be 16 cal. degree^{-1} mole^{-1}. This value is sufficiently large to change the total entropy of association from a positive value, such as is found for other anions, to a negative value defined by the present experiments, and, hence, can account for the very slight tendency toward association noted for SCN^-.

Photoreduction of Eosin in the Bound State[1a,b]

BY JUDITH S. BELLIN AND GERALD OSTER

RECEIVED NOVEMBER 30, 1956

The spectral and photochemical properties of eosin Y bound to polyvinylpyrrolidone differ considerably from those of the free dye. The bound dye exhibits self-quenching of fluorescence at much lower concentrations than does the free dye, whereas for self-quenching of phosphorescence (in rigid media) the opposite is true. Furthermore, *p*-phenylenediamine which quenches the phosphorescence of the free dye is without effect on the bound dye. Nitrobenzene retards the photoreduction of free eosin but inhibits the photoreduction of bound eosin, the duration of the inhibition period being proportional to the concentration of the inhibitor. *p*-Phenylenediamine both inhibits and retards the photoreduction of bound eosin while it only retards the reaction for the free dye. For small dye concentrations the quantum yield of photoreduction of bound eosin increases with increasing dye concentration while for free dye the opposite is the case. These rate studies suggest that a bound dye molecule in the first electronically excited state rapidly exchanges energy with a bound dye molecule in the ground state to produce a long-lived excited species which reacts with the reducing agent (here ascorbic acid). A mechanism is proposed for dye-sensitization in silver halide photography based on photoreduction of bound dye.

Introduction

The photochemical properties of dyestuffs when bound to substrates are considerably different from those of the free dye in solution. For example, rose bengal (2′,4′,5′,7′-tetraiodo-3,4,5,6-tetrachlorofluorescein) is readily photooxidized in solution whereas the dye when bound to polyvinylpyrrolidone (PVP) resists photooxidation even when exposed to sunlight for one month.[2] On the other hand, dyes which are bound to high polymeric substrates are more readily photoreduced than are the free dyes.[3–5]

The present paper is concerned with the photoreduction of eosin Y (2′,4′,5′,7′-tetrabromofluorescein) when bound to PVP in solution. The kinetics of photoreduction of free eosin Y have been studied.[6] It has been shown that the kinetics of photoreduction of free fluorescein and its halo-

genated derivatives are qualitatively similar.[7] Likewise, we have found that the photochemical properties of the fluorescein-type dyes, erythrosin, phloxine and rose bengal, when bound to PVP are similar to those of bound eosin which are described in detail in the present paper.

The results of the present studies have direct bearing on the phenomena underlying dye-sensitization in silver halide photography.

Experimental

Materials.—Eosin Y as obtained from Eastman Kodak Co. was used without further purification. Polyvinylpyrrolidone (PVP) of molecular weight 5.6×10^5 was obtained from Schenley Laboratories. All the other reagents were obtained from Fisher Scientific Co. as C.P. grade. Helium (Airco) was used to flush oxygen from the solutions.

Procedures.—The methods used for determining the rate of photoreduction of eosin Y in the presence of ascorbic acid as well as the methods used in the measurements of absorption spectra, fluorescence spectra and fluorescence and phosphorescence intensities are identical with those described in our previous paper.[5] The wave length of the actinic light employed was that maximally absorbed by eosin Y, namely, 518 mμ.

Precautions were necessary in measuring the fluorescence quenching by *p*-phenylenediamine (PPD) since the oxidation of this substance is sensitized by eosin.[8] Freshly prepared mixtures were used for each measurement. A buffered stock solution of PPD was kept under helium in order to prevent its oxidation by air.

Results

Spectra.—A dilute solution of eosin Y is orange (absorption maximum at 518 mμ) and exhibits a yellow-green fluorescence when excited by blue light. With excess PVP the color changes to red (absorption maximum at 528 mμ with excess PVP) and the fluorescence is yellow and is of greater intensity. In contrast to our observations with triphenylmethane dyes,[5] the shape of the absorption spectra of eosin Y is unchanged on binding to the high polymer and is merely shifted to longer wave lengths.

By following the change in optical density at the wave length where the spectral changes are the largest (518 mμ for eosin Y) as a function of the amount of PVP added, we obtained a binding curve.[9] Employing the customary analysis of the binding data, we find at *p*H 5.0 that one gram of PVP binds 1.0×10^{-5} mole of eosin (see Fig. 1).

Fluorescence and Phosphorescence.—Solutions of free eosin show evidence of self quenching of fluorescence at a dye concentration of about 10^{-4} *M* (Fig. 2). An actual decrease in fluorescence intensity occurs at concentrations exceeding 10^{-3} *M*. On the other hand, in presence of PVP self-quenching becomes evident at concentrations of dye as low as 10^{-6} *M* and the fluorescence intensity is a maximum at 10^{-5} *M* (Fig. 2).

PPD quenches the fluorescence of eosin Y in the bound as well as in the free state. In all cases the quenching obeys the Stern–Volmer equation. At *p*H 5.0 the quenching constants of PPD for the dye in the free and in the bound states are, respectively, 4.37 and 3.14 liters/mole.

Oxygen-free solutions of eosin Y in glycerol at temperatures below −90° exhibit a yellow phosphorescence when the system is excited by blue light. Addition of PVP enhances the intensity of the phosphorescence and makes the phenomenon observable at temperatures as high as −60°.

Self quenching of the phosphorescence of eosin Y in glycerol at −90° is evident at dye concentrations of 10^{-4} *M*. In the presence of PVP, however, this self quenching does not occur. PPD up to a concentration of at least 10^{-4} *M* is not a quencher of the phosphorescence of bound eosin Y, whereas it is a powerful quencher of the phosphorescence of free eosin.

Photoreduction.—The quantum yield of photobleaching with ascorbic acid at *p*H 5.0 of eosin Y, rose bengal, phloxine and fluorescein is greater in the bound than in the free state. The resulting colorless solutions exhibit a weak yellow fluorescence when excited by near ultraviolet light. Both bound and free fluorescein-type dyes reduce tetrazolium salts to insoluble formazans under the conditions of the photobleaching reaction, while in the dark no formazan is produced. This shows that in the photobleaching process a reduced form of the dye is produced which in turn is capable of reducing the tetrazolium salts. As is the case with free fluorescein-type dyes,[6] the quantum yield ϕ of the photoreduction of bound eosin Y as a function of reductant (A), here ascorbic acid, follows the relation $\phi = (A)/\alpha + \beta(A)$ where α and β are constants, independent of incident light intensity; there is, however, a striking difference between the free and the bound dye as regards their dependency of quantum yield on dye concentration. Whereas, with free dye the quantum yield of photoreduction decreases with increasing dye concentration, in the case of bound dye the quantum yield increases with increasing dye concentration up to about 6×10^{-4} *M* in eosin and a limiting value is attained at higher dye concentrations (Fig. 3). The photoreduction of bound triphenylmethane dyes[5] is similar in all these respects to those of bound eosin.

Photoreduction of bound eosin Y is inhibited by small amounts of nitrobenzene. For example, the addition of 10^{-6} *M* nitrobenzene causes an induction period of one minute during which the nitrobenzene is destroyed and after which the reaction proceeds at a rate equal to that of the inhibitor-free system. The induction period is directly proportional to the amount of nitrobenzene added. This phenomenon is similar to that observed for the case of bound triphenylmethane dyes.[5] In the case of free eosin, however, nitrobenzene acts as a retarder rather than as an inhibitor.

The effect of PPD on the rate of photoreduction of bound eosin Y is illustrated in Fig. 4. There is a period of inhibition, after which the photoreduction takes place at a reduced rate compared with that of the inhibitor-free system.

Discussion

The increased fluorescence yield of eosin on binding to PVP may be due to the increased planarity of the dye when bound.[10] The data of Fig. 1 show that the rate of photoreduction of bound eosin is not directly proportional to the degree of

binding; a maximum rate of fading is attained at a ratio of dye to polymer at which not all the dye molecules are considered by the absorption criterion to be bound. This suggests a redistribution of dye molecules on the polymer chain resulting in further changes in optical density but with a decreased rate of fading due to decreased possibilities of dye–dye interaction (see below).

As in the case of the bound triphenylmethane dyes,[5] the following kinetic scheme is consistent with the fading data of bound eosin: (1) $D + h\nu \rightarrow D^*$, (2) $D^* \rightarrow D + \text{heat}$ (and/or $h\nu_f$), (3) $D^* \rightarrow D'$, (4) $D^* + D \rightarrow D' + D$, (5) $D' \rightarrow D + h\nu_p$, (6) $D' + A \rightarrow D + A$, (7) $D' + A \rightarrow M$, (8) $M \rightarrow$ colorless products (I), (9) $M + \times \rightarrow$ colorless products (II) + D. In our terminology, D, D* and D′ refer to bound dye molecules in the ground, first electronically excited, and long-lived electronically excited states, respectively, the unbound dye being photochemically inert under the conditions employed in these studies. The reductant A reacts only with D′ either to quench the phosphorescence (step 6) or to form an intermediate complex M (step 7). This complex in turn can decompose to give reduced dye products or, in the presence of inhibitor X, can cause the destruction of X with the regeneration of dye. The justification for this formulation is treated in detail in our previous paper.[5] Using steady-approximations for the transient species (D*, D′ and M) these reaction steps lead to the following equation for the quantum yield of photoreduction

$$\Phi = \left[\frac{k_8}{k_8 + k_9(\mathrm{X})}\right]\left[\frac{k_7(\mathrm{A})}{k_5 + (k_6 + k_7)(\mathrm{A})}\right]\left[\frac{k_3 + k_4(\mathrm{D})}{k_9 + k_3 + k_4(\mathrm{D})}\right]$$

where the *k*'s are the rate constants for the reactions indicated by the subscripts. Since the quantum yield is zero when extrapolated to zero dye concentration (Fig. 3), $k_4(\mathrm{D})$ is much larger than k_3 and hence, as with bound triphenylmethane dyes, step 3 is negligible compared with step 4. In contrast to the behavior of bound triphenylmethane dyes, however, $k_4(\mathrm{D})$ for bound eosin must be comparable to k_2, since a plateau in the rate of fading is reached at higher dye concentrations. As in the case of bound triphenylmethane dyes we evaluate the ratio of the constants[5] which for eosin are $k_4/k_2 = 2.24 \times 10^5$, $k_6/k_5 = 450$, $k_7/k_5 = 211$, liters per mole, respectively. We estimate that k_2, the reciprocal of the lifetime of bound

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized By Arya Samaj Foundation Chennai and eGangotri

eosin, is about 3×10^8 sec.$^{-1}$ [11] so that k_4 would be 6×10^{13} l./mole/sec. As might be expected, this value of k_4 cannot be accounted for on the basis of diffusion-controlled bimolecular encounters (6.6×10^9 encounters/sec./mole/liter in aqueous systems at 25°) but more likely represents the rate constant for energy transfer between dye molecules fixed on the polymer chain to yield dye molecules in the long-lived excited state. The quenching of this long-lived state by reductant (step 6) is twice as efficient as step 7 which leads to the intermediate complex.

Small amounts of PPD retard the rate of photoreduction of free eosin[6] whereas with bound eosin inhibition as well as retardation occurs (Fig. 4). Since there is no appreciable fluorescence quenching at these low PPD concentrations, the step $D^* + X \rightarrow D + X$ is unimportant but reaction occurs as in step 9 to account for the observed inhibition (compare ref. 5). The retardation effect of PPD requires that products formed in step 9 quench the long-lived excited dye molecules, *i.e.*, (10) D′+ products (II) → D + products (II). Assuming steady-state concentrations for D*, D′ and M we derive the following expression for the ratio R_0/R_x of the rates of photoreduction in the absence and in the presence of substance X

$$\frac{R_0}{R_x} = \left[1 + \frac{k_9}{k_8}(\mathrm{X})\right]\left[1 + \frac{k_{10}(\text{Products (II)})}{k_5(k_6 + k_7)(\mathrm{A})}\right]$$

Since no photofading occurs until the inhibition period is ended k_9 must be much larger than k_{10}. Step 9 requires that the concentration of Product II be proportional to the amount of PPD added (X_0). We may express the amount of retardation which occurs after the inhibition period is completed as

$$\frac{R_0}{R_x} = 1 + \frac{k_{10}'(X)_0}{k_5 + (k_6 + k_7)(\mathrm{A})}$$

Thus, as shown in Fig. 4, the retardation is directly proportional to the amount of PPD originally added. From the slope of this line and using the ratios of the rate constants enumerated above we obtain $k'_{10}/k_6 = 1.35 \times 10^6$. If the concentration of Products II is comparable in magnitude to that of X_0 then quenching by this product is much more efficient than quenching by reductant. These results are consistent with the observation that PPD itself does not quench the phosphorescence of bound eosin although it strongly quenches the phosphorescence of free eosin.

The purely inhibiting action of nitrobenzene on the photoreduction of bound eosin is explainable in exactly the same way as that for bound triphenylmethane dyes.[5] In this case, step 10 is not important since no retardation occurs.

It has been known for many years that eosin applied to silver halide photographic emulsions will render the emulsion sensitive to green light.[12] Silver bromide emulsions sensitized with eosin have been studied in our laboratory.[13] The sensitivity of the emulsion is a maximum at the wave length where the bound dye absorbs light maximally. The binding curve for the dye as a function of silver bromide concentration is similar to that of Fig. 1. The emulsion exhibits sensitivities as a function of silver halide concentration and eosin concentration in a manner analogous to the fading curves of Figs. 1 and 3. Small amounts of nitrobenzene suppress the green sensitivity while the blue sensitivity (a property of the silver halide itself) is unchanged. It would appear that in this system, at least, the bound dye is photoreduced and the reduced dye donates electrons to the silver halide to form the latent image. This is an alternative suggestion to those contained in current theories of dye-sensitization in photography which postulate photoelectric phenomena.[14]

Spectroscopic Studies on Dyes. IV. The Fluorescence Spectra of Thioindigo Dyes[1]

BY DELBERT A. ROGERS, J. DAVID MARGERUM AND GEORGE M. WYMAN[1a]

RECEIVED JANUARY 28, 1957

The fluorescence spectra of eight thioindigo dyes in benzene solution were determined, using the 546 mμ Hg-line for excitation. Each dye has a fluorescence band at a wave length somewhat longer (usually by *ca.* 35 mμ) than its first absorption maximum. Exposure of the dye solutions to yellow light prior to the measurement results in decreased fluorescence. The intensity of fluorescence was found to be proportional to the concentration of *trans* isomer present. This behavior, which is similar to that observed for stilbene,[2] indicates that *trans*-thioindigo possesses a tightly-held coplanar structure, while its *cis* isomer is non-coplanar. These conclusions are shown to be consistent with the visible and infrared absorption data. The addition of ethanol quenches the fluorescence of these dyes. The possible implications of this phenomenon with regard to the photochemistry of thioindigo-dyed cellulosic materials are discussed.

Introduction

In their study of the fluorescence spectra of *cis*- and *trans*-stilbene, Lewis and his co-workers have found that only the *trans* isomer exhibits fluorescence.[2] While a large number of articles dealing with fluorescence spectra have appeared in the lit-

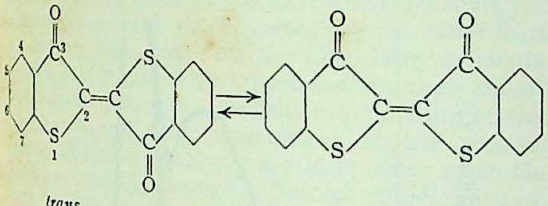
erature since that time, further mention of the fluorescence of *cis-trans* isomers has been limited to the derivatives[3a,3b] or the vinylogs[4a,4b] of stilbene. In harmony with the behavior of stilbene, in each of these instances the solutions containing the largest concentration of *trans* isomers showed greatest fluorescence intensity.

Brode and Wyman have reported the existence of an equilibrium between *cis* and *trans* isomers in



trans I *cis*

solutions of thioindigo (I) dyes in inert solvents.[5] They found that the position of the equilibrium was a function of the wave length range of the light to which the solution had been exposed. It was also possible to separate the two isomers by chromatographic adsorption in the dark. These findings made it appear desirable to undertake a study of the fluorescence of thioindigo dyes for the following reasons: (1) to find out whether the behavior of these dyes followed the pattern shown by the aromatic olefins; and (2) to see if an examination of their fluorescence spectra would yield additional information concerning the structure of dyes of this type.

Experimental

Preparation of Solutions.—Approximately 10 mg. of each dye was dissolved in *ca.* 300 ml. of benzene by heating near the boiling point for several hours. The solution was then cooled to room temperature and diluted to a suitable concentration. The concentrations were determined spectrophotometrically, using appropriate data from reference 3a and 3b.

Pre-irradiation of Solutions.—The dye solution contained in a 2-cm. or 5-cm. absorption cell was exposed for five minutes to filtered light from a Bausch and Lomb Microscope Illuminator (Catalog No. 31-35-85-11), using either a blue or a yellow filter. The blue filter used for all of the dyes was Corning No. 5543. Three yellow filters were used: Corning No. 3385 for dyes VII and VIII; No. 3484 for dye II and Filter No. 3482 for the five other dyes (*cf.* Table I). The cell length was selected to give an absorption measurement in the range of maximum sensitivity of the spectrophotometer.

Measurement of Absorption Spectra.—The absorption spectra of the pre-irradiated dye solutions were determined in the 400–650 mμ region by means of a Cary Recording Spectrophotometer (Model 11), against the solvent as the reference. The solutions resulting from the chromatographic separation described below were measured on a Beckman DU spectrophotometer.

Measurement of Fluorescence Spectra.—The Fluorescence Attachment of the Model 11 Cary Spectrophotometer was used to measure the fluorescence spectra. All measurements were made at a slit width of 0.5 mm., using the 546 mμ Hg-line for excitation. Whenever fluorescence measurements were desired, immediately upon completion of the pre-irradiation in the longer cell, the solution was transferred to a 1-cm. absorption cell and its fluorescence determined. This operation was necessary because, probably due to self-absorption, the amount of *trans* to *cis* conversion was found to be a function of cell length. In no instance was there evidence for a shift in the *cis–trans* equilibrium caused by the exciting light of the Hg-arc of the fluorescence attachment.

Chromatographic Separation of *cis*- and *trans*-Thioindigo.—The chromatographic separation of the two isomers of thioindigo was carried out as described in reference 3a. However, in view of the quenching action of ethanol on the fluorescence of thioindigo, it was necessary to evaporate the solution containing the *cis*-isomer to dryness and dissolve the residue in benzene before measuring its fluorescence spectrum.

Results

The behavior of 4,4′-dimethyl-6,6′-dichlorothioindigo, which is shown in Fig. 1, is characteristic of all the dyes studied in this investigation. Each dye has a band of fluorescent emission in the visible region at a wave length somewhat longer than its first absorption band. Thioindigo dyes enriched with respect to the *cis* isomers (by pre-irradiation with yellow light) show fluorescence at the same wave lengths but with diminished intensity. There was also no evidence for any new fluorescence bands that may be attributable to the *cis*-isomers when the 436 or 366 mμ Hg-lines were used for the excitation, even for dyes VII and VIII, the *cis* isomers of which absorb strongly near 450 mμ (*cf.* Table I). Consequently this suggests that only the *trans* isomers exhibit fluorescence.

Further confirmation of this conclusion was obtained from a comparison of the fluorescence intensity with the relative concentration of the *trans* isomer as shown in Table I. The last column in this table shows that the ratio of the fluorescence in-

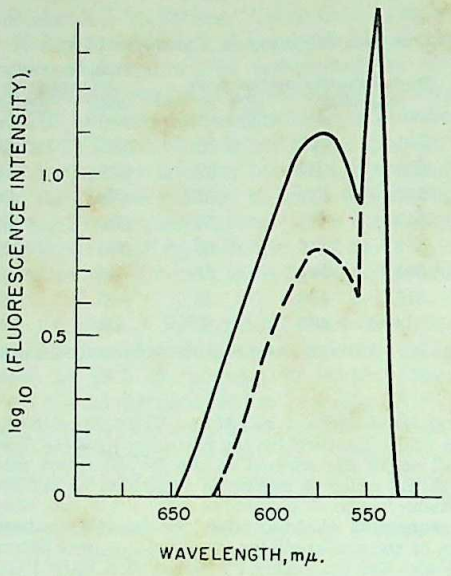

Fig. 1.—Fluorescence spectrum of 4,4′-dimethyl-6,6′-dichlorothioindigo in benzene: (———) pre-irradiated with blue light; (– – – –) pre-irradiated with yellow light. Concentration: 2.8 mg./l.; exciting light, 546 mμ.

tensity of each dye solution that had been preirradiated with yellow light (*i.e.*, enriched with respect to *cis*) to that of the same solution pre-irradiated with blue light (*i.e.*, essentially all-*trans*). Correspondingly, the fourth column in the table gives the ratio of the concentrations of the *trans* isomer present under these two sets of conditions, determined independently from absorption measurements. The good agreement between these two figures shown for each dye indicates that the fluorescence intensity is directly proportional to the concentration of *trans* isomer. It is then evident from these data that the *cis* isomers can possess little or no fluorescence in this region of the spectrum.

In order to obtain direct proof of this conclusion it was decided to measure the fluorescence of a solution of *cis*-thioindigo. Accordingly, the chromatographic separation of the isomers was carried out and the fluorescence and absorption spectra of the resulting solutions were measured, as shown in Fig. 2. While the solution contained mostly *cis*-thioindigo, the absorption at 550–570 mμ showed that there was also an appreciable amount (*ca.* 10%) of *trans* isomer present. (It is believed that the *trans* compound formed during the additional operations required for the removal of the ethanol.) However, a comparison of the fluorescence spectra obtained on this solution before and after irradiation with blue light (thus representing the two extremes with respect to the concentration of each isomer) disclosed that the fluorescence intensity was again proportional to the concentration of the *trans* form (*cf.* Fig. 2.) On the basis of all this evidence it is possible to conclude that only the *trans* isomers of thioindigo dyes exhibit fluorescence.

The quenching of fluorescence that is caused by the addition of a small amount of ethanol to a solution of a thioindigo dye in benzene is readily noticeable even to the naked eye. This interesting effect, which was inadvertently noticed during

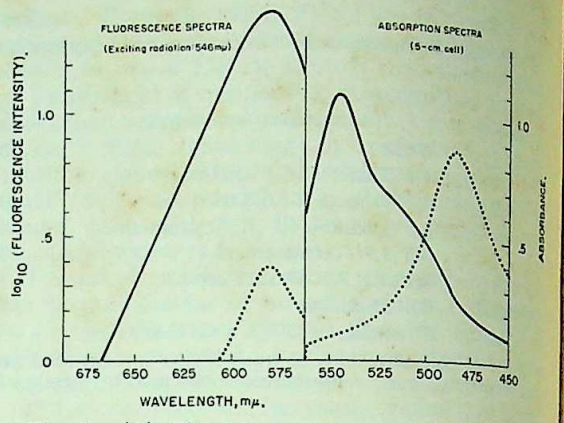

Fig. 2.—(A) Fluorescence spectrum of thioindigo in benzene: (. . . . . .) mainly *cis* form, from chromatographic separation; (———) the same solution, after irradiation with blue light. (B) Absorption spectra of the same two solutions; concentration, 4 mg./l.

the feasibility of using ethanol in the chromatographic separation of the two thioindigo isomers was explored, is shown in Fig. 3.

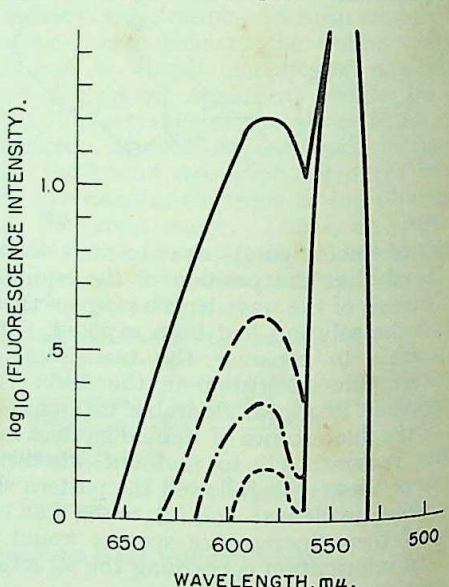

Fig. 3.—Effect of ethanol on the fluorescence spectrum of thioindigo in benzene. Concentration of dye, 2 mg./l.; concentration of ethanol, (———) 0%; (– – – –) 5%; (—·—·—) 10%; (·····) 20% by volume. Exciting light, 546 mμ.

In order to show that the fluorescence quenching by ethanol is not brought about by conversion of the *trans* isomer to the non-fluorescing *cis* form of thioindigo, the following experiment was carried out. Two solutions of equal thioindigo concentration were made up, one in benzene and the other in benzene containing 10% ethanol. The visible absorption spectra of these solutions were recorded after pre-irradiation with blue light and then after pre-irradiation with yellow light. The pre-irradiations were for five minute periods and were made under the same conditions for each solution. The results (cf. Table II) show that the presence of etha-

Blue light	1.00	1.00
Yellow light	0.38	0.72

[a] Calculated from absorbancies at 562 mμ, where the *cis*-thioindigo does not absorb appreciably. [b] In 10% ethanol the *trans* absorption band is shifted slightly (*ca.* 2 mμ) to longer wave length.

Discussion of Results

While at the present time our understanding of the relation between fluorescence spectra and chemical structure is not as thorough as it is with respect to electronic or vibrational spectra, nonetheless, it has been possible to arrive at certain correlations in this respect.[6] A molecule which has been raised to an electronically excited state by the absorption of a quantum of light of appropriate frequency, can lose this excess energy and return to the ground state by one of three processes: internal conversion, external conversion or fluorescent emission. *Internal conversion* occurs when the energy of electronic excitation is converted to some other form of energy (*e.g.*, heat) by the absorbing molecule. While it is believed that most radiationless transitions occur in this manner, the exact nature of this process is not fully understood at the present time. *External conversion* is said to occur when the excited molecule through collisions transfers its excess energy to one or more other molecules, *e.g.*, solvent molecules. *Fluorescent emission* occurs only when the excited molecule cannot readily lose its energy by either of these processes. The probability for *internal conversion* depends principally on the structure of the molecule, while the ease of external conversion is a function of the solvent and the temperature. Consequently, whether or not a given molecule will exhibit fluorescence under certain conditions will be determined by both structural and environmental factors. By studying the fluorescence of different compounds under comparable conditions, it is possible to cancel out the environmental variables and thus to correlate fluorescence with chemical structure.

The failure of *cis*-stilbene to exhibit fluorescence (in contrast with its *trans*-isomer) was attributed by Lewis, Magel and Lipkin to its non-coplanar structure, which results from the steric interference of the *ortho*-hydrogen atoms of the two benzene rings.[2] According to their views the coplanar *trans*-stilbene molecule is prevented from *internal conversion* of its electronic energy because of its rigidly-held compact structure. In the non-coplanar *cis* isomer, on the other hand, which is not constrained by nearly as much resonance energy, the energy of electronic excitation is relatively readily converted to vibrational energy and/or dissipated as heat. Studies of the fluorescence of 4,4′-stilbenedicarboxamidine,[3a] 9,9′-diphenanthrylethylene and 1,4-diphenylbutadiene[4a,4b] have indicated that this behavior was characteristic of aromatic olefins and have thus provided further support for this interpretation.

It is clear from the results of the present investigation that thioindigo derivatives also follow the pattern set by the aromatic olefins. This immediately suggests a compact, coplanar structure for the *trans* compounds and a less constrained non-coplanar configuration for the *cis* isomers. Recent X-ray diffraction studies on crystalline thioindigo indicated that in the solid phase the dye exists in a tightly-held, coplanar *trans* configuration.[7] The unusually short distance (2.82 Å.) between the sulfur and oxygen atoms of adjacent rings was considered to indicate the existence of secondary bonds (probably stemming from electrostatic attraction) between these atoms, thus resulting in further stabilization of the *trans* structure.

A scale drawing of the structure of the two thioindigo isomers is shown in Fig. 4. The *trans* isomer

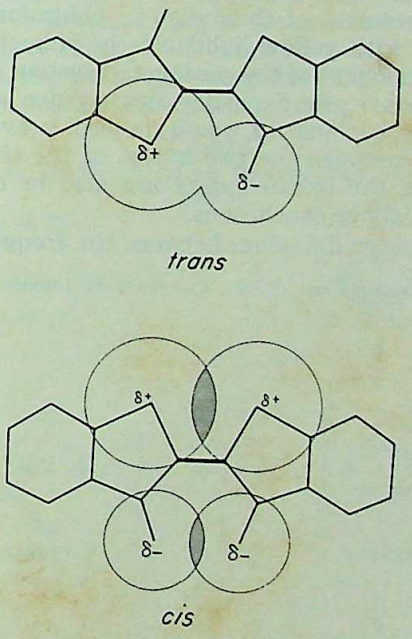

Fig. 4.—Diagram of the spatial arrangement of atoms in *cis*- and *trans*-thioindigo.

was drawn on the basis of Mme. v. Eller's data[7] while the structure of the *cis* isomer was constructed by rotating half of the *trans* molecule 180° about the central axis. The circles were drawn to scale using the van der Waals radii of 1.40 Å. for oxygen and 1.85 Å. for sulfur. It is readily apparent from Fig. 4 that the steric interference of the two carbonyl oxygen atoms and the two sulfur atoms would be expected to cause a departure from coplanarity in the *cis* isomers. Since oxygen atoms of carbonyl groups carry a partial negative charge[8] and the sulfur atoms in a resonating system of this type are probably carrying a slight positive charge, the steric

effect will be further augmented by electrostatic repulsion. Since the hemithioindigoid dye Vat Scarlet G also behaves in a similar manner even though it only possesses one sulfur atom, it appears that the steric hindrance induced by the overlapping and the repulsion of the carbonyl groups alone is sufficient to induce non-coplanarity.

The departure from coplanarity brought about in the *cis*-thioindigo dyes by a combination of steric hindrance and electrostatic repulsion is further substantiated by the visible and infrared spectra of these compounds. In the visible region the *cis* isomers have been reported to show absorption of much shorter wave lengths (by *ca.* 60 mμ) than do their *trans* counterparts.[5a,5b] This hypsochromic shift has been attributed to the higher potential energy of the *cis* over the *trans* in their excited states, with these excited states pictured as having a central carbon–carbon single bond and charged oxygen and sulfur atoms. Electrostatic repulsion of the two oxygen atoms and of the two sulfur atoms in the excited *cis* form would give it a higher potential energy and would also force non-coplanarity. In the infrared spectrum the observed shift of the carbonyl stretching band from 6.04 to 5.90 μ when a solution of thioindigo in chloroform is irradiated with yellow light[9] clearly indicates a severe curtailment of the conjugated system in which the carbonyl group participates. Since a departure from coplanarity would, indeed, prevent conjugation between the two halves of the thioindigo molecule, the infrared data are also in harmony with the above conclusions.

The energy difference between the frequencies of the *trans* absorption maximum and that of the maximum fluorescence intensity is small for the thioindigo dyes I through VII. It varies between 2.1 kcal./mole for dye V and 3.8 kcal./mole for dye VII. These low energy differences indicate that *trans* to *cis* conversion probably cannot accompany fluorescence, but instead is a competitive photochemical process.

The observed effect of the addition of ethanol to a benzene solution of *trans*-thioindigo indicates that not only is the quantum yield of fluorescence decreased, but that the efficiency of the *trans* to *cis* photoisomerization is also diminished. This suggests that a third, competing photochemical reaction is involved. Perhaps this is due to the formation of a loosely held complex between the alcohol and the dye, or, alternatively, some other mechanism by which energy can be transferred from the dye to an ethanol molecule. While the carbonyl stretching frequency of thioindigo in chloroform is only slightly affected by the addition of ethanol,[10] the possibility of complex formation cannot be definitely ruled out. It is interesting to note in this connection that thioindigo dyes do not exhibit fluorescence when dyed on cellophane or on cellulosic fibers. Since these polysaccharides are chemically similar to ethanol, this suggests an analogy between the mechanism by which the fluorescence of these dyes is quenched by ethanol and their reported "tendering" effect on cotton.[11]

Relative Extents of Catalytic Hydrogen–Deuterium Exchange in the Nuclear Positions of Phenylacetamide[1,2]

BY WILLIAM A. BONNER

RECEIVED DECEMBER 19, 1956

When phenylacetamide was treated with deuterated Raney nickel in refluxing deuteroethanol, 49% of the α-hydrogens and 42% of the nuclear hydrogens underwent hydrogen–deuterium exchange. The product was degraded to aniline, and various nuclear positions of the aniline were selectively brominated. Deuterium assays of the brominated samples indicated the nuclear deuterium distribution as 26% *ortho*-, 46% *meta*- and 28% *para*-. Repetition of this deuteration in benzene solvent for thrice the reaction time led to H–D exchange at only 6.5% of the α-hydrogens and 2.6% of the nuclear hydrogens of phenylacetamide. These results are discussed briefly with regard to the mechanism of nuclear H–D exchange under these catalytic conditions.

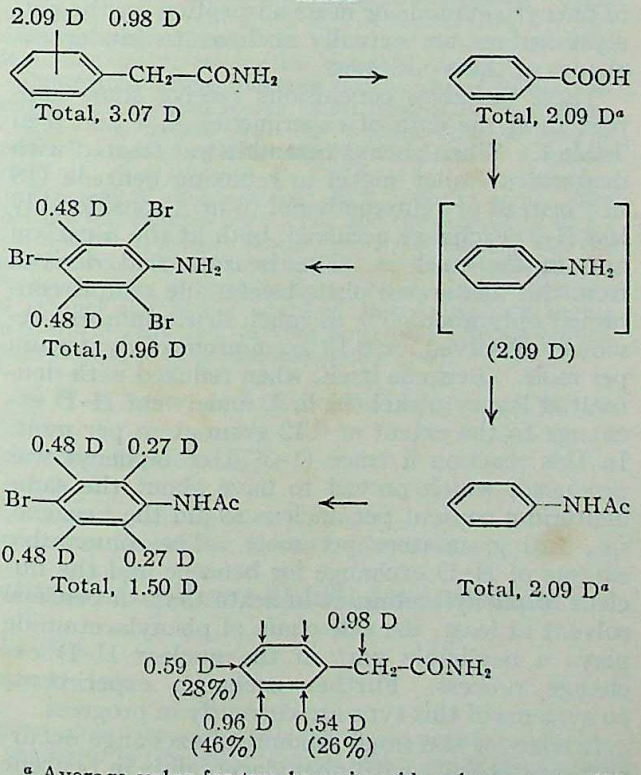
Recently we reported[3] that both α-hydrogen and nuclear hydrogen atoms in mandelamide and phenylacetamide undergo exchange with deuterium on treatment with deuterated Raney nickel catalyst in refluxing deuteroethanol. When these studies were extended to optically active 2-phenylpropionamide, it was found[4] that such exchange processes occurred more rapidly than did racemization, indicating a certain stereospecificity for such exchange reactions. This stereospecificity, as well as the occurrence of ring and methyl-group exchange, were tentatively rationalized[4] in terms of a stereospecifically adsorbed carbonium ion intermediate. Ethylbenzene was similarly shown[4] to undergo nuclear hydrogen–deuterium exchange under the same conditions.

If nuclear H–D exchange occurred as postulated[4] *via* a benzyl type carbonium ion intermediate and its nuclear canonical stabilizing structures, then nuclear H–D exchange ought to occur predominantly in the *o*- and *p*-positions of the aromatic ring. In order to test this hypothesis we have again engendered α-position and nuclear H–D exchange in phenylacetamide by the action of deuterated Raney nickel in refluxing deuteroethanol. The deuterated phenylacetamide product was oxidized to benzoic acid, and deuterium assays of the two substances provided an indication of nuclear *vs.* chain deuteration. The relative extents of ring deuteration at the *o*-, *m*- and *p*-positions of the benzoic acid product were determined by conversion of the latter to aniline, then by selective bromination of appropriate derivatives of the aniline, followed by deuterium assay of the bromination products. The results of these experiments are indicated in Table I, and the conclusions regarding relative positions of H–D exchange reached therefrom are summarized in Chart I.

Chart I indicates approximately 1:1.8:1.1 ratios, respectively, for the *o*, *m*- and *p*-distribution of deuterium atoms in the phenyl nucleus of phenylacetamide. Ratios for random nuclear exchange would be 2:2:1. It is interesting to compare these results with those of Lauer and Errede[5] who studied the action of Raney alloy in refluxing deuterium oxide with sodium deuteroxide on aniline. Using similar techniques, they found exchange ratios of about 6.5:1.0:1.2, respectively, for the *o*-, *m*- and *p*-positions of aniline under these conditions. The predominant exchange at the *o*-position was attributed to the anchoring of the aniline molecule to the catalyst through the electron pair of nitrogen, thus locating the *o*-hydrogens sterically in the most favorable position for exchange.

CHART I

DEUTERIUM DISTRIBUTION IN DEUTERATED PHENYLACETAMIDE



ᵃ Average value for two benzoic acid and one acetanilide assays.

From the data in Table I and Chart I it is clear that there is no marked selectivity for any specific nuclear position in the catalytic H–D exchange of phenylacetamide. This argues against such nu-

[a] Reaction employing deuterated Raney nickel in absolute C_2H_5OD. [b] Reaction employing deuterated Raney nickel in benzene. [c] Obtained from the relation $18 \times \% D_2O/20 \times \% H_2O = D/H$. [d] Total number of H-species atoms in the product molecule. [e] Average of two determinations.

clear exchange resulting as a consequence of resonance stabilization of a benzylcarbonium ion intermediate as previously hypothesized[4] and suggests rather that nuclear H–D exchange here is a more or less random process occurring *independently* of any additional exchange taking place at the α-carbon. Also, by Lauer's argument, our relatively low value for exchange at the *o*-positions indicates that the benzyl carbon was in all probability in no way involved in attaching the molecule to the catalyst surface. The lower than statistical exchange value at the *o*-positions, in fact, argues that steric factors in phenylacetamide or in its adsorption on the catalyst surface are actually such as to hinder exchange at these positions.

These tentative conclusions receive some support from the data of experiments, 6, 7 and 8 in Table I. When phenylacetamide was treated with deuterated Raney nickel in refluxing benzene (18 hr.) instead of deuteroethanol (6 hr.), considerably less H–D exchange occurred, both at the α-carbon and in the nucleus. The benzoic acid derived from this deuterated phenylacetamide sample contained only about 6% as much deuterium as previously observed, or 0.13 gram-atom of deuterium per mole. Benzene itself, when refluxed with deuterated Raney nickel (30 hr.), underwent H–D exchange to the extent of 0.12 gram-atom per mole. In this reaction a trace (1–3%) of biphenyl was produced, which proved to have about the same deuterium content per nucleus as did the benzene, *i.e.*, 0.20 gram-atom per mole. The comparable extents of H–D exchange for benzene and the nucleus of phenylacetamide indicate that, in benzene solvent at least, the side chain of phenylacetamide plays a negligible part in the nuclear H–D exchange process. Further exchange experiments on systems of this type are currently in progress.

In view of the small amount of exchange occurring catalytically with phenylacetamide in benzene solution, we have again[3] attempted the dehydroxylation of optically active mandelamide to produce optically active α-deuterophenylacetamide. When L(+)-mandelamide was treated with deuterated Raney nickel in refluxing benzene solution for 5 hr., the phenylacetamide recovered proved, however, to be optically inactive.

Experimental

Deuterated Raney Nickel. Sample A.—About 50 g. of Raney nickel[6] was equilibrated three times for 24-hr. periods with heavy water (30-ml. portions) (recovered from previous experiments[4]; distilled from a trace of sodium hydroxide; containing some dioxane), then for 2.5 days with 18 ml. of 99+% deuterium oxide. The catalyst so prepared was filtered damp-dry by suction immediately prior to its use.

Sample B.—Freshly prepared Raney nickel[6] was filtered damp-dry (55 g.) on a sintered funnel, then treated with thorough mixing with 8 ml. of 99+% deuterium oxide having d^{20} 1.077. After two days the mixture was sucked damp-dry at the aspirator, then treated with thorough mixing with an additional 8 ml. of 99+% D_2O. The filtrate had d^{20} 1.038. After a second 2-day period the mixture was again filtered damp-dry and treated with an additional 8 ml. of 99+% D_2O. The second filtrate had d^{20} 1.064. After seven days the mixture was again sucked damp-dry, and the filtrate was found to have d^{20} 1.077. The catalyst sample was assumed at this point to be completely deuterated and was used without further equilibration.

Deuterated Raney Nickel with Phenylacetamide.—Phenylacetamide (6.00 g.) was dissolved with heating in absolute deuteroethanol[3] (34 ml.), whereupon the entire sample of deuterated Raney nickel was added after sucking damp-dry from its final equilibration rinse. The mixture was heated under reflux (calcium chloride tube protection) with occasional swirling during an 8-hr. period, then filtered on a sintered funnel. The filter cake was rinsed thoroughly with ethanol and acetone, then sucked damp-dry (50 g.). The filtrate was evaporated to dryness, and the residue was dissolved in ethanol (100 ml.) to exchange $-ND_2$ for $-NH_2$. The solution was again evaporated, to yield 5.64 g. (94%) of deuterated phenylacetamide. A small portion of this product was recrystallized from a mixture of ethanol and ligroin to provide a sample for deuterium assay. The deuterium content was measured as previously[3] by combustion, collection of the combustion water and mass spectrographic assay of the latter[7]; combustion water, % D_2O, 36.5.

Hydrolysis and Oxidation of Deuterated Phenylacetamide.—The above deuterated phenylacetamide (5.57 g.) was stirred under reflux with 10% sodium hydroxide solution (100 ml.) and glass beads. After ten minutes, solution of the amide was complete, and potassium permanganate (10 g.) was gradually added to the reaction mixture. After initial foaming had subsided, an additional 10 g. of potassium permanganate was added, and the mixture was stirred under reflux during 2 hr. Excess sodium sulfite was added to destroy residual permanganate, and the mixture was filtered to remove MnO_2. The cake was rinsed well with water, and the filtrate was acidified. The precipitated benzoic acid was filtered, and the filtrate was extracted four

times with C.P. ether. The extract was washed, dried and evaporated. The total crude benzoic acid weighed 4.78 g. (95%). A sample of this acid was recrystallized (Norit) from water, then sublimed *in vacuo* prior to assay, m.p. 121.5–122.5°; combustion water, % D_2O, 35.1.

Deuterated Benzamide.—The above deuterated benzoic acid (4.06 g.) was converted to benzamide by refluxing with thionyl chloride, followed by treatment of the residue therefrom with chilled ammonium hydroxide. The crude amide was recovered in 1.60 g. (40%) yield. It was recrystallized from a mixture of ethanol (1 ml./g.) and ligroin (3 ml./g.) to yield two crops: (1) 1.26 g., m.p. 126–127° and (2) 0.25 g., m.p. 121–123.5°.

Hofmann Degradation of Diluted Deuterated Benzamide.—1.487 g. of the above deuterated benzamide was diluted with 1.487 g. of recrystallized stock benzamide. The mixture was treated with a solution of potassium hydroxide (4.2 g.) and bromine (1.42 ml.) in water (38 ml.). The mixture was swirled thoroughly, then treated with a solution of potassium hydroxide (5.9 g.) in water (10 ml.). The temperature was maintained at 70–80° for 35 minutes, whereupon the mixture was steam distilled, collecting 75 ml. of distillate. The distillate was salted and extracted four times with ether. The extract was dried over potassium hydroxide, filtered and freed of solvent through a small column. The residue was 2.24 g. (98%) of crude aniline.

Deuterated Tribromoaniline.—Bromine (0.5 ml.) in acetic acid (3 ml.) and water (2 ml.) was added with stirring to 0.3 ml. of the above aniline dissolved in a mixture of acetic acid (2 ml.) and water (3 ml.). After five minutes the mixture was diluted with water, and the crude tribromoaniline (0.95 g., 89%) was collected. The latter was recrystallized twice (Norit) from dilute ethanol, to give 0.29 g. of a sample having m.p. 119.5–120°; combustion water, % D_2O, 13.1; corrected for dilution, 26.2%.

Deuterated Acetanilide.—One and nine-tenths grams of the above aniline was converted to acetanilide by the method described by Fieser.[8] The crude product was obtained in 1.13 g. (41%) yield. A sample was purified by vacuum sublimation prior to deuterium assay, m.p. 113.5–114.5°; combustion water, % D_2O, 13.5, 12.5; corrected for dilution, 26.0%.

Deuterated *p*-Bromoacetanilide.—One gram of the above acetanilide was brominated according to the procedure of Fieser,[9] using proportional reagent quantities. The crude product, 1.51 g. (95%), was recrystallized twice from dilute ethanol prior to deuterium assay, m.p. 167–167.5°; combustion water, % D_2O, 10.2; corrected for dilution, 20.4%.

Action of Deuterated Raney Nickel on Benzene.—About 4 g. of the above sample B deuterated Raney nickel was sucked damp-dry and treated with 40 ml. of azeotropically dried benzene. The mixture was distilled to a small volume, then treated with additional benzene and distilled to a residual volume of about 10 ml. At this point the clumped catalyst had become evenly dispersed through the solvent, no more D_2O was apparent in the distillate and the catalyst was quite pyrophoric. The mixture was refluxed during 30 hr., then filtered damp-dry. The residual catalyst was markedly pyrophoric. Odor and infrared examination of the filtrate suggested the presence of a product other than benzene. Evaporation of 5.38 g. of the filtrate left a pasty residue of 0.07 g. (1.3%). This smelled like biphenyl and was purified twice by sublimation at 70° (0.5 mm.). The white sublimate had m.p. 69–70° and showed no mixed m.p. depression with a sublimed sample of biphenyl (m.p. 69–70°). In another experiment 2.40 g. of the above filtrate left 0.08 g. (3.7%) of crude biphenyl. This was purified by sublimation and combusted for deuterium assay; combustion water, % D_2O, 2.3.

A 0.25-ml. sample of the above benzene filtrate was freed of its deuterated biphenyl by passage through a 4-foot Celite–Silicone vapor phase chromatographic column.[10] The benzene fraction was collected[10] and combusted for deuterium assay; combustion water, % D_2O, 2.3.

Deuterated Raney Nickel in Benzene on Phenylacetamide.—A portion of sample B deuterated Raney nickel above was sucked damp-dry (25 g.). The damp sample was added to azeotropically topped benzene (300 ml.), and the mixture was distilled down to 60 ml., driving off the majority of residual D_2O and giving a uniform suspension of catalyst. Phenylacetamide (6.00 g.) and dry benzene (10 ml.) were added, and the mixture was refluxed for 18 hr. under $CaCl_2$-tube protection. The hot mixture was filtered and the cake was rinsed twice with boiling benzene and five times with boiling acetone. Solvent evaporation left 5.40 g. (90%) of product. A portion thereof was recrystallized twice from an ethanol–ligroin mixture, m.p. 157–158°; combustion water, % D_2O, 3.1.

In a separate experiment it was found that ordinary Raney nickel in benzene had no readily detectable chemical action on phenylacetamide during 65 hr. of refluxing.

Hydrolysis and Oxidation of Deuterated Phenylacetamide.—A 5.20-g. portion of the above deuterated phenylacetamide was hydrolyzed as before with refluxing 10% sodium hydroxide solution (100 ml.), then oxidized by treatment with excess potassium permanganate. Usual processing led to 4.11 g. (87.5%) of benzoic acid. A portion was recrystallized from water and sublimed prior to deuterium assay; combustion water, % D_2O, 2.5.

Deuterated Raney Nickel in Benzene on L(+)-Mandelamide.—Deuterated Raney nickel (sample B, 23 g. damp weight) was treated with dry benzene (200 ml.). The mixture was azeotropically dried by distillation to a volume of 60 ml., then treated with 1.00 g. of L(+)-mandelamide ($[\alpha^{25}]D$ +69.0° (*c* 2, acetone), 96% optically pure). The mixture was refluxed for 5.2 hr., and the product (0.40 g.) was isolated as usual. It was dissolved in ethanol, and the solution was allowed to stand 18 hr., then evaporated to dryness. Two recrystallizations (Norit) from a mixture of ethanol and ligroin produced phenylacetamide having m.p. 157.5–158° and showing no optical activity beyond experimental error in acetone solution (*c* 3).

The Dipole Moments and Molecular Structures of *ac-trans*-Dihalogenotetralins[1]

BY TOSHIO FUJITA

RECEIVED SEPTEMBER 11, 1956

The dipole moments of 2,3-dihalogenotetralins and 1,2-dihalogenotetralins were measured in solution at various conditions, to show that each of these compounds has a half-chair ring and can occur in two conformations which are in equilibrium through ring conversion. Then, the energy difference ΔE between the two conformations of each compound is estimated. From comparison of the ΔE values, it is concluded that the properties of 2,3-dihalogeno compounds are very similar to those of corresponding dihalogenocyclohexenes, and the *aa* conformation of the 1,2-isomers is more stable than that of the 2,3-isomers.

The concept of "non-bonded energy"[2] in cyclohexane derivatives has given clear explanations to

the stereostructures of polycyclic perhydro-systems, especially those of the steroids, and has been generally considered to be applicable to the partially unsaturated polycyclic compounds involving the cyclohexene or tetralin systems.[3] It has been concluded by several investigators[4–6] that, as in the case of cyclohexane derivatives, cyclohexene derivatives also are more stable in the half-chair form than in the half-boat form and can occur in two conformations which are in equilibrium through ring conversion, unless the energy difference between the two is too large.

If the small difference between the double bond lengths of cyclohexene and tetralin be neglected, quite similar arguments may be applied in these two systems. There has been, however, relatively little experimental evidence about the stereostructures of tetralin derivatives other than the X-ray analysis by Lasheen,[7] who has shown that naphthalene tetrachloride has a half-chair ring.

In the work herein reported, dipole moments of four dihalogenotetralins (I–IV) were measured at various conditions to shed more light on the stereostructures of tetralin derivatives, especially that of 1,2,3,4-tetrahydro-1-naphthoic acid, a synthetic plant growth substance,[8] which has been investigated in the author's laboratory.

Experimental

Preparation of Materials.[9] **2,3-Dihalogenotetralins (I) and (II).**—To a solution of 10 g. (0.077 mole) of 1,4-dihydronaphthalene,[10] b.p. 89–92° (20 mm.), in 50 ml. of carbon tetrachloride, 50 ml. of carbon tetrachloride containing 5.5 g. (0.078 mole) of chlorine or 12.5 g. (0.078 mole) of bromine was dropped slowly with stirring at 0°. The solvent was removed *in vacuo*, and the residue was recrystallized several times from ethanol to give 8 g. of I, m.p. 83.5–84° (reported[11] 84–85°), or 15 g. of II, m.p. 73–73.5° (reported 71.5–72°,[10] 73.5–74°),[12] respectively.

1,2-Dihalogenotetralins (III) and (IV) were prepared by halogen addition to 1,2-dihydronaphthalene,[10,13] b.p. 90° (20 mm.), in a procedure similar to that used in preparing the 2,3-isomers. From 3 g. of 1,2-dihydronaphthalene, there was obtained 2.5 g. of III, m.p. 40–41°. *Anal.* Calcd. for $C_{10}H_{10}Cl_2$: Cl, 35.28. Found: Cl, 35.43. Braun and Kirschbaum[13] prepared liquid 1,2-dichlorotetralin, b.p. 155–160° (20 mm.), by direct chlorination of tetralin at 100°, and reported that this substance did not crystallize on cooling. It seems likely that this liquid was a mixture of *cis*- and *trans*-isomers.

In a similar manner, 5 g. of IV was obtained, m.p. 71–72° (reported 70–71°,[10] 70°[13]).

Solvents.—Benzene, freed from thiophene by treatment with anhydrous aluminum chloride, was dried over metallic sodium and then distilled, and the fraction boiling at 80–80.5° was collected. *n*-Heptane was treated with coned. sulfuric acid, dried over metallic sodium and then distilled, and the fraction boiling at 95.5–98° was collected.

Measurement.—The dielectric constant ϵ of the solution was measured with the heterodyne beat apparatus as described by Morino and Miyagawa.[14] The density d was determined with a pycnometer similar to that designed by Lipkin, Davison, Harvey and Kurtz.[15] The total molar polarization $P_{2\infty}$ was calculated by a modified Hedestrand method similar to that introduced by Halverstadt and Kumler,[16] differing in that densities were used rather than specific volumes

$$P_{2\infty} = \frac{\epsilon_1 - 1}{\epsilon_1 + 2}\frac{M_2}{d_1}\left[1 + \frac{3a}{(\epsilon_1 - 1)(\epsilon_1 + 2)} - \frac{b}{d_1}\right]$$

where M_2 is molecular weight of solute, ϵ_1 and d_1 are, respectively, the dielectric constant and density of the solvent, and a and b are the coefficient of linear expansion of ϵ and d of solution with respect to the weight fraction of the solute w; $\epsilon = \epsilon_1 + aw$, $d = d_1 + bw$. The dipole moment μ is given by the equation

$$\mu = 0.0128[\{P_{2\infty} - (P_E + P_A)\}T]^{1/2}$$

where P_E and P_A are the electronic and atomic polarization of the solute, respectively, and T is the temperature in absolute scale. $P_E + P_A$ was taken to be equal to the molecular refraction calculated from the atomic refractions given in the Landolt–Börnstein table. The values thus obtained are listed in Table I. The experimental error in μ is ± 0.02 *D* in I and III and $\pm$ 0.03 *D* in II and IV.

Discussion

An appropriate model of the tetralin molecule is required for the analysis of the moment values obtained. First, the half-chair model will be discussed. It is assumed that unsaturated and allylic carbon atoms are coplanar, and the intramolecular distortions are minimum when the bond distances

and bond angles in Fig. 1 are taken as follows: C=C, 1.38 Å.; C—C, 1.54 Å.; $\angle\theta = 122°$, $\angle\gamma = 111°04'$, $\angle\delta = 108°$, $\angle\beta = \angle\beta' = 109°28'$, $\angle\alpha = 109°50'$, $\angle\alpha' = 109°04'$. To calculate the dipole moments, (i) as the moment value of tetralin itself, 0.52 *D* in benzene obtained by Sidgwick and Springall[17] is used, and (ii) the empirical rule suggested by Morino, Miyagawa and Oiwa[18] is applied, which is as follows: (1) C → Cl, C → Br and C → H bond moments are assumed to be 1.86, 1.79[19] and 0.00 *D*, respectively. (2) In the C—C bond in which C atom locates in the α-position to the first halogen atom, a moment of 0.27 *D* (hal. = Cl) or 0.51 *D* (hal. = Br) is induced in the direction of C ← C. (3) In the C—C bond in which C atom locates in the β-position to the first halogen atom, a moment of 0.15 *D* is induced in the direction of C ← C. (4) In the C—halogen bond in which C atom locates in the β-position to the first halogen atom, a moment of 0.24 *D* (hal. = Cl) or 0.42 *D* (hal. = Br) is induced in the direction of C ← halogen.

The calculation by this rule, instead of using 1.91 *D* for C—halogen bond moment,[20] seems reasonably accurate because of the good agreement of observed and calculated moment values of a number of halogenated hydrocarbons, especially polyhalogenocyclohexanes.[18,21]

In III and IV, this rule cannot be directly applied; therefore, the double bond in the benzene ring is regarded to be a single bond. This assumption may be quite adequate, because the induction effect estimated from this assumption is nearly equivalent to that from the moment values of benzyl halide and methyl halide.

TABLE II

DIPOLE MOMENTS CALCULATED FROM MOLECULAR MODEL[a]

	cis		*trans*	
	ae	*ea*	*aa*	*ee*
I, 2,3-Dichloro-	2.70	2.70	0.09	3.15
II, 2,3-Dibromo-	2.57	2.57	.51	3.10
III, 1,2-Dichloro-	3.13	3.28	.96	3.24
IV, 1,2-Dibromo-	3.01	3.08	1.32	3.26

[a] Symbols *a* and *e* are used as in cyclohexane derivatives; *a*, nearer to the perpendicular of the benzene ring; *e*, nearer to the plane of the benzene ring than the other.

The moments thus calculated for different conformations of each geometrical isomer are shown in Table II. From this table it is clear that if these compounds are of *trans* configurations, the apparent average moment values should vary with the abundance ratio of two conformations at a given temperature unless the energy difference ΔE between them is too large, because the calculated moment values

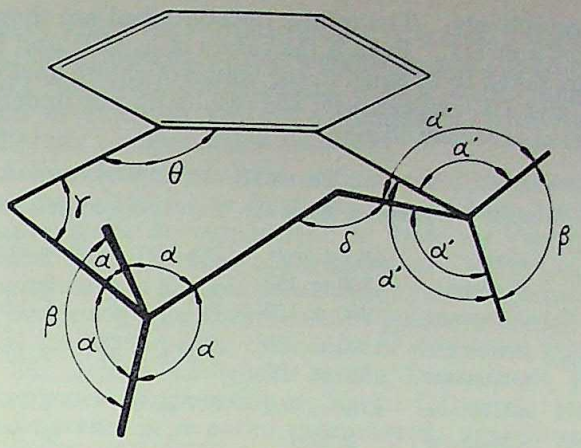

Fig. 1.

undergo appreciable change through ring conversion. On the other hand, if these are of *cis* configurations, their moment values should be observed in the neighborhood of 2.5–3.0 *D* relatively independent of the temperature. But actually, as shown in Table I, the observed values are found around 1.6 *D* (I), 1.1 *D* (II), 1.5 *D* (III) and 1.3 *D* (IV), and apparent moments of I, II and III increase with temperature. Therefore, it is concluded that these four compounds are of *trans* configurations and that the addition of halogen to dihydronaphthalene proceeds as a *trans* addition.

The more stable conformation of I, II or III is obviously *aa*. In IV, $d\mu/dT \fallingdotseq 0$. If the energy difference ΔE between two conformations were equal to zero, then the apparent moment value should become 1.8 *D* independently of temperature. Because the observed moment values 1.35 *D* are in good agreement with the calculated value for the *aa* conformation, 1.32 *D*, IV exists almost entirely as the *aa* conformation.

Let the number of the *aa* molecules be N_a and that of the *ee* molecules be N_e, then the following equation is obtained; $N_e/N_a = e^{-\Delta E/RT}$, and the apparent dipole moment $\bar{\mu}$ is calculated as

$$\bar{\mu}^2 = \frac{N_e\mu_e^2 + N_a\mu_a^2}{N_e + N_a} = \frac{\mu_a^2 + \mu_e^2 \exp(-\Delta E/RT)}{1 + \exp(-\Delta E/RT)}, \text{ or}$$

$$\bar{\mu}^2 - \mu_a^2 = \frac{\mu_e^2 - \mu_a^2}{1 + \exp(\Delta E/RT)}$$

where μ_a and μ_e are the theoretical moment values of *aa* and *ee* conformations, respectively. Using the apparent moment values $\bar{\mu}$ observed at different temperatures and the calculated moment values μ_a in Table II, the energy differences ΔE and the moments μ_e of the *ee* conformations are calculated for I, II and III, according to the method proposed by Lennard-Jones and Pike.[22] The lower limit of ΔE of IV is obtained from the equation[23]

$$4\Delta\mu\cdot\bar{\mu} \geqq (\mu_e^2 - \mu_a^2)[1/\{1 + \exp(\Delta E/RT)\} - 1/\{1 + \exp(\Delta E/RT')\}]$$

where $\Delta\mu$ is the experimental error, T and T' are the highest and lowest temperatures at which the moments are measured. In this equation, $\Delta\mu$, $\bar{\mu}$, μ_a and μ_e are taken to be 0.03, 1.35, 1.32 and 3.22 *D*,

respectively. The results thus obtained are shown in Table III. Even if the values of μ_a of II and IV are taken to be equal to the values of chloro analogs I and III, respectively, the results do not undergo an appreciable change.

TABLE III

ENERGY DIFFERENCE BETWEEN TWO CONFORMATIONS

	Solvent	ΔE, cal./mole	μ_e, D	μ_a (D) calcd. from model
I	Benzene	800 ± 150	3.6 ± 0.3	3.15
	n-Heptane	900 ± 150		
II	Benzene	1400 ± 200	3.5 ± 0.3	3.10
	n-Heptane	1550 ± 200		
III	*n*-Heptane	1350 ± 150	3.7 ± 0.4	3.24
IV	*n*-Heptane	≧2000	.....	3.26

As discussed above, the half-chair model can well explain the observed moment values. On the other hand, the model of the half-boat form cannot, because the calculated moment values become considerably larger than the observed values, *e.g.*, in the compound I, *cis* form, *2e3e* (3.3 *D*) ⇄ *2a3a* (3.5 *D*); *trans* form, *2a3e* = *2e3a* (2.2 *D*). Recently, Kumler and Huitric[24] have demonstrated that "six-membered ring compounds with two or more atoms in the ring that do not have sp^3-binding, such as a bivalent atom or a carbonyl which has essentially sp^2-binding, are most likely to have flexible forms" from the study of the molecular structures of α-halocyclohexanones. These dihalogenotetralins are such a type of compound since the ring with halogens has two carbon atoms with sp^2-binding. Even if the observed facts can well be explained by the half-chair model, it is too much to decide only from dipole moment values that these dihalogenotetralins have the half-chair structure and have not any contributions from the half-boat or the other flexible structures. The fact that compounds I, II and III have different moments in benzene and *n*-heptane and that the moments in any one solvent vary with temperature, may be accounted for by the alternative hypothesis that a flexible form makes an appreciable contribution to the structure, according to Kumler and Huitric's idea.

However, taking into consideration Sakashita's results,[6] from Raman spectra of *trans*-4,5-dichloro-1-cyclohexene, that this compound has only two possible structures in the liquid state or solution, and from the dipole moment values, that the observed facts can well be explained only when these two possible structures are the *aa* and *ee* conformations of the half-chair structure, it is quite reasonable to conclude that these tetralin derivatives, structurally very similar compounds to dichlorocyclohexene, are also of half-chair ring structure.

The fact that ΔE of II or IV is, respectively, larger than that of I or III in the same solvent, may be caused by the larger van der Waals radius of the bromine atom, as in the case of dihalogenocyclohexanes and -cyclohexenes.

The structural chemical properties of 2,3-dihalogenotetralins are very similar to those of the corresponding dihalogenocyclohexenes, as shown in Table IV. It seems that in these substances, where a condensed benzene ring is compared with a double bond, there are no remarkable differences in the properties, as the various interactions about halogen atoms opposite to a double bond or a benzene ring are nearly the same. The change of ΔE with solvent may be explained as in the case of the rotational isomers of 1,2-dihalogenoethanes,[25] in which the energy difference decreases with the increasing dielectric constant of the solvent.

TABLE IV

ΔE VALUES (CAL./MOLE) OF I AND II, AND THEIR RELATED COMPOUNDS IN VARIOUS SOLVENTS

X	Solvent			Cl	C_6H_6	−400[a]	700[b]	800
	n-C_7H_{16}	..	...	900

Br	C_6H_6	80[a]	1300[c]	1400
	n-C_7H_{16}	500[a]	...	1550
	CCl_4	500[a]	1400[c]	..

[a] K. Kozima, K. Sakashita and S. Maeda, THIS JOURNAL, 76, 1965 (1954). [b] Ref. 6. [c] K. Sakashita, private communication, April, 1956.

The increase of ΔE from dihalogenocyclohexanes to -cyclohexenes or -tetralins is supposed to be caused partly by the following factor. In these compounds, the *aa* conformation is subjected to the mutual repulsion between hydrogen and halogen atoms which are in so-called *meta-axial* relationship. In dihalogenocyclohexane, there are 4 *meta-axial* pairs in *aa* conformation, but in dihalogenocyclohexene and -tetralin, owing to the disappearance of two hydrogen atoms, there are only 2 *meta-axial* pairs. Therefore, it seems that *aa* forms of the latter two are less subjected to such repulsion than the former, so *aa* forms of dihalogenocyclohexene and -tetralin are more stable than that of dihalogenocyclohexane.

It is clear from Table III that ΔE values of 1,2-dihalogenotetralins are considerably larger than those of the corresponding 2,3-dihalogenotetralins. The bonds attached to C-1 are not truly equatorial or axial in character, and the directions of these bonds are less distinguishable than those attached to C-2, but the interactions of halogen atom at C-1 with C-8 and H at C-8 do not exist in the 2,3-isomers, and it is considered that these interactions play an important role in the increase of ΔE. Then it is reasonable to consider that in 1,2-dihalogenotetralin, both halogen–H at C-8 and halogen–C-8 distances are considerably shorter in *ee* than in *aa*, therefore, the steric repulsion in *ee* of 1,2-dihalogenotetralin becomes greater than in that of the 2,3-isomer, making the former considerably more unstable than the latter.

From the discussions above, the following conclusions are obtained: (1) Each of these *ac-trans*-dihalogenotetralins has a half-chair ring and can occur in two conformations through ring conversion, as in the case of dihalogeno-cyclohexane and -cyclohexene. (2) The structural chemical prop-

(24) W. D. Kumler and A. C. Huitric, THIS JOURNAL, 78, 3369 (1956).

Digitized by Arya Samaj Foundation Chennai and eGangotri

erties of *trans*-2,3-dihalogenotetralin are very similar to those of *trans*-4,5-dihalogeno-1-cyclohexene. (3) As to *trans*-1,2-dihalogenotetralin, probably because of the sterical repulsions of halogen at C-1 with C-8 and H at C-8, the *ee* conformation become more unstable than that of the 2,3-isomer, therefore, ΔE becomes larger than that of 2,3-dihalogenotetralin.

From these conclusions the following could be speculated: (1) In regard to *ac*-monosubstituted positional isomers, the abundance ratio of *axial* conformation to *equatorial* one may become larger in α-substituted tetralin than in the β-substituted one. (2) In 1,2-disubstituted tetralin, not only of *trans* configuration but of *cis* configuration, the more stable conformation may be generally the one in which the substituent at C-1 is *axial*. When two substituents are fused together to make another ring, the *trans* configuration cannot occur other than in *1e2e;* in the *cis* configuration, however, *1a2e* may be more stable than *1e2a*.

Acknowledgment.—The author wishes to express his sincere thanks to Professor Tetsuo Mitsui for his invaluable encouragement, to Professor Yonezo Morino and Dr. Ichiro Miyagawa of Tokyo University and Dr. Kiyoshi Sakashita of Tokyo Institute of Technology for their constant guidance and advice, rendered during the course of this work, and to Mr. Ichiro Taniguchi of the Department of Electronical Engineering of Kyoto University for his assistance in preparing the measuring apparatus.

Ionization and Dissociation Equilibria in Liquid Sulfur Dioxide. VI. Hexaphenylethane[1]

BY HARRY P. LEFTIN AND NORMAN N. LICHTIN

RECEIVED OCTOBER 4, 1956

The effects of solute purity, light and oxygen on the electrical conductivity of sulfur dioxide solutions of hexaphenylethane have been investigated. Contrary to previous reports, pure solutions of hexaphenylethane do not conduct significantly. Electrolytes are, however, generated by the action of light and of oxygen. Comparison of the data for oxygenated solutions of hexaphenylethane with the conductivity of tetramethylammonium sulfate in liquid sulfur dioxide at 0.1° over the dilution range 200 to 100,000 liters per mole suggests that a 2–1 electrolyte is present. These observations make possible simple explanation of earlier reports on the properties of solutions of hexaarylethanes in sulfur dioxide.

Introduction

The differences in behavior of solutions of hexaphenylethane[2] in sulfur dioxide and in organic solvents has been the subject of considerable discussion. Thus in so called "non-ionizing" solvents, molecular weight,[3] magnetic susceptibility[4] and spectral[5] data in conjunction with photochemical instability[6] and rapid reaction with oxygen[7] demonstrate conclusively the dissociation of hexaarylethanes into free radicals. In sulfur dioxide, however, the solutions have been reported to conduct the electric current,[8] to be photochemically stable[9] and to fail to react with oxygen.[10] Moreover, the observed color[11] and spectrum[12] in SO_2 have been described as differing markedly from those observed in many other solvents.[13]

This anomalous behavior has received several chemical interpretations[14] which differ in detail but which all assume an ionization mechanism involving only hexaphenylethane and sulfur dioxide. These proposed mechanisms can be divided into two general classes depending upon the valence type of the electrolyte produced and, therefore, in view of the recent demonstration[15] of the applicability of modern electrolyte theory to solutions of electrolytes in sulfur dioxide, would be distinguishable on the basis of conductivity data alone. Unfortunately the data of Walden[8a] and of Gomberg[8b] lack precision and do not extend over a sufficient concentration range to be useful for this purpose. Accordingly, attempts were made initially to obtain precise conductivity data employing crystalline samples of pure hexaphenylethane. These investigations revealed[16] that the observed conductivity is an artifact of interaction with light or oxygen and is not characteristic of pure solutions.

Experimental

Hexaphenylethane.—This was prepared in an all-glass apparatus by shaking a solution of 30 g. (0.108 mole) of triphenylchloromethane in 300 ml. of acetone with 80 g. (0.40 mole) of mercury. The reaction was carried out in a 580-ml. sealed flask, A, shielded from light by wrapping with aluminum foil and equipped with a side arm closed by a fragile glass membrane. Prior to sealing, the reaction flask and contents were cooled to −40° and evacuated to the autogenous pressure of the mixture. Shaking was provided at room temperature by a Burrell model CC shaker set at speed 10. After a 9-hour shaking period the side arm (containing a sealed in coarse sintered disk) of a receiving flask, B, was sealed onto the side arm of the reaction flask. The receiving flask was then dried by flaming and pumping and finally evacuated to a pressure of 10^{-4} mm. through a stopcock, C, sealed to its neck. With the stopcock closed, the apparatus was removed from the vacuum line and transferred to a darkened room where the synthesis was completed. The fragile glass membrane was smashed by means of a glass bead and the orange solution was filtered through the coarse sintered disk by rotating the apparatus. A small side bulb on flask A served to prevent plugging of the filter disk by trapping most of the mercury residue. This residue was washed free of product with solvent distilled back into A from B. During such distillations the solutions were never warmed above 30° and the process was speeded by cooling the receiving bulb to −78°. The product was crystallized by concentrating the solution to one-fourth of its original volume and cooling in an ice-bath for several hours. The mother liquors were decanted into vessel A, and the product then recrystallized from solvent freshly distilled from A into B. Usually three recrystallizations were executed prior to final product isolation. Following the removal of mother liquors from the final recrystallization the apparatus was dismembered by sealing off at the connecting arm.

The vessel containing the yellow or buff colored crystalline product was wrapped with aluminum foil and pumped through C for 24 hours at a pressure of 10^{-5} mm. It was next sealed off from the vacuum line directly below C and transferred to a vacuum dry-box.[17] The dry-box was evacuated overnight to a pressure of 10^{-3} mm. and filled with "Seaford"[18] nitrogen which had been passed over fine copper turnings at 800°, cooled to −78° and finally passed over Drierite. The dry-box atmosphere was further purified by exposure to sodium until a freshly cut surface of the metal showed no signs of tarnish after two hours. Light entering the dry-box was kept to a minimum with the aid of a red filter fashioned from a watch glass made of Corning L. A. glass.

After the flask was opened in the dry-box the yellow solid was transferred to a sintered glass funnel and washed rapidly with a small quantity of pure acetone. This simple washing procedure effectively removes all of the colored surface impurity[19] leaving pure white crystalline hexaphenylethane. The pure product was next distributed into glass bulbs for analysis, conductivity measurement (*vide infra*) and melting point determination. In this way several samples of identical history could be obtained.

Several batches of hexaphenylethane were prepared by this method and one batch was prepared by the method of Lichtin and Thomas.[20]

At least two samples or each lot of hexaphenylethane were transferred to bulbs and analyzed by quantitative oxygenation in the absence of pyrogallol according to the procedure of Lichtin and Thomas.[20] Melting point capillary tubes were filled in the dry-box, temporarily sealed with a plug of Apiezon "Q" putty, removed from the dry-box and immediately sealed with a needle point flame. Melting points were determined using an electrically heated stirred H type bath and were not corrected. Table I summarizes the relevant data for different batches.

TABLE I

PHYSICAL PROPERTIES OF HEXAPHENYLETHANE

Color	Melting range,[a] °C.	Oxygen absorption (% of theory)
White	153.5–154	99.5 ± 0.1
White	153–154	97.2 ± .1
Pale yellow	.....	95.8 ± .3
Pale yellow	146–148	94.0 ± .1
Yellow	144–146	90.4 ± .3

[a] Literature values: 145–147°, M. Gomberg, THIS JOURNAL, 36, 1144 (1914); 150–152° (cor.) ref. 20.

Reagents and Solvents.—Triphenylchloromethane was prepared from Eastman White Label triphenylcarbinol by reaction with acetyl chloride in dry ether. A pure white product was obtained by rapid crystallization from a hot saturated solution. Recrystallization from ether and vacuum drying at room temperature afforded 93 to 97% yields of pure white crystalline product, m.p. 112.5–113° (uncor.).

Mercury was triple distilled C.P. grade and was outgassed at 100° for several minutes before use. The following solvents were of C.P. grade: acetone was stored over Drierite for several weeks, filtered, refluxed over calcium hydride and distilled before use; ether was dried over calcium hydride and filtered.

Sampling Technique for Conductivity Runs.—Samples (50–200 mg.) for conductivity measurements were stored in sealed preweighed break-off type bulbs (equipped with female standard taper joints) which were filled in the vacuum dry-box. The filled bulbs were then attached to a manifold, which was then evacuated by means of an external pump connected through the base plate of the dry-box. The evacuated manifold and bulbs were transferred from the dry-box to a vacuum line and pumped at 10^{-5} mm. for several hours. The sample bulbs were then sealed off at their necks. During the sealing operation the lower portion of the bulb containing the sample was kept immersed in an ice-bath in order to prevent thermal decomposition.

Sample weights (usually 50–200 mg.) were determined by difference with an accuracy of better than ±1 mg. An appropriate vacuum correction, based on the measured bulb volume, was applied in each case and was usually of the order of 3–4 mg. with an uncertainty of about 0.5 mg. due to the volume occupied by the sample. The bulbs were wrapped in aluminum foil and stored in a light-proof box in the freezing compartment of a refrigerator. Samples stored in this manner showed no visible evidence of deterioration after 18 months.

Conductivity Measurements.—The conductivity cell, thermostat and bridge assembly employed in this work have been described previously.[21] The temperature of measurement was −8.93 ± 0.03°. The vacuum line was similar to that used in earlier work.[21] Procedures employed in preparing solutions in the cell differed from those previously reported in the following respects.

Hexaphenylethane was introduced into the conductivity cell by smashing the breakoff diaphragm of an evacuated sample bulb sealed to the inlet tube of the sealed, evacuated, sulfur dioxide-filled cell. A glass grid was installed in the inlet tube in order to support the glass-sheathed, gold-plated, solenoid-activated, iron rod used for this purpose. That this grid did not introduce significant drainage errors was established by measurements employing triphenylchloromethane as solute. The small quantity of glass fragments introduced into the electrode compartment by this procedure caused a negligible error in the measured volume of the solution. All conductivity measurements as well as the preparation of the solutions were carried out under dark-room conditions except where otherwise indicated. Only light provided by a Kodak ruby-red safelight was permitted.

(18) Containing 1% hydrogen, supplied by Air Reduction Co.

(19) Gomberg[2a] claimed that even in the solid state hexaphenylethane undergoes a slow photochemical transformation. Since light of the wave length most active in effecting this transformation[12] was rigorously excluded in the present procedures, it seems unlikely that the surface color is due to this cause. The ease with which the color can be removed suggests that it may be due to adsorption of a soluble colored impurity or of the monomeric radical from the mother liquors. In this respect it is interesting that color was not produced when white hexaphenylethane in an evacuated sealed tube was exposed either to sunlight or to ultraviolet light for several days at room temperature. In the absence of light, however, a yellow coloration developed when the ethane was exposed to the atmosphere.

to contact the solutions. Sulfur dioxide, Virginia Smelting Co., Extra-Dry Es-O-Too refrigeration grade, was dried in the gas phase over $Mg(ClO_4)_2$ and distilled into the cell from a helix-packed bulb. In about half of the runs the solvent was degassed prior to distillation into the cell by pumping at −78° for varying periods of time. In two runs the degassed solvent was further purified by distillation from about 2 g. of hexaphenylethane. Solvent conductivity determined at the end of each run was usually in the range 1.0×10^{-7} to 2.2×10^{-7} mho cm.$^{-1}$.

Sulfur dioxide solutions of the product formed by the reaction of hexaphenylethane with oxygen were prepared by the following procedure. A stopcock was added to the exit arm of the cell. The cell was filled with degassed sulfur dioxide, removed from the line and a solution of hexaphenylethane prepared in the usual way. The solution was then thermostated, its resistance measured, and dry tank oxygen admitted through the stopcock with the aid of the vacuum line. Equilibration with oxygen was considered complete when the conductivity of the solution remained unchanged for two hours. The cell was then evacuated to the autogenous pressure of the solution at −35°, sealed off at the stopcock and conductivity behavior measured at −8.9° in the usual way. After several dilutions these runs had to be terminated because the residue was so strongly solvated that a sufficient volume of solvent could not be recovered by distillation from the reservoir bulb.

Experiments in which the influence of light was examined were carried out at 0° using an unsilvered Dewar ice thermostat. Illumination of the electrode compartment of the cell was provided by a Burton long wave length ultraviolet lamp.

Recovery of Solutions.—The design of the conductivity cell did not permit recovery of solutes after a conductivity run without atmospheric contamination. Therefore, solutions for this purpose were prepared with the aid of the vacuum line in a separate reaction vessel. A solution of hexaphenylethane (99.5% purity by oxygenation) in degassed sulfur dioxide was maintained in the dark at about −10° for four hours. Removal of the solvent under reduced pressure left a bright yellow residue which was pumped at 10^{-5} mm. for 24 hours. This residue, dissolved in acetone, showed the presence of unchanged hexaphenylethane by a positive Schmidlin test[22] and by the formation of triphenylmethyl peroxide (m.p. 185–186°) on exposure to oxygen.

The addition of oxygen to a solution of the ethane in degassed sulfur dioxide in the dark afforded a blood-red residue which failed to satisfy Schmidlin's criterion and did not yield any dityrityl peroxide. The color of the residue changed to a dirty brown on exposure to atmospheric moisture. The residue was insoluble in hydrocarbon solvents, chloroform and carbontetrachloride. Yellow solutions were obtained in methanol, ethanol, acetone, ether and glacial acetic acid. However, attempted crystallization from these solvents afforded only intractable gums. Hydrolysis of an acetone solution gave an almost white, gummy precipitate which could not be crystallized. This hydrolysis product behaved like a triarylcarbinol in Bowden's[23] test. Its visible spectrum in 98% sulfuric acid solution was similar but not identical to that of triphenylcarbinol. An intense absorption band with its maximum at 440 mμ and a shoulder at 410 mμ was observed with the hydrolyzate, whereas triphenylcarbinol displays maximum absorption at 435 mμ with an only slightly less intense maximum at 410 mμ. Since the hydrolyzate was impure these data can only be regarded as suggestive. The aqueous filtrate from the hydrolysis did not show the presence of sulfate ion when tested with barium chloride.

Triphenylmethyl Peroxide.—This was prepared by oxygenation of hexaphenylethane in benzene solution in the dark. Recrystallization from chloroform afforded white crystals, m.p. 186–187°. This material (3.4 mg.) ground to a fine powder failed to dissolve completely in degassed liquid SO_2 (45 ml.) even after standing at 0° for three hours with occasional mixing. Contrary to Walden's[8a] observations, the solution remained colorless and its specific conductivity (3×10^{-7} mho cm.$^{-1}$ compared to 1×10^{-7} for the pure solvent) remained constant. These results establish that trityl peroxide, present as an impurity in hexaphenylethane, cannot account for the observed conductivity of sulfur dioxide solutions of the parent hydrocarbon.

Tetramethylammonium Sulfate.—This was prepared by shaking for 24 hours a solution of 19 g. (0.12 mole) of Eastman White Label tetramethylammonium bromide in 50 ml. of distilled water with 15 g. (0.06 mole) of C.P. silver sulfate at room temperature in the absence of light. The silver bromide was removed and the solution treated for three 10-hour periods with fresh batches (10 g.) of silver sulfate until no further reaction could be detected. The solution was carefully evaporated to dryness on a steam-bath and the residue was dissolved in 95% ethanol, filtered, and crystallized by adding acetone. The product, recrystallized three times from an acetone–alcohol mixture, washed with acetone, pulverized and dried over P_2O_5 for two weeks, was a white, hygroscopic powder. Its purity by gravimetric sulfate analysis was 99.4 ± 0.1%.

Results and Discussion

Data.—The conductivity of a solution of hexaphenylethane in liquid sulfur dioxide purified only by passage through $Mg(ClO_4)_2$ and distillation increases significantly under the influence of ordinary fluorescent tube room illumination or daylight. Under dark-room conditions the conductivity of such a solution does not change with time. Measurements performed in the dark are, however, not reproducible from sample to sample even when carried out on samples of high purity and identical history. Yet, though the Λ *vs.* v curves are quite different, they resemble each other in a way which suggests that the same electrolyte is present in all cases but at concentrations which deviate from the stoichiometric values by factors that differ from run to run. This is illustrated in Fig. 1. Included for comparison are plots of the data for typical 2:1 and 1:1 electrolytes, tetramethylammonium sulfate and bromide, respectively. The former, but not the latter, resembles the hexaphenylethane curves.

The data of Table II illustrate the effect on the conductivity of solutions of purification of the solvent. Evidently, conductivity is associated with the presence of a volatile impurity which can be removed efficiently by preliminary treatment with hexaphenylethane. These facts, combined

TABLE II

EFFECT OF SOLVENT PRETREATMENT ON CONDUCTIVITY AT −8.9° OF HEXAPHENYLETHANE SOLUTIONS PREPARED IN THE DARK

(22) A solution of hexaphenylethane in an organic solvent loses its yellow color instantly when agitated in the presence of air. The color returns slowly when the solution is then allowed to stand undisturbed. This phenomenon, first described by Schmidlin[7b], can be repeated several times until all of the hexaphenylethane has been converted to the peroxide.

(23) S. T. Bowden, *Analyst*, **59**, 618 (1934). An intense color characteristic of a triarylcarbonium ion is produced when a triarylcarbinol dissolved in ether is treated first with a drop of concentrated HCl and then with a saturated ether solution of cupric chloride.

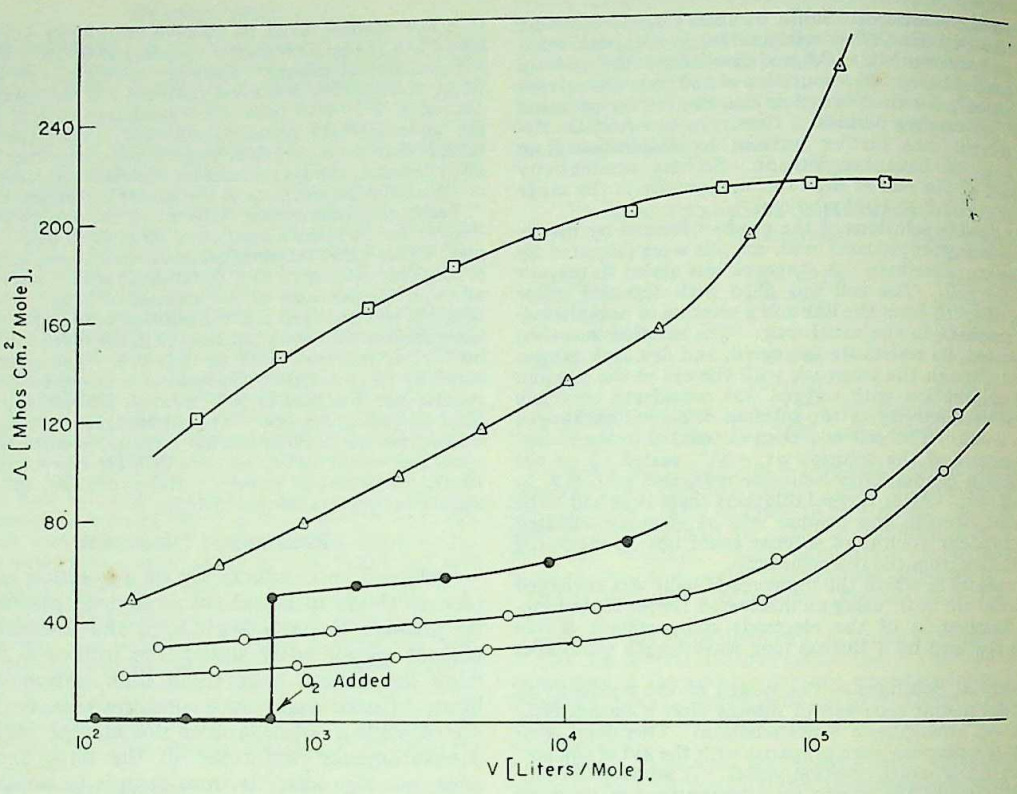

Fig. 1.—Conductivity data in sulfur dioxide solution: —O—, hexaphenylethane (99.5% by O_2 analysis) in ordinary SO_2 (containing O_2 as impurity) at −8.9°; —●—, hexaphenylethane (99.5% by O_2 analysis) in degassed SO_2 at −8.9°, data to the right of the arrow indicate behavior after the addition of O_2; —△—, tetramethylammonium sulfate at 0.1° (typical 1–2 electrolyte); —⊡—, tetramethylammonium bromide at −8.9° (typical 1–1 electrolyte).

with the very large increase in conductivity consequent upon addition of oxygen to a feebly conducting degassed solution, lead to the conclusion that this impurity is molecular oxygen. Other facts support this conclusion.

The conductivity achieved on saturating with oxygen is greater than that observed for solutions prepared without degassing (*cf.* Fig. 1) although of the same order of magnitude. As detailed in the Experimental section, hexaphenylethane can be recovered, apparently unchanged, from solution in degassed sulfur dioxide, but the residue remaining after removal of solvent from an oxygenated solution is neither hexaphenylethane nor its peroxide. Ditrityl peroxide is, in fact, only slightly soluble in sulfur dioxide and its saturated solutions do not conduct significantly. The oxygenation of hexaphenylethane in sulfur dioxide is irreversible, however, as demonstrated by the use of hexaphenylethane as a getter from which purified sulfur dioxide can be distilled and by the fact that thorough degassing of an oxygenated solution does not affect its conductivity materially. Solutions resulting from oxygenation are similar in appearance (blood-red) to these prepared in sulfur dioxide which has not been degassed. Solutions in degassed sulfur dioxide are yellow and visually appear to be identical with solutions of hexaphenylethane in common organic solvents.

The action of near ultraviolet light on the conductivity of a solution of hexaphenylethane in degassed sulfur dioxide and of an oxygenated solution is illustrated in Fig. 2. Degassed solutions are strongly and irreversibly affected while oxygenated solutions appear to be inert. Irradiation of solutions in degassed sulfur dioxide produces a change in color from yellow to brown. Removal of solvent from such irradiated solutions yields a dark red gum which responds negatively to tests for the presence of hexaphenylethane.

Information on the nature of the oxygenation product is, at present, fragmentary and inconclusive. Observations on the product of hydrolysis of the oxygenation product suggest the presence of impure triphenylcarbinol. This is supported by the spectroscopic observations reported for solutions in sulfur dioxide which very probably contained the oxygenation product as the principal solute. That the anion probably bears a charge of minus two is indicated by the comparisons of Fig. 1. The same conclusion follows from the application of Shedlovsky's procedure[24] for determining equilibrium constants to the data of a typical run with hexaphenylethane in ordinary sulfur dioxide and to the data for tetramethylammonium sulfate on the basis of the assumption that *both solutes are 1:1 electrolytes.* Relevant conductivity data are summarized in Table III. The resulting similar strongly inflected plots of $1/\Lambda S(z)$ *vs.* $c\Lambda f_{\pm}^{2}S(z)$[25] are

(24) T. Shedlovsky, *J. Franklin Inst.*, **225**, 739 (1938).

(25) $S(z)$ is Shedlovsky's function, c the concentration in moles per liter and $f_{\pm}$ the mean ionic activity coefficient.

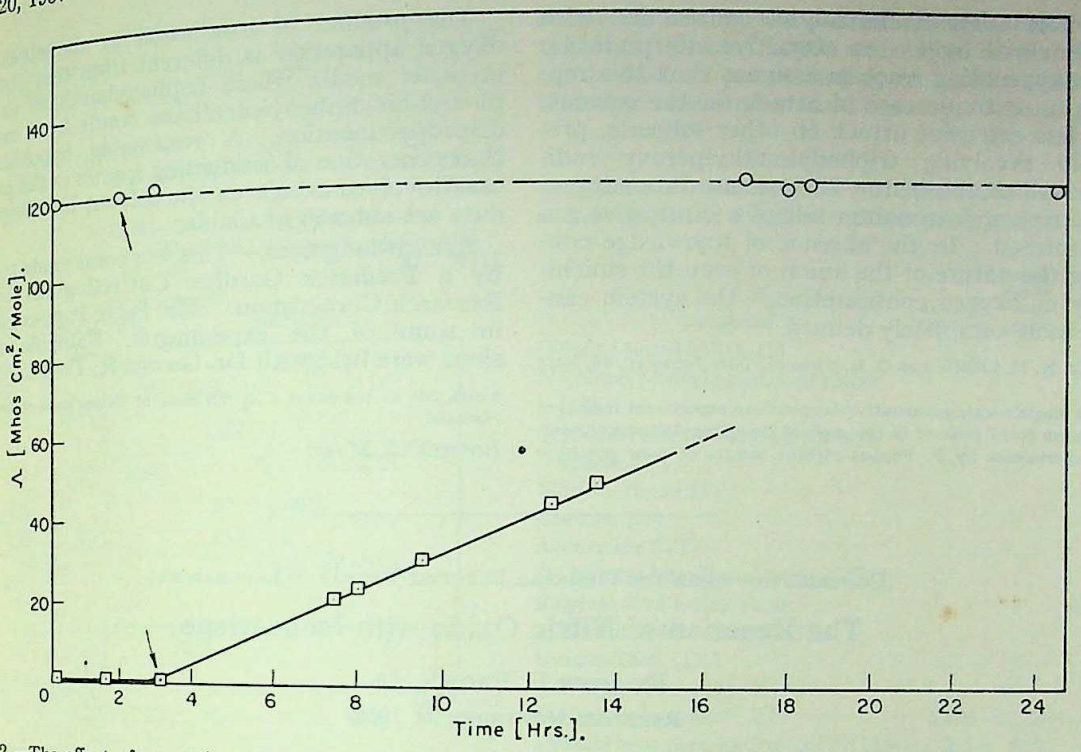

Fig. 2.—The effect of near ultraviolet light on the conductivity of hexaphenylethane solutions at 0°; arrow indicates the time at which illumination was started: —⊡—, degassed SO_2, 6750 liters/mole; —O—, oxygenated SO_2, 2600 liters/mole.

compared in Fig. 3 with the straight line Shedlovsky plot obtained from the data for a typical 1:1 electrolyte. There is, however, the possibility that the sulfur dioxide solution of the oxygenation product contains several electrolytes, and that the similarity to 2:1 electrolyte behavior is illusory. No evidence on the nature of the anion was obtained other than the failure to detect sulfate in the hydrolyzate.

Discussion

It is now apparent that earlier work involved solutions in sulfur dioxide of hexaarylethanes that were either completely oxygenated or nearly so. Although spectroscopic and magnetic studies on oxygen-free solutions in sulfur dioxide are lacking, qualitative observations of color, oxygen absorption and sensitivity to irradiation as well as conductivity data make it seem highly probable that the usual triphenylmethyl–hexaphenylethane equilibrium mixture is present in such solutions.

to the formation of electrolytes on reaction with oxygen or with light. An attractive interpretation of the oxygenation reaction assumes that this represents an extreme case of attack on the solvent. Much less extensive attack on other solvents, presumably involving triphenylmethylperoxy radical[26] is well established. The present data suggest that a triphenylcarbonium salt of a dinegative anion is formed. In the absence of knowledge concerning the nature of the anion or even the stoichiometry of oxygen consumption,[27] the system cannot be more completely defined.

(26) *Cf.* N. N. Lichtin and G. R. Thomas, THIS JOURNAL, **76**, 3021 (1954).

(27) A single rough quantitative oxygenation experiment indicated consumption of 0.7 mole of O_2 per mole of hexaphenylethane. Additional experiments by P. Pappas yielded results of poor precision which fell in the range 1 ± 0.5 mole of O_2 per mole of hexaphenylethane.

The product of irradiation in the absence of oxygen apparently is different from that obtained in other media where triphenylmethane and diphenyl-bis-diphenyleneethane result from induced disproportionation. A reasonable hypothesis is that generation of conducting species in the present case involves attack on the solvent but diagnostic data are not now available.

Acknowledgment.—This work was made possible by a Frederick Gardner Cottrell grant by the Research Corporation. Mr. Peter Pappas assisted in some of the experiments. Valuable discussions were held with Dr. George R. Thomas.

The Reaction of Nitric Oxide with Isobutylene

BY JOHN F. BROWN, JR.

RECEIVED NOVEMBER 28, 1956

Nitric oxide containing traces of nitrogen dioxide reacts readily with liquid isobutylene to give nitrogen and a mixture of nitrated products. This mixture is believed to contain β-nitroisobutylene (22%); nitro-*t*-butanol (9%); traces of isobutylene pseudonitrosite, nitro-*t*-butyl nitrate and α-hydroxyisobutyraldoxime; and major amounts (66%) of a substance having the partial structure (nitro-*t*-butyl)$_4N_2O_2$. The latter is very unstable and decomposes on standing or gentle warming to give α-nitroisobutylene and N-(nitro-*t*-butyl)-hydroxylamine, which also decomposes on standing or heating. Thus, the net result of treating isobutylene with nitric oxide and then distilling the product is the formation of nitroisobutylene (74%) and small quantities of substances having nitro-*t*-butyl groups joined to nitro, nitroso, nitrate ester, hydroxyl, hydroxylamino and oximino groups. It is suggested that the (nitro-*t*-butyl)$_4N_2O_2$ is representative of the unidentified unstable oils which have frequently been obtained by treating olefins with N_2O_3 or N_2O_4. A mechanism for the NO–isobutylene reaction is proposed.

In the past, the nature of the reaction between nitric oxide and olefins has been virtually unknown. There are about a dozen references in the technical literature suggesting the possibility of such a reaction, but the only workers to identify any products were Bloomfield and Jeffrey,[1] who obtained 1-nitrocyclohexene and cyclohexene pseudonitrosite from cyclohexene. As late as 1949, an authoritative text stated that reactions between nitric oxide and the normal ethylenic double bond did not occur.[2]

An extensive study of the nitric oxide–olefin reaction has recently been made in this Laboratory. This study established three general characteristics of the reaction. First, the reaction is initiated by nitrogen dioxide. Scrupulously purified nitric oxide can be stored in contact with liquid olefins for days without reaction, but in the presence of traces of NO_2, such as are usually present in nitric oxide, reaction occurs readily with many types of olefins and other hydrocarbons.[3] Second, the product of a nitric oxide–olefin reaction is usually a mixture of the crystalline pseudonitrosite (dimeric nitro nitroso adduct) and an unstable liquid mixture which will undergo a "fume-off" or low-order explosion upon attempted distillation. It was found that the decomposition of these liquids could be controlled by steam distillation or passage through a falling film still, but no means of fractionating any significant quantity without decomposition was discovered. Third, the distilled liquid reaction products consist mainly of mixtures of nitroölefins. For example, 1-octene gives 1-nitro-1-octene and 1-nitro-2-octene.[3] In general, the linear olefins give fair yields of both nitroölefins and pseudonitrosites, while the branched olefins give good total yields of nitroölefins but little pseudonitrosite.

It was evident, however, that any detailed understanding of the nitric oxide–olefin reaction would require considerably more information about the nature of the reaction products. The present investigation of the products from the nitric oxide–isobutylene reaction was undertaken in order to obtain such information.

Basically, this objective required that a detailed analysis be made on a complex mixture which was changing composition continually during the course of the analysis. In order to accomplish this, a large batch of nitric oxide–isobutylene reaction product was prepared and the stoichiometry of the reaction determined. The product was fractionated, mainly by distillations under mild conditions, until a large number of fractions representing individual compounds or simple mixtures had been obtained. Analysis of these then permitted

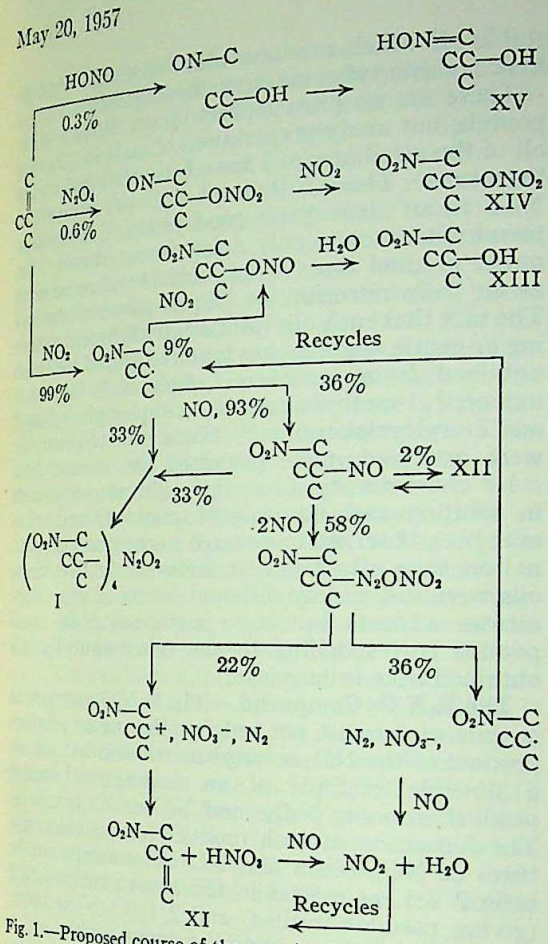

Fig. 1.—Proposed course of the reaction between nitric oxide and liquid isobutylene.

complete identification and estimation of the constituents of the separated fractions. During the fractionation, the refractive indices, infrared spectra and other properties of the mixtures were followed closely in order to detect changes in product composition as they occurred. The nature of the changes that the individual product constituents underwent under the conditions of the fractionation were then determined and used as the basis for estimates of the product composition at earlier stages. Finally, the resulting estimate of the initial product composition was checked by comparing the stoichiometric ratios which it predicted against those actually observed.

Results

The results of this investigation are summarized in Table I. The composition "after fractionation" shows corrected analytical values for the aggregate composition of 45 liquid and solid organic fractions separate from the crude product. The composition "initially present" represents these values adjusted for all the changes that were observed to be occurring during the fractionation, while that at the "intermediate stage" represents a somewhat hypothetical product in which the decomposition of I, the most sensitive constituent, has gone to completion, while that of II, the next most sensitive, has not yet begun.

The major primary product of the reaction between nitric oxide and isobutylene is a thick, unstable oil having the partial structure (nitro-*t*-butyl)$_4$N$_2$O$_2$ (I) and hence referred to as the R$_4$N$_2$O$_2$ compound. Upon standing or gentle warming it undergoes elimination and decomposition to give α-nitroisobutylene (1-nitro-2-methyl-1-propene, X) and N-(nitro-*t*-butyl)-hydroxylamine (II).

Table I

Estimated Composition of the Product from the Reaction of Nitric Oxide with Excess Liquid Isobutylene at 28°

$$(C_4H_8NO_2)_4N_2O_2 \longrightarrow 3C_4H_7NO_2 + (C_4H_8NO_2)NHOH + (HNO)$$

However, as might be expected for a β-nitroalkylamine,[4] II is also rather unstable and undergoes three further types of decomposition under conditions like those employed in the fractionation. These may be termed disproportionation, dealdolization and reversion to starting materials.

The disproportionation occurs mainly when solutions of II are allowed to stand in the cold and gives the O,N-bis-(nitro-*t*-butyl)-hydroxylamine (III).

$$2(C_4H_8NO_2)NHOH \longrightarrow (C_4H_8NO_2)NHO(C_4H_8NO_2) + NH_2OH$$

Dealdolization occurs on heating and results in a cleavage of the II into nitromethane and acetoxime.

$$(CH_3)_2C(CH_2NO_2)NHOH \longrightarrow CH_3NO_2 + (CH_3)_2C{=}NOH$$

A similar reaction of the dialkylhydroxylamine III gives O-(nitro-*t*-butyl)-acetoxime (VII).

$$(CH_3)_2C(CH_2NO_2)NHO(C_4H_8NO_2) \longrightarrow CH_3NO_2 + (CH_3)_2C{=}NO(C_4H_8NO_2)$$

The reaction termed "reversion to starting materials" is a complex autocatalytic process which is induced by heating with nitrogen oxides. It appears to involve the steps

$$(CH_3)_2C(CH_2NO_2)NHOH + NO_2 \longrightarrow (CH_3)_2C(CH_2NO_2)NO \quad (XII)$$

$$(CH_3)_2C(CH_2NO_2)NO \overset{\Delta}{\rightleftharpoons} (CH_3)_2C{=}CH_2 + NO + NO_2$$

$$(CH_3)_2C(CH_2NO_2)NO + NO_2 \longrightarrow NO + (CH_3)_2C(CH_2NO_2)NO_2 \quad \text{(VIII)}$$

$$(CH_3)_2C{=}CH_2 + NO \longrightarrow N_2, (CH_3)_2C{=}CHNO_2, \text{etc.}$$

The net result of this process is the formation of gaseous products such as isobutylene, nitrogen and nitric oxide, along with XII, VIII and considerable tar. The thermal dissociation and disproportionation of the pseudonitrosite, represented by the last three equations, was examined independently and found to give good yields of dinitroisobutane VIII, along with regenerated isobutylene, X, N_2 and NO.

Finally, it was noted that a little isomerization[5] of the α-nitroisobutylene (X) to the more volatile β-nitroisobutylene (XI) occurred during one distillation in which the base II was present.

By adjusting the values of the final composition listed in Table I for the observed conversions of II and IX into III–X and XVI, of X into XI and of I into II, X and probably IX, the composition listed in Table I as "initially present" was calculated. This composition predicts that the stoichiometric ratios of isobutylene consumed to nitric oxide consumed to nitrogen produced to water produced should be 1.00:2.54:0.58:0.063. The observed values, 1.00:2.50:0.60:0.064, are within experimental error of these and hence provide independent support for the estimated initial composition of the product.

Discussion

Relationship to Other Nitrations.—It would appear from Table I that the products of the nitric oxide–olefin reaction are qualitatively, though not quantitatively, the same as those obtained in other olefin nitrations. Except for the hydroxylamine derivatives, all of the NO–isobutylene reaction products are representative of those obtained by treating isobutylene or other olefins with N_2O_3, N_2O_4 or nitric acid. Thus, the reaction of N_2O_4 with isobutylene in ether gave 54.9% VIII, 36.5% XIII, 2.3% XIV and 8.0% 1,3-dinitro-2-methylpropanol-2, which was stated to have resulted from the further nitration of XI.[6] In addition, the formation of X and of substances giving gaseous decomposition products during distillation was noted. The reaction of N_2O_3 with isobutylene in ether gave 24% XII, 14% XIII, 4% of the dinitro alcohol, a little VIII, and a large quantity of an unidentified oil which gave X on treatment with alkali.[6] α-Hydroxyisobutyraldoxime has not been identified in such reaction products, but the corresponding compound, 3-hydroxy-3-methyl-2-butanoxime, has been obtained from 2-methyl-2-butene,[7] and the nitrate ester of α-hydroxyisobutyraldoxime, isobutylene nitrosate, has been obtained by treating isobutylene with N_2O_4 in the absence of a solvent.[8] The latter reaction also gave VIII, XII, nitroisobutylene and a very unstable oil which produced diisobutylamine and β-hydroxyisobutylamine upon hydrogenation.

There are no prior reports of any $R_4N_2O_2$ compounds, but many preparations of materials having all of the attributes of I have been described in the literature. The addition of "nitrous fumes" or N_2O_3 to an olefin gives good yields of crystalline pseudonitrosites in only a few cases; usually, the major product is a viscous, unstable oil referred to as an "oily nitrosite" or "liquid pseudonitrosite." The fact that such oils form α-nitroölefins on standing or gentle warming has been recognized for those obtained from camphene,[9] β-pinene,[10] styrene,[11] indene,[12] 1-methylindene,[12] 1,1-diphenylethylene[13] and 1-arylcyclohexenes.[14] Since none of these oils were analyzed, none possessed the intense blue color characteristic of tertiary nitroso compounds in solution and no isolated pseudonitrosite has ever been observed to undergo a spontaneous elimination to α-nitroölefin, it seems likely that these oils were not simply different forms of the nitro-nitroso adducts but were instead $R_4N_2O_2$ compounds corresponding to the (nitro-*t*-butyl)$_4N_2O_2$ obtained from isobutylene.

The $R_4N_2O_2$ Compound.—The $R_4N_2O_2$ compound is thus of interest not only as the major primary product of the NO–isobutylene reaction but also as a possible example of an unrecognized major product in many N_2O_3– and N_2O_4–olefin reactions. The formation of such products means that mixtures of NO_2, olefin and NO can combine in the ratio 2:2:1, as well as in the known ratios 1:1:1 (giving pseudonitrosites) and 2:1:0 (giving nitrosates, nitro nitrites and dinitro compounds).

The available data do not seem to permit an unambiguous structural assignment to our $R_4N_2O_2$ compound, but a fairly good case can be made for the structure $\begin{matrix} R \\ RO \end{matrix}\!\!>\!NN\!<\!\!\begin{matrix} R \\ OR' \end{matrix}$, which we prefer. It is believed that the compound is formed by a combination of nitro-*t*-butyl radicals and NO in a 2:1 ratio. This could occur by the steps

$$C_4H_8 + NO_2 \longrightarrow \cdot C_4H_8NO_2{\equiv}R\cdot$$

$$R\cdot + NO \longrightarrow RNO$$

$$RNO + R\cdot \longrightarrow R\dot{N}OR \longrightarrow (RNOR)_2$$

Several similar processes have been described in the literature. Gingras and Waters found that 2-cyano-2-propyl radicals could combine with NO in a 3:1 ratio to give the trialkylhydroxylamine and with aromatic nitroso compounds to give aryldialkylhydroxylamines.[15] On the other hand, the triarylmethyl radicals produced by reducing triphenylmethane dyes with zinc combined with NO in a 2:1 ratio, especially in the presence of excess reducing agent, giving bis-(triarylmethyl)-hydroxylamines.[16] A 2:1 adduct of triphenylmethyl radicals and NO was obtained once by Schlenk and

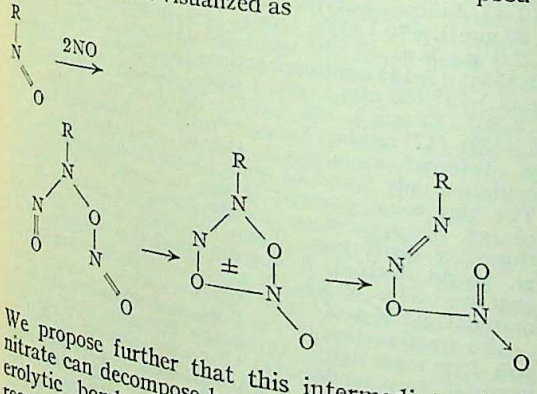
Mair.[17] The exact structure of none of these 2:1 adducts is known with certainty, but Schlenk and Mair's adduct is clearly different from the N,N(?)-bis-(triphenylmethyl)-hydroxylamine obtained from triphenylcarbinol and hydroxylamine.[18]

Mechanism.—The reaction between nitric oxide and isobutylene is remarkable in that under very mild conditions it gives a complex mixture of products, none of which bears much obvious structural relationship to the starting material, nitric oxide. In order to rationalize this fact, it seems desirable to set forth our conception of the mechanism of the reaction, even though much of the detailed evidence in its support must await the publication of our observations on other olefin nitrations. This mechanism, shown in Fig. 1, is based upon the following considerations.

First of all, the need for catalytic quantities of NO_2 in the reaction, the structures of the organic products and the similarity of those products to those obtained from N_2O_3– and N_2O_4–olefin reactions all suggest that these products must be formed *via* such species as NO_2, N_2O_3, N_2O_4, HNO_2, etc. The available information on the mechanisms of the reactions of these substances with olefins,[19] as well as our own studies of the stereochemistry of the nitric oxide–cyclohexene reaction products, indicates that products such as VIII, XII and XIII are mainly formed by free radical processes involving addition of NO_2 to the double bond, while products such as XIV and XV are formed by ionic processes involving attack of NO^+ on the double bond.

The central problem of the mechanism thus becomes that of accounting for the formation of NO_2 in the reaction medium. We have proposed[20] that this occurs *via* a diazo nitrate, as shown in Fig. 1. The formation of this diazo nitrate from the pseudonitrosite can be visualized as



We propose further that this intermediate diazo nitrate can decompose by either homolytic or heterolytic bond rupture. The homolytic process regenerates the original radical and hence accomplishes a simple disproportionation of the NO into N_2 and NO_2, which is a thermodynamically feasible reaction ($\Delta F = -59.6$ kcal.).

$$R\cdot + 3NO \longrightarrow RN_2ONO_2$$
$$RN_2ONO_2 \longrightarrow R\cdot + N_2 + NO_3\cdot$$
$$NO_3\cdot + NO \longrightarrow 2NO_2$$
$$\overline{4NO \longrightarrow N_2 + 2NO_2}$$

The heterolytic decomposition gives diazonium nitrate, thence carbonium nitrate, thence β-nitroisobutylene and nitric acid. It also accomplishes a conversion of NO to NO_2, but does so less efficiently than the homolytic route.

$$NO_2 + C_4H_8 \longrightarrow R\cdot$$
$$R\cdot + 3NO \longrightarrow RN_2ONO_2$$
$$RN_2ONO_2 \longrightarrow RN_2^+NO_3^- \longrightarrow R^+NO_3^- + N_2$$
$$R^+NO_3^- \longrightarrow C_4H_7NO_2 + HNO_3$$
$$HNO_3 + 0.5NO \longrightarrow 0.5H_2O + 1.5NO_2$$
$$\overline{C_4H_8 + 3.5NO \longrightarrow C_4H_7NO_2 + 0.5H_2O + 0.5NO_2 + N_2}$$

These proposals are based upon the known reactions of nitrosobenzene with 2NO to give benzenediazonium nitrate,[21] of certain triarylmethyl radicals with 3NO to give triarylcarbonium nitrates[16] and upon the formation of β-nitrocarbonium ion rearrangement products in some other nitric oxide–olefin reactions.[20] Similar mechanisms involving intermediate diazo nitrates have been proposed to account for other unexpected products from the reactions of NO, NOCl and N_2O_3 with organic compounds[20] and for the nitric oxide–benzaldehyde reaction.[22]

Experimental

All melting points are corrected, boiling points are uncorrected. Elementary analyses, done by Mrs. J. Northrop and Mrs. J. Martin, represent single determinations and are reliable to ±0.5%. The C.P. isobutylene and nitric oxide used were purchased from the Matheson Co. Analyses showed that the nitric oxide cylinders used contained 93.0–94.5% NO, 1.5–2.0% N_2O, 4–5% N_2 and traces of NO_2 while the isobutylene was free of non-olefinic constituents.

General Characteristics of the Reaction.—Preliminary experiments showed that the nitric oxide and isobutylene would react when the gases were mixed and held in a glass bulb at 24–35°, when the mixed gases were passed through an 18 × 1200 mm. glass tube at 30–60° or when gaseous nitric oxide was passed into liquid isobutylene under pressure. Induction periods were observed in the glass bulb runs unless the liquid products of a previous run were present; once started, the reactions proceeded with a reproducible velocity which was readily followed by the pressure drop. Starting with 200 mm. of isobutylene and 550 mm. of nitric oxide, the roughly third-order reactions had half-times of 5–11 minutes in the range 24–35°. In the 18 × 1200 mm. tube, with a 3:1 NO–isobutylene mixture flowing at 200 ml./min. at 50°, formation of liquid products occurred only in the last 200 mm. of the tube unless a few ml./min. of air were admitted along with the reactants to help catalyze the reaction. The product in each of these cases was a green oil which slowly evolved gas on standing at 0°. Attempts to fractionate these oils by distillation at 10 mm. or by chromatographing over alumina led to low-order explosions or "fume offs." The infrared spectra showed that the products from the reactions of isobutylene vapor contained oxidation products (formic acid, aldehydes and ketones) as well as nitration products (nitrate esters and nitro compounds), while the products from liquid isobutylene contained only nitration products. Effort was therefore concentrated on the latter reaction.

Liquid Phase Reaction.—The apparatus used was designed and operated by R. L. Myers and C. S. Herrick. It consisted of a one-liter stainless steel autoclave equipped

with a stirrer, cooling coil, gas inlet tube, reflux condenser, pressure regulating valve set to hold the internal pressure at 150 p.s.i. and tanks for collecting and measuring the reactant and product gases. In operation, the system was flushed with nitrogen, a weighed quantity of isobutylene admitted to the autoclave and nitric oxide passed in at a rate of 4.8 moles/hr. The product gases passed through the Dry Ice cooled reflux condenser and pressure regulating valve into accumulator tanks. At the end of the run, the apparatus was flushed with a known quantity of nitrogen and the total gaseous product analyzed; except for small quantities of unreacted nitric oxide, nitrous oxide and isobutylene, nitrogen was the sole gaseous product. Next, the autoclave was cooled to −50°, most of the liquid product poured out and the remainder rinsed out with acetone. The liquid product was allowed to come to room temperature, and then finally degassed *in vacuo* by pumping through a −78° trap; the resulting weight loss was taken to represent unreacted isobutylene. In this way, 281 g. (5.01 moles) of isobutylene was treated with 217 g. (7.23 moles) of nitric oxide at 28° to give 121 g. (2.16 moles) of unreacted isobutylene, 3.0 g. (0.10 mole) of unreacted nitric oxide, 48.1 g. (1.72 moles) of nitrogen and 325.7 g. of deep blue-green liquid reaction product, which consisted of a 295.9 g. main portion and 29.8 g. recovered from the acetone rinsings. Thus, the reaction could be estimated to have been proceeding under an NO partial pressure of 0.4 atm. and to have consumed 160 g. (2.85 moles, 57% conversion) of isobutylene and 214 g. (7.13 moles, 99% conversion) of nitric oxide.

Distillation.—The conversion of the crude product to distillates suitable for fractionation was carried out only on the main portion of the crude liquid reaction product. This was passed twice through a falling film still[23] maintained at 60° under 5 mm. pressure and the volatiles collected in −78° traps. The two portions of the distillate, 63.5 and 36.7 g., n^{20}D 1.4450 and 1.4516 on oil phases, both separated aqueous layers on warming to 0° (3.0 ml., n^{20}D 1.3425, and 0.1 ml., respectively). The aqueous layers were combined, saturated with sodium sulfate, and the 0.1 ml. of oil which separated combined with the other oils to give a total first distillate, which was a blue oil, 97.2 g., n^{20}D 1.4475. The residue was a viscous green liquid, 195.7 g., n^{20}D 1.4850. It became somewhat more mobile after standing nine days at 5° and was then passed through the still at 100° under 1 mm. pressure to give a second distillate (blue-green oil, 116.7 g., n^{20}D 1.4624) and a viscous brown residue (79.0 g., n^{20}D 1.4838). The latter was extracted with two 350-ml. portions of water, and the aqueous extracts saturated with salt and extracted with ether. This gave 8.2 g. of recovered water-soluble liquid, 12.1 g. of unrecovered water-soluble products and 58.7 g. of water-insoluble residue. An attempt to crystallize the latter from an ether–hexane solution at −78° was unsuccessful, and 5.9 g. of the material was accidentally lost during the solvent removal. The remaining 52.8 g. was distilled in two portions from an oil-bath; gas evolution was noted, but no explosion occurred. This gave a third distillate (43.9 g., n^{20}D 1.4638, 1.4650 and 1.4492 on successive thirds), a residual tar (5.5 g., b.p. >100° (1 mm.)) and a 3.4-g. loss, presumably due mostly to the gaseous products evolved. In all of these operations, all apparatus used was rinsed with ether after use in order to minimize handling losses.

Fractionation Procedure.—In fractionating the first three mixtures obtained from the crude product, effort was made to separate the less stable higher boiling products first, meanwhile accumulating the stabler lower boiling materials (indicated by *) for a single fractional distillation later.

The recovered water-soluble products were distilled to give (a), 5 ml., b.p. <85° (2.5 mm.); (b), 2.7 g., b.p. 85–96° (2.5 mm.); and 0.5-g. residue. Redistillation of (b) in a small molecular still gave (c) 0.6 g., trap condensate; (d) 1.9 g., partially solid; and 0.2 g. of residue. Crystallization of (d) from cold ether gave 0.7 g. of II and mother liquors (d′), n^{20}D 1.4698.

The first distillate from the falling film still was allowed to stand five days at 0° and then 3.8 g. of crystalline XII removed. Distillation of the mother liquors from a flask held at 35–40° gave distillate (e)*, 49.2 g., very pale blue, n^{20}D 1.443; and a deep blue residue, 44.2 g., n^{20}D 1.4591, which deposited 2.2 g. more XII on standing. Another distillation under the same conditions gave (f)*, 27.5 g., n^{20}D 1.462, and another deep blue residue which deposited 0.7 g. XII on standing. The residual liquid was combined with fraction (a) and the second falling film still distillate and carefully distilled, giving (g)*, 4.5 ml. trap condensate; (h)*, 77.0 g., b.p. 35–40° (4 mm.), n^{20}D 1.4651; (i) 11.0 g., deep blue, b.p. 40 (4 mm.)–40° (1.5 mm.) n^{20}D 1.4567; and (j) 47 ml., pale blue residue, n^{20}D 1.4571. On standing at 5°, (i) deposited 0.3 g. of XII, leaving liquid (i′).

The fraction (j) at this point presumably consisted mainly of II and XIII; a small sample which was not distilled immediately was examined after two weeks storage at 0° and found to be mostly extractable with water. Infrared examination of the water-insoluble portion, (j′) indicated the presence of III, IX, and XIV; VIII could not be detected. The distillation of (j) was commenced under 2 mm. pressure, using a 110° oil-bath. At first, distillation proceeded normally, giving a light blue distillate (b.p. 55° (2 mm.), probably XIII). Then the contents of the pot turned a deep blue-green and a vigorous evolution of gases commenced. The heating bath was removed, but the evolution of gases (estimated at 10 g. from weight loss) continued for several minutes, the pressure remained at 30–60 mm. despite continued pumping, and about 10 ml. of deep blue liquid distilled into the receiver. At the completion of this gas evolution, normal distillation was continued, giving fractions (k)*, 4.5 ml., trap condensate; (l), 17 ml., b.p. 55–75° (2 mm.), but including the deep blue liquid which distilled during the gas evolution; (m), 1.5 g., b.p. 65–85° (1 mm.), n^{20}D 1.4511; (n), 3.0 g., b.p. *ca.* 85° (1 mm.), n^{20}D 1.4532; and a clear brown residue, 9.5 g., n^{20}D 1.4865. On standing at 5°, (*l*) deposited 2.0 g. XII, m.p. 81–82°, leaving mother liquors (l′), n^{20}D 1.4464. A solution of (n) in ether deposited 1.5 g. of VIII on cooling to −78°, leaving liquid (n′).

The fractions (i′) and (l′) were combined and redistilled, giving (o)*, 1.0 ml., in trap; (p)*, 8 ml., b.p. 40–50° (4 mm.), n^{20}D 1.4594; (q)*, 7.5 ml., b.p. 50–61° (4 mm.), deep blue, n^{20}D 1.4483; (r) 9.0 g., b.p. 61 (4 mm.)–50° (1 mm.) almost colorless, n^{20}D 1.4438; and 0.5 g. of yellow-brown residue. Fraction (r) largely solidified to crystalline XIII after long standing at 5°.

All of the fractions marked * were combined to give a single lot, 173.0 g., n^{20}D 1.4557, which was distilled through a six-plate column by Mr. E. M. Hadsell. This gave seventeen fractions: (1) trap condensate, 2.0 g., n^{20}D 1.4127; after removing 0.5 g. water by drying over sodium sulfate; (2) forerun, 1.3 g., b.p. 44.5–47.5° (20 mm.), n^{20}D 1.4243; (3–4) β-nitroisobutylene (XI), 37.6 g., b.p. 47.5–50.0° (20 mm.), n^{20}D 1.4326–1.4342; (5–6) intermediate fractions, 22.0 g., b.p. 49 (19 mm.)–55° (11 mm.), n^{20}D 1.4370–1.4556; (7–14) α-nitroisobutylene (X), 89.8 g., b.p. 55 (11 mm.)–73° (23 mm.), n^{20}D 1.4695–1.4702; (15) 5.3 g., b.p. 73–86° (23 mm.), n^{20}D 1.4647; (16) hold-up; 5.0 g., n^{20}D 1.4472; (17) residue, 7.0 g., n^{20}D 1.4501; handling loss, 3.0 g. Infrared examination showed that fractions 3–17 contained only X and XI, while 16 and 17 were largely XIII. The blue color, presumably due to traces of XII in the charge, disappeared completely during the course of the three-day distillation. From the plots of b.p. and n_D *vs.* weight distilled, it was concluded that fractions 1–17 contained 53 g. of XI, 101 g. of X, 2.0 g. of lower boiling material and 14 g. of higher boiling material.

The fractionation of the third crude distillate (43.9 g.) was done separately. Distillation through a short column gave (s), trap condensate, 3.2 g., two phases; (t) 3.8 g., b.p. 51–60° (19 mm.), n^{20}D 1.4514; (u), 8.4 g., b.p. 60–62° (19 mm.), n^{20}D 1.4590; (v), 8.2 g., b.p. 61.5° (18 mm.), n^{20}D 1.4615; (w), 7.9 g., b.p. 61.5–65° (18 mm.), n^{20}D 1.4614; and residue (x). Fractions (u), (v) and (w) consisted essentially entirely of X and XI. The constancy of their ratio through three successive fractions and the drop in refractive index during the fractionation were interpreted to mean that the known[6] base-catalyzed interconversion of X and XI was effecting a transformation of X to the more volatile XI during the distillation. Fraction (s) smelled distinctly of hydroxylamine, and its vapor gave a weakly alkaline reaction to test paper. It was neutralized with a little sulfuric acid and saturated with sodium sulfate to remove the water, giving (s′), 2.0 g., n^{20}D 1.3887. On cooling to −78°, a little VI, m.p. and mixed m.p. 59–61°, separated from fractions (t) and (u).

The distillation of (x) gave (y), trap condensate, 1.4 g., (z), 3.5 g., b.p. 50–65° (5 mm.), n^{20}D 1.4532; (aa), 3.5 g.

(23) N. Levy and C. W. Scaife, *J. Chem. Soc.*, 1094 (1946).

Digitized by Arya Samaj Foundation Chennai and eGangotri

b.p. 65–70° (5 mm.), $n^{20}D$ 1.4489; (bb), 3.5 g., b.p. 70 (5 mm.)–120° (1 mm.), $n^{20}D$ 1.4688; and 0.2 g. of residue. Drying (y) over sodium sulfate gave (y'), 1.0 g., $n^{20}D$ 1.4400. After removing analytical samples, fractions (z) and (aa) were first extracted with 6-ml. portions of water until no further volume change was notable, then shaken with sodium bisulfite solution to remove X and finally dried over sodium sulfate. The proportions of water-soluble, bisulfite-soluble and insoluble materials in (z) and (aa) were 34, 33 and 33%; and 27, 6 and 67%, respectively. About 60% of the water-soluble material was recovered by saturating the solutions with salt and extracting with ether, giving (cc), 1.2 g., $n^{20}D$ 1.4445, which was found to be >95% XIII. The combined insoluble oils, 2.9 g., were distilled through a Holzman column giving (dd), 0.18 g., b.p. 74.5–76° (5 mm.), $n^{20}D$ 1.4532; (ee), pure VII, 1.40 g., b.p. 77° (5 mm.), $n^{20}D$ 1.4460; (ff), 0.84 g., b.p. 77° (5 mm.), $n^{20}D$ 1.4465; and residue, 0.3 g. Finally, fraction (bb) was observed to have deposited some crystals after standing a month at 0°. These were extracted with aqueous sulfuric acid, the extracts made alkaline and extracted with ether to recover 0.4 g. of II, which was considerably less than the content indicated by the infrared spectrum to have been present originally. The acid-insoluble portion was distilled in a small molecular still to give (gg), 2.1 g.; this rapidly deposited crystals of III, 1.0 g., leaving (gg'), 1.0 g., yellowish oil, $n^{20}D$ 1.4655.

The net result of this fractionation was the isolation of all of the stable reaction products listed in Table I except for IV, V, XIV, and XV; and the separation of the crude reaction product into 50 organic fractions which represented either individual compounds or simple mixtures of substances having similar volatilities.

Analytical Procedures.—In general, qualitative analyses of the separate product fractions were based upon infrared spectra and the isolation of constituents, while the quantitative analyses were based upon the infrared spectra and other physical properties of the fractions.

First of all, the infrared spectra of authentic specimens of all of the stable product components were determined. The major features of most of these spectra have already been reported and discussed.[24] Next, qualitative analyses of the product fractions were made by comparing their spectra with those of the authentic materials. It was possible to identify all of the bands of the product spectra with bands of the appropriate intensity in the standards; thus the presence of appreciable amounts of stable products other than those listed in Table I could be eliminated.

In making quantitative estimates from the infrared spectra, use was made of the "internal standard" technique in most cases. This took advantage of the fact that most of the products were nitro-*t*-butyl derivatives and hence gave primary nitro NO_2 asymmetrical stretching bands near 6.42 μ which had molar extinction coefficients (in $CHCl_3$) near 550. Thus, the ratio of the intensity of any given band in the sample to that of the 6.42 μ band, divided by the corresponding ratio in the standard, gave the ratio of that constituent to the total primary nitro content of the sample. The relative content of α-nitroisobutylene (X), which was present to a greater or lesser extent in most of the samples analyzed, was estimated from the intensities of its 6.58 and 7.37 μ bands relative to the 6.42 μ band, adjusted for the lower extinction coefficients (380 and 280, respectively) of these bands. This method was checked where possible by a comparison of the refractive index of the sample with those of the components. The estimated compositions of fractions (z) and (aa) were checked by selective extraction, as already noted, and that of (d') was checked by an elementary analysis.

It was thus determined that the compositions of the various fractionated product mixtures were as follows: Fraction c, 0.6 g.: 0.1 X, 0.5 XIII. Fraction d', 1.2 g.: 0.7 II, 0.5 XV. Fraction m, 1.5 g.: 0.5 VIII, 0.2 X, 0.3 XIII, 0.5 XIV. Fraction n', 1.5 g.: 0.8 VIII, 0.2 XIII, 0.5 XIV. Fraction r, 9.0 g.: 0.7 VII, 7.0 XIII, 1.3 XIV. Low boilers from fractions 1–17, other than water, 1.5 g.: 0.6 IV, 0.6 V, 0.1 VI, 0.1 X, 0.1 XI. High boilers from fractions 1–17, 14 g.: 13.0 XIII, 1.0 XVI. Fraction s', 2.0 g.: 1.6 IV, 0.2 V, 0.1 X, 0.1 XI. Fraction t, 3.8 g., 0.3 IV, 0.3 V, 0.2 VI (by isolation), 2.2 X, 0.8 XI. Fractions u, v, w, 24.5 g.: 18.4 X, 6.1 XI. Fraction y', 1.0 g.: 0.3 IV, 0.5 X, 0.2 XI. Fraction z, 3.5 g.: 1.2 VII, 1.2 X, 1.1 XIII. Fraction aa, 3.5 g.: 2.4 VII, 0.2 X, 0.9 XIII. Fraction bb, 3.5 g.; 1.4 II, 1.2 III, 0.6 VII, 0.3 XVI.

The aggregate weights of the constituents of these mixtures, along with those of X and XI in fractions 1–17, of the II, VIII and XII separated in crystalline form during the fractionation, and of the residues and water obtained are listed in Table II as weights of compounds present "In Fractions."

Treatment of Losses.—The total weight of the water and the 45 liquid and solid organic fractions obtained up through fraction bb was 257.8 g. The remainder of the 295.9 g. of crude product taken for fractionation was accounted for by three types of losses. These were unrecovered water-soluble materials lost in the first extraction, 12.1 g.; gases evolved during degradative distillations, 13.4 g.; and mechanical losses due to handling, spillage, sampling, evaporation, etc., 12.6 g.

In order to obtain some understanding of the nature of the unrecovered water-soluble materials, known quantities of the water-soluble products II, XIII and XV were separately run through the water extraction and recovery procedure used. Each was recovered in about 65% yield, which was in line with a previous report of high losses during the extraction of isobutylene nitration products with water.[6] Since 8.2 g. of these products were recovered, this suggests that another 4.4 g. of the same materials were lost in the extraction. This 4.4 g. was assumed to represent 3.0 g. of XIII, 0.7 g. of II, 0.3 g. of XV and 0.4 g. of XVI, on the basis of the contents of these substances in the recovered water-soluble product after fractionation.

TABLE II

PRODUCTS OBTAINED BY FRACTIONATING 295.9 G. OF CRUDE REACTION PRODUCT

Compound	In fractions, g.	Corrected weight, g.	Mole C_4-units
II	2.8	3.6	0.0268
III	1.2	1.3	.0110
IV	2.8	2.9	(.0475)[c]
V	1.1	1.2	.0207
VI	0.3	0.3	.0041
VII	4.9	5.1	.0585
VIII	2.8	2.9	.0196
X	124.0	130.1	1.2869
XI	60.3	63.3	0.6261
XII	9.0	9.4	.0710
XIII	23.0	27.1	.2275
XIV	2.3	2.4	.0146
XV	0.5	0.8	.0078
XVI	17.7	19.0	.1880[d]
Inorg.[a]	5.1	25.0[b]	....
C_4H_8	...	1.5	.0274
	257.8	295.9	2.59
Losses			
H_2O sol.	12.1		
Gases	13.4		
Mechan.	12.6		
	295.9		

[a] Inorganic products: H_2O, NH_2OH, N_2, NO, etc. [b] Includes 5.4 g. corrected weight of recovered water, 7.7 g. H_2O water-soluble materials not otherwise accounted for and 11.9 g. of gases not accounted for as isobutylene. [c] In totaling the C_4-units, the C_3-units in V, VI and VII were counted as C_4, while the C_1 of IV, obtained in nearly equivalent amount, was not counted. [d] Assumed to have average composition of a nitroisobutylene polymer.

An attempt was made to divide up the 12.6 g. of mechanical losses on the basis of the estimated compositions of the various intermediate fractions on which they were incurred. This indicated that the losses were rather uniformly distributed among the product constituents and hence that the most satisfactory procedure would be to assume that these

(24) J. F. Brown, Jr., THIS JOURNAL, 77, 6341 (1955).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

losses were proportional to the quantities of constituents found present in the 257.8 g. of recovered product fractions. By adding these distributions of the 12.6 g. of mechanical losses and the 4.4 g. of unrecovered water-soluble products to the quantities of constituents present in the recovered fractions, the corrected yield figures shown in the third and fourth columns of Table II were determined.

It was noted that these corrected yields of organic products accounted for 2.56 moles of isobutylene. Since the 295.9 g. of product fractionated had originally come from 2.59 moles of isobutylene (*i.e.*, 2.85 × 295.9/325.7) this left 0.03 mole unaccounted for. This was assumed to represent regenerated isobutylene, lost during the fractionation along with the other gaseous products. However, this yield figure for regenerated isobutylene must be taken only as an order of magnitude, since it represents a small difference between large quantities. The percentage yields listed in the last column of Table I are calculated directly from the molar yields in Table II.

(Nitro-*t*-butyl)$_4$N$_2$O$_2$ (I).—The 29.8-g. portion of the crude reaction product which was not fractionated was kept at 0° for 4 weeks and 0.6 g. of crystalline XII removed. A 14.7-g. portion of the remaining liquid was extracted with four 100-ml. portions of cold water to remove II, XIII and XV, once with a disodium phosphate solution and twice more with water. The remaining oil was devolatilized by very brief stirring at 50° under 0.5 mm. pressure to give 4.0 g. of a concentrate of I. This was a viscous, yellow-brown oil, n^{20}D 1.4911, which was insoluble in solutions of sodium bisulfite or dilute acids. It was stored at −78° between analyses, the sequence of which was infrared spectrum, ultraviolet spectrum, elementary analyses and molecular weight; during this sequence sufficient decomposition occurred to lower the n^{20}D to 1.4904.

The usual infrared analysis indicated that the sample contained about 13% X, 12% III, 2% XIV, 2% of a hydroxylic impurity, later identified as XIII, and possibly a little IX. The remaining 65–70% of the sample, namely, I, gave an infrared spectrum which was very similar to those of the other nitro-*t*-butyl derivatives. It showed the strong bands of a primary nitro compound at 6.43, 7.00 and 7.27 μ, but no bands indicative of OH, NH, olefinic CH, C=C, C=N or C=O groups, nor were there any ultraviolet absorption bands above 230 μ. Prominent characterizing infrared bands lay at 7.95, 8.25, 8.70, 10.97 and 13.55 μ. In chloroform solution, the intensities of the 6.43 and 6.58 μ bands ($E^{1\%}_{1cm.}$) were 40 and 4.9, respectively; on the basis of the previously indicated molar extinction coefficients, this indicated that for each C$_4$-residue in the sample there were 0.85 primary nitro group and 0.15 conjugated nitro group, or a total of 1.00 nitro group per C$_4$-residue. Since each of the identified contaminants contained one nitro group per C$_4$-residue, it follows that Compound I must also have contained one nitro group per C$_4$-residue.

The analysis (found: C, 41.3; H, 6.5; N, 17.7; mol. wt., benzene cryoscopic, 232) corresponded almost exactly with the formula C$_8$H$_{15}$N$_3$O$_5$ for the over-all mixture. Fortuitously, this turned out to be very close to the aggregate elementary composition of the identified contaminants, so that the calculated elementary composition of I would be little affected by small errors in the estimates of the impurity content. At any rate, by allowing for the known contaminants and for the uncertainties resulting from decomposition during analysis and the standard error in the analyses, it was concluded that the analyses fixed the composition of the I contained in the sample within the limits (C$_8$H$_{15-16}$N$_3$O$_5$)$_{1-2}$.

Assuming that I is not a free radical, the three permissible formulas within these limits are C$_8$H$_{15}$N$_3$O$_5$, (C$_8$H$_{15}$N$_3$O$_5$)$_2$ and (C$_8$H$_{16}$N$_3$O$_5$)$_2$. The last formula was supported by three other facts. First, the compound was known to contain 1.0 primary nitro group per C$_4$-residue and to give entirely α-nitroisobutylene and nitro-*t*-butyl derivatives on decomposition. This indicated that all of the C$_4$-residues were present as nitro-*t*-butyl (C$_4$H$_8$NO$_2$) groups. Second, the high index and viscosity of the compound, despite the absence of conjugated structures or hydrogen bonding groups such as OH or NH, supported the formulas of higher molecular weight. Third, as already noted, the over-all stoichiometry of the reaction was in support of the conclusion that the major initial product was (C$_8$H$_{16}$N$_3$O$_5$)$_2$.

The I had a half-life of about three weeks at 0° and a similar stability in dilute chloroform solution at room temperature. Successive infrared spectra on the solution showed the 6.43 μ band of the I decreasing and the 6.58 μ (and other) bands of the X increasing steadily. Complete decomposition resulted when an attempt was made to distil 2.0 g. of the concentrate in a molecular still under a high vacuum at 50°. Infrared analyses indicated that the products had the following compositions: trap condensate (1.2 g., n^{20}D 1.4673), 1.1 g. of X, 0.1 g. of XI and XIII; liquid distillate (0.4 g.), 0.3 g. of II, 0.05 g. of X, 0.05 g. of XIV; residue, 0.3 g. The decomposition of the 1.3–1.4 g. of I contained in the sample thus gave 0.3 g. of II and 0.9 g. of X, in addition to that already present. The residue gave a little more X on further heating.

To confirm the identification of II in the liquid distillate, the portion remaining after analysis was divided into two 0.1–0.2-g. portions. Both were noted to become partly crystalline on standing a week at 0°. The solid from one was removed and recrystallized twice from chloroform–hexane to give 0.035 g. of II, m.p. and mixed m.p. 56.5–58°. The other was left at 0° for 6 months and then filtered. The solid, 0.11 g., was recrystallized from methanol and found to be III, m.p. 60–61.5°, mixed m.p. with II, 41–51°. The liquid contained VII; however, neither III nor VII could be detected in the original liquid distillate.

N-(Nitro-*t*-butyl)-hydroxylamine (II).—Recrystallization of the crude product from fractions (d) and (bb) from ether or methanol gave white crystals, m.p. and mixed m.p. 57–58°. The infrared spectrum showed the expected bands of primary nitro and hydroxylamino groups.[24]

Anal. Calcd. for C$_4$H$_{10}$N$_2$O$_3$: C, 35.8; H, 7.5; N, 20.9. Found: C, 35.9; H, 7.7; N, 21.1.

The compound was synthesized independently by shaking 2.0 g. of X with a solution of 2.0 g. of hydroxylamine hydrochloride and 0.8 g. of sodium hydroxide in 5 ml. of water for a few minutes. The odor of the X disappeared, and on cooling II crystallized out. Extraction of the mother liquors with ether and crystallization of the crude product from the extract at −78° gave 1.8 g. of crude II, m. 46–57°. After two recrystallization from methanol, 1.6 g. (60%) of pure II, m.p. 57–58.5°, was obtained.

The formulation of II as an N- rather than an O-alkyl hydroxylamine was based upon the infrared spectrum, which showed no NH$_2$ deformation band and upon its oxidation to the nitroso compound XII. One gram of II was dissolved in a solution of 2 ml. of concentrated sulfuric acid in 10 ml. of water at 0°, and a solution of 2 g. of sodium dichromate was added dropwise with stirring until the yellow color persisted. The mixture was allowed to stand an hour at 0° to permit the deep blue oil to dimerize and solidify. The crude solid, m. 74–78°, weighed 0.8 g. Recrystallization from carbon tetrachloride gave 0.7 g. (71%) of XII, m.p. 82.5–83.5°. The oxidation could also be effected by N$_2$O$_4$. When this was added to a solution of II in chloroform at 0°, the deep blue color of the nitroso compound XII appeared instantly. As more N$_2$O$_4$ was added, however, this pseudonitrosite was oxidized to the dinitro compound[25] and the color disappeared.

The pyrolysis of II was examined by a procedure which we have employed with a variety of unstable olefin nitration products. This consisted of heating 0.1–0.3 g. of the compound in a small test-tube whose bottom was in an oil-bath and whose sides were at room temperature. It was found that working with larger quantities frequently led to uncontrollable decomposition reactions. When 0.276 g. of II was thus heated an hour at 120°, there was a 15% weight loss, apparently due to the volatilization of IV and VI. The residual 0.234 g. of colorless liquid largely crystallized on cooling to give VI, m.p. and mixed m.p. 59–61°. This dealdolization of II to IV and VI appeared to be irreversible; when a mixture of IV, VI and piperidine was allowed to stand several days at room temperature, removal of the volatile reactants *in vacuo* left only a trace of residue, and this was completely unaffected by chromic acid.

The pyrolytic experiment was repeated using 0.148 g. of II, but this time several small (0.5–1.0-mg.) portions of fuming nitric acid were added as an NO$_2$ source. After each addition, a blue-green color appeared, and a steady evolution of gas began and continued for several minutes before subsiding. After an hour, further additions of the acid provoked no additional gas evolution; 3 mg. had been added in all. The tube then contained 0.047 of a brown oil;

[24] A. Hantzsch and O. W. Carlson, *J. Org. Chem.*, **4**, 169 (1939).

Digitized by Arya Samaj Foundation Chennai and eGangotri

i.e., 70% of the II had been converted to vapors and lost. The residual oil could not be crystallized from solution in a little methanol at −78°, even after seeding with VIII and II. Other strong acids produced no visible effects when added to hot II.

O,N-Bis-(nitro-*t*-butyl)-hydroxylamine (III).—The crude product from fraction (gg) was recrystallized from methanol to give large monoclinic tablets, m.p. 61–62.5°. The compound was insoluble in dilute acids, and the infrared spectrum indicated that the NH group was not hydrogen bonded (very sharp band of medium intensity at 3.07 μ). Otherwise, the infrared spectrum was quite similar to that of II.[14]

Anal. Calcd. for $C_8H_{17}N_3O_5$: C, 40.8; H, 7.2; N, 17.9. Found: C, 41.4, 40.4; H, 7.0, 6.9; N, 17.9.

The compound was synthesized independently by allowing a mixture of 0.37 g. of II, 2.0 g. of X and 0.01 ml. of triethylamine to stand overnight at room temperature. The amine and unreacted II were then extracted with dilute acid and the excess X evaporated *in vacuo*. Crystallization of the residue from methanol gave a 23% yield of III, m.p. and mixed m.p. 61–62°.

When 0.5 g. of III was heated in a bath at 180° for a few minutes (no discoloration), 0.2 ml. of distillate b. 103–130°, was obtained. This deposited some crystalline VI on cooling and left a liquid indicated by its infrared spectrum to be largely IV. The spectrum of the distillation residue indicated that it contained roughly equal amounts of VII and X.

Low Boiling Products.—Nitromethane (IV), acetone (V) and acetoxime (VI) were identified in the various cold trap condensates and fore-runs from their infrared spectra. Commercial samples were used for the infrared reference spectra and mixed m.p. determinations.

O-(Nitro-*t*-butyl)-acetoxime (VII).—The pure specimen obtained as fraction (ee) (b.p. 77° (5 mm.), $n^{20}D$ 1.4460) was a colorless liquid having a pleasant, somewhat camphoraceous odor, which showed the characteristic infrared bands of primary nitro and oxime ether groups.[24] The same material was synthesized independently by allowing a mixture of 3.65 g. (0.05 mole) of VI, 5.05 g. (0.05 mole) of X and 10 drops of triethylamine stand for three days at room temperature. The resulting mixture was extracted with dilute sulfuric acid and with strong sodium bisulfite solution, washed, dried and distilled to give 6.3 g. (72%) of VII, b.p. 77° (5 mm.), $n^{20}D$ 1.4460.

Anal. Calcd. for $C_7H_{14}N_2O_3$: C, 48.2; H, 8.1; N, 16.1. Found: C, 48.5, 49.0; H, 7.7, 8.1; N, 15.9.

1,2-Dinitroisobutane (VIII).—The solid obtained from fraction (n) was recrystallized from ether at −78° to give soft, waxy crystals, m.p. 53°, reported[6] m.p. 52–53°. The infrared spectrum[24] showed all the bands expected for this structure.

Unidentified Products.—Fraction (j′) showed a strong infrared band at 10.10 μ which was not present in the spectra of any of the redistilled product fractions or identified products. This band was presumed to indicate the presence of an unidentified unstable product component IX, which was probably another nitro-*t*-butyl derivative.

The portion of the crude reaction product which was allowed to stand four weeks at 0° contained some substance, possibly a nitrolic acid, which could be extracted with water or weakly alkaline buffers to give yellow or orange solutions. These solutions were reversibly decolorized by acidification with strong acids. The same behavior was shown by fractions (d′) and (s) (weak test), by specimens of X which had stood in glass bottles for several months (but not by fresh X) and by the crude products of the isobutylene vapor–nitric oxide and the isobutylene–N_2O_4 reactions (strong tests).

α-Nitroisobutylene (1-Nitro-2-methyl-1-propene, X).—The best specimen obtained, fraction 10, was a pale yellow oil, b.p. 64° (18 mm.), $n^{20}D$ 1.4702; reported[5] b.p. 72° (25 mm.), $n^{20}D$ 1.4710.

β-Nitroisobutylene (3-Nitro-2-methyl-1-propene, XI).—The best specimen obtained, fraction 3, was a colorless oil, b.p. 47.5–48.5° (20 mm.), $n^{20}D$ 1.4326; reported[5] b.p. 56° (25 mm.), $n^{20}D$ 1.4330.

Isobutylene Pseudonitrosite, Bis-(1-nitro-2-nitroso-2-methylpropane) (XII).—The five portions of XII recovered from the crude distillates (m.p. 81–82°) were recrystallized once from ether–acetone to give pure XII as large, orthorhombic tablets, m.p. 85–86°, to a deep blue liquid; reported, m.p. 80–82°,[8] 81°,[6] 87–88°.[26] When dissolved in solvents at room temperature, the solutions were initially colorless, but turned deep blue within a minute or two.

The pyrolysis of XII was conducted as described for II. When 0.200 g. was held at 120°, there was a gradual evolution of gas and fading of the blue color. After 25 minutes, 0.153 g. of light yellow liquid, $n^{20}D$ 1.4548, remained. The composition estimated from the infrared spectrum was 70% VIII, 20% X and 10% uncertain. Crystallization of a solution of this pyrolysate in methanol at −78° gave 0.080 g. of VIII, m.p. 47–50°. Other runs showed that the composition of the pyrolysate was very little affected by 10° variations in the temperature, by carrying out the pyrolysis under nitrogen or by operating in an evacuated sealed ampoule. In the last case, a mass spectrometric analysis (by F. J. Norton) on the gaseous product showed that it was mainly isobutylene and nitrogen, with lesser quantities of nitric oxide and traces of nitromethane, acetone, etc.

In looking for other possible transformations of XII under the conditions of the product fractionation, a novel reaction with nitric acid was discovered. When 0.2 g. of XII was dissolved in 3 ml. of cold absolute nitric acid, a reddish-brown solution was formed, which soon changed to light yellow. Dilution and washing with water gave an oil which distilled completely to give pure XIV (by infrared), $n^{20}D$ 1.4500. However, this reaction was markedly inhibited by traces of water and did not occur at all with 70% nitric acid, so that it probably could not have occurred during the product fractionation.

Nitro-*t*-butanol (XIII).—This was obtained in >80% purity in fractions (c), (r), 16, 17 and (cc). The sample used for the infrared standard (b.p. 55° (2 mm.), m.p. 24°, $n^{20}D$ 1.4435) was prepared by the condensation of nitromethane with acetone.[27]

Nitro-*t*-butyl Nitrate (XIV).—The isolation of this compound was not undertaken since the infrared identification (in fractions (m), (n′) and (r)) was particularly unambiguous. The strong bands of nitrate esters[24] are detected readily even in dilute solutions, and in XIV there also occurs a rare type of splitting of the nitrate NO_2 symmetrical stretching band into a pair of bands at 7.70 and 7.91 μ. The sample used for the infrared standard was prepared by nitrating 1.00 g. of XIII with 4 ml. of absolute nitric acid in 17 ml. of chloroform for 15 minutes at 0°. Extraction with water, solvent removal, further repeated extractions with water and distillation in a small molecular still gave 0.39 g. of XIV, $n^{20}D$ 1.4500, which solidified completely upon storage in a 5° refrigerator; reported[6] $n^{20}D$ 1.449, m.p. 6°.

α-Hydroxyisobutyraldoxime (XV).—This was detected only in fraction (d′), which was estimated from the infrared spectrum to be a roughly 2:1 mixture of II and XV. However, since the "internal standard" method was not applicable to such a mixture, an elementary analysis was made, which indicated that the actual proportions were about 62 and 38%.

Anal. Calcd. for 38% $C_4H_9NO_2$ + 62% $C_4H_9N_2O_3$: C, 40.1; H, 7.5; N, 18.2. Found: C, 40.1; H, 6.7; N, 17.8, 18.2, 18.4.

The specimen used for the infrared standard ($n^{20}D$ 1.4847) was prepared by the alkaline hydrolysis of the corresponding nitrate ester.[28]

Calculation of Initial Product Composition.—In calculating the initial product composition from that of the fractionated products, the major assumption made was that all of the products II through X, along with a little XII, the regenerated isobutylene, and XVI came from I, mostly *via* II, by the paths already indicated in the Results section. This assumption is based upon the observed behavior of compounds I, II, III and XII under conditions like those used in fractionating the product mixture and upon a number of observations made during the fractionation. Two of these seem particularly significant to the assumption in point. First, even though some decomposition of I must have occurred during the falling film distillation at 60°, the first crude distillate contained less than a third of the

X ultimately obtained. This is shown by its refractive index and the indices of the mixed nitroisobutylene fractions (e and f) obtained from it. Second, even though all of the intermediate fractions gave high boiling residues upon redistillation, the original distillations of the 295.9 g. of crude product converted all but 5.5 g. to materials b. <100° (1 mm.). This indicates that there was very little or no formation of stable telomeric or condensed products in the original reaction.

The one point left in doubt concerns the origin of the acetone (V) which could have come either from the dealdolization of XIII or the dealdolization of II, followed by reaction of the resulting acetoxime with water and/or nitrous acid. We have arbitrarily selected the latter route in our calculation because of the greater instability of II.

Thus, the initial contents of XIII, XIV and XV were assumed to be the same as the corrected values for those in the final products. The content of XII was taken as the final amount less that formed in the distillation of fraction (j) and the initial content of XI taken as the final content less the 10% formed during the distillation which gave fractions (u-w). The resulting estimate of the initial product composition is shown in Table I.

This estimate means that in our reaction, which consumed 2.85 moles of isobutylene, the initial product mixture should have contained (1/4 × 1.89) moles of I, 0.62 mole of XI, 0.06 mole of XII, 0.25 mole of XIII, 0.02 mole of XIV and 0.01 mole of XV. The formation of such a mixture would require the consumption of 7.195 moles of NO and would produce at the same time 1.66 moles of N_2 and 0.18 mole of water. These are within experimental error of the observed values, namely, 7.13 moles of NO consumed, 1.72 moles of N_2 produced and 0.183 mole of H_2O (3.0 g. × 325.7/295.9) removed from the first falling film distillate.

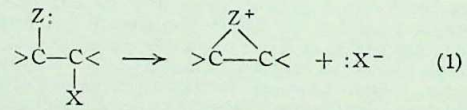
Rates of Acetolysis of *cis*- and *trans*-2-Nitroxycyclohexyl *p*-Bromobenzenesulfonates and *p*-Toluenesulfonates

BY STANLEY J. CRISTOL AND BORIS FRANZUS

RECEIVED NOVEMBER 6, 1956

The rates of solvolysis of *cis*- and *trans*-2-nitroxycyclohexyl *p*-bromobenzenesulfonates and *p*-toluenesulfonates in acetic acid at 87.9° have been measured. Solvolyses with the *trans* isomers proceed at a rate less than twice that of the *cis* isomers, indicating that the nitroxy group is not an effective anchimeric group. The preparations of these arenesulfonates and of *cis*- and *trans*-1,2-cyclohexanediol mononitrates are described.

Winstein and his co-workers[1] have shown that rate enhancement occurs when a group on a β-carbon atom participates in solvolysis of another group on the α-carbon atom, *viz.*



(1)

For example, the *p*-bromobenzenesulfonate (brosylate) of *trans*-2-acetoxycyclohexanol—where the acetoxy group is sterically situated so as to permit participation as in (1)—solvolyzes in acetic acid 630 times as rapidly as the *cis* isomer (where participation is sterically impossible). In similar fashion *trans*-2-bromocyclohexyl brosylate reacts 800 times as rapidly as the *cis* isomer. These groups therefore are effective participants. However, both *cis* and *trans*-cyclohexanediol dibrosylate react at about the same rate. Thus arenesulfonoxy groups are ineffective in this participation.

The rates of solvolysis of *cis*- and *trans*-2-nitroxycyclohexyl *p*-bromobenzenesulfonate and *p*-toluenesulfonate were determined in acetic acid at 87.9°, substantially as described by Winstein and co-workers.[1] The rate constants are given in Table I (average of two runs), along with data of Winstein for 2-acetoxycyclohexyl and 2-*p*-bromobenzenesulfonoxycyclohexyl brosylates and/or tosylates.

It will be noted that the *trans*-nitroxy compounds are less than twice as reactive as the corresponding *cis* compounds and that their rate constants for solvolysis are of the same order of magnitude as the *cis*-2-acetoxy compounds or the 2-arenesulfonoxy compounds. The results indicate clearly that effective participation of nitroxy does not obtain and that an intermediate such as I is not being formed in the rate-determining step in solvolysis. The effect of the nitroxy group appears limited to its inductive effect (similar to the *cis*-acetoxy and the arenesulfonoxy group), which thus slows down the rate significantly with respect to cyclohexyl

TABLE I

REACTION RATE CONSTANTS FOR ACETOLYSIS OF 2-SUBSTITUTED CYCLOHEXYL *p*-TOLUENESULFONATES AND *p*-BROMOBENZENESULFONATES

2-Substituent	Temp., °C.	10^5k, sec.$^{-1}$

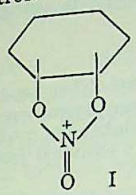
arenesulfonates, but it would be of interest to determine the stereochemistry of the solvolysis to see whether compound I may be still involved in stereochemical control.



I

Many of the compounds for this study were prepared for the first time. The *trans* compounds were prepared by the reaction sequence: cyclohexene oxide plus nitric acid to *trans*-1,2-cyclohexanediol mononitrate; mononitrate plus arenesulfonyl chloride to nitroxycyclohexyl arenesulfonate. The *cis* compounds were prepared from *cis*-1,2-cyclohexanediol monoacetate.[2] This was nitrated, and the nitroxy acetate was hydrolyzed selectively with dilute base to remove the acetoxy group and retain the nitrate group. The resulting *cis*-diol mononitrate was then arenesulfonated. The structure of each of the mononitrates was established by hydrogenolysis.

Acknowledgments.—The authors are indebted to the Office of Ordnance Research, U. S. Army, for support of this research under a contract between that Office and the University of Colorado. The analyses were performed by Galbraith Microanalytical Laboratories.

Experimental

Determination of Rate Constants.—The rate constants were determined substantially as described by Winstein, Hanson and Grunwald.[3] The solvent was acetic acid containing excess sodium acetate, 0.05 *M*, and water, 0.36 *M*, and the solutions were titrated with standard perchloric acid in acetic acid, using either brom phenol blue or methyl violet as indicator.

***trans*-2-Nitroxycyclohexyl *p*-Toluenesulfonate.**—A solution of 0.50 g. (3 mmoles) of *trans*-cyclohexanediol mononitrate[4] and 0.6 g. of *p*-toluenesulfonyl chloride in enough pyridine to dissolve the reagents was kept in a refrigerator for 3.5 days. The reaction mixture was poured into water, the solid removed by filtration and recrystallized once from benzene–petroleum ether and twice from cyclohexane. It then melted at 84.0–84.3°.

Anal. Calcd. for $C_{13}H_{17}O_6NS$: C, 49.51; H, 5.43. Found: C, 49.71; H, 5.57.

***trans*-2-Nitroxycyclohexyl *p*-bromobenzenesulfonate** was prepared in the same fashion (time 1.5 days) with *p*-bromobenzenesulfonyl chloride. After three recrystallizations, it melted at 89.6–90.3°.

Anal. Calcd. for $C_{12}H_{14}O_6BrNS$: C, 37.90; H, 3.71. Found: C, 37.81; H, 3.82.

***cis*-1,2-Cyclohexanediol Mononitrate.**—A solution containing[2] 13.0 g. (0.082 mole) of 1,2-cyclohexanediol monoacetate and 6.43 g. of diacetate (estimated by saponification equivalent) in 40 ml. of chloroform was added dropwise over a period of 2 hr. to a solution of 10.7 ml. of nitric acid (d. 1.50, 98% nitric acid) in 50 ml. of 96% sulfuric acid. A temperature between −25 and −7° was maintained during the addition. The reaction mixture was poured into ice-water, and the chloroform layer was separated. The water layer was extracted once with 50 ml. of chloroform. The combined chloroform extracts were washed with water, saturated sodium bicarbonate and water. The chloroform solution was dried over anhydrous magnesium sulfate, and the material was distilled. The product, which was a mixture of *cis*-2-acetoxycyclohexyl nitrate and *cis*-1,2-cyclohexanediol diacetate, boiled at 68–73° (0.5 mm.) and weighed 16.7 g. The product was estimated to contain 9.4 g. (58% of mixture, 56% yield) of 2-acetoxycyclohexyl nitrate by quantitative hydrogenolysis over platinum oxide catalyst.

Sixteen grams of this mixture was treated with 100 ml. of 1.4 *M* sodium hydroxide solution in 75 vol. % ethanol at room temperature for 50 minutes. The extent of reaction was followed by titration of aliquots with standard hydrochloric acid, and it was apparent that hydrolysis of the acetate ester groups from the diacetate and nitrate–acetate was substantially complete at the end of this time. This method takes advantage of the relative inertness of nitrate esters to hydrolysis with alkali.[5-7] The solution was then neutralized with dilute acid, saturated with sodium chloride and extracted with three 100-ml. portions of ether. The ether extracts were combined and washed with 400 ml. of saturated salt solution. The ethereal solution was dried overnight over anhydrous magnesium sulfate, and the ether was distilled. The product, *cis*-1,2-cyclohexanediol mononitrate, boiled at 63–63.2° (0.3 mm.), $n^{20}D$ 1.4787, and weighed 3.81 g. (54% yield).

Anal. Calcd. for $C_6H_{11}NO_4$: C, 44.71; H, 6.88; N, 8.69. Found: C, 44.62; H, 6.72; N, 8.55.

Hydrogenolysis of this nitrate over platinum oxide at atmospheric pressure gave crude *cis*-diol, m.p. 89–96°, mixed m.p. with *cis*-diol,[2] 89–96°, mixed m.p. with *trans*-diol,[2] 66–80°.

cis-2-Nitroxycyclohexyl *p*-toluenesulfonate was prepared as described above for the *trans* isomer, m.p. after recrystallization from cyclohexane, 74.5–75.2°.

Anal. Calcd. for $C_{13}H_{17}O_6NS$: C, 49.51; H, 5.43. Found: C, 49.50; H, 5.52.

cis-2-Nitroxy *p*-bromobenzenesulfonate was prepared as described above for the *trans* isomer, m.p. after recrystallization from cyclohexane, 94–94.5°.

Anal. Calcd. for $C_{12}H_{14}O_6BrNS$: C, 37.90; H, 3.71. Found: C, 37.97; H, 3.72.

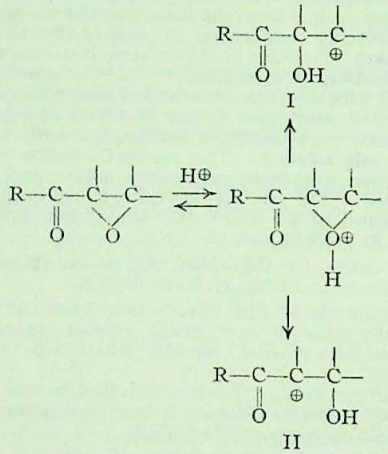
The Rearrangement of α,β-Epoxy Ketones. VI. 1,1-Disubstituted Ethylene Oxides

BY HERBERT O. HOUSE, DONALD J. REIF[1] AND RICHARD L. WASSON[1]

RECEIVED NOVEMBER 12, 1956

α,β-Epoxy-α-phenylpropiophenone, α,β-epoxy-α-ethylpropiophenone and 1,2-dimesityl-2,3-epoxy-1-propanone have been isomerized to α-formyldesoxybenzoin, α-formylbutyrophenone and the enol of α-formyldesoxymesitoin, respectively, by treatment with boron trifluoride. The analogous rearrangement of α,β-epoxypropiophenone produced 1,3,5-tribenzoylbenzene. The interpretation of the results suggests that a carbonium ion adjacent to a carbonyl group is either equivalent in stability or more stable than a primary carbonium ion.

The products derived from the acid-catalyzed isomerization of a variety of α,β-epoxy ketones have been rationalized by the assumption that the initial step in the isomerization involves cleavage of the oxirane ring to leave a positive charge on the carbon atom beta to the carbonyl group (I).[2,3] The fission of the oxirane ring to form the transient cation I rather than II appeared to be justified; the formation of structure II would be expected to be energetically unfavorable since this structure places partial positive charges on adjacent atoms.



Although a carbonyl group is usually considered to destabilize an adjacent carbonium ion (such as II),[4,5] there is little evidence bearing on the extent of this destabilization relative to the effect of other substituents. Since the mode of cleavage (*i.e.*, I or II) of the oxirane ring accompanying the acid-catalyzed rearrangement of α,β-epoxy ketones appeared to offer a measure of the relative stability of a carbonium ion (or a partial positive charge)[3] adjacent to a carbonyl group, we were led to study the isomerization of certain 1,1-disubstituted ethylene oxides III. The products formed by rearrangement of these oxides III would provide a measure of the relative stabilities of a primary carbonium ion (Fig. 1, reaction path A) and a carbonium ion adjacent to a carbonyl group (Fig. 1, reaction path B).

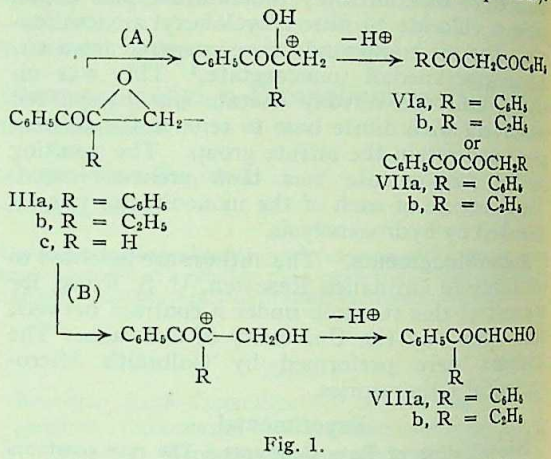


Fig. 1.

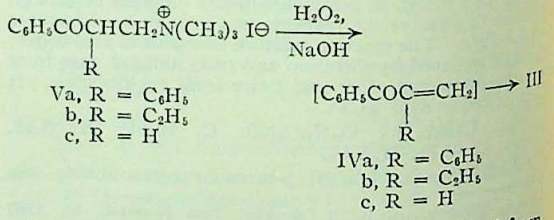
For the preparation of the keto oxides III, we investigated procedures which would avoid isolation of the unstable acrylophenone precursors IV. Direct reaction of the appropriate Mannich base methiodides V with alkaline hydrogen peroxide was found to produce the desired oxides.[6]



In a previous study[2b] the product derived from the isomerization of α-phenyl-*cis*-benzalacetophenone oxide appeared to be best explained by the assumption that the reaction proceeded *via* an ion of the type II. This observation suggested that the formation of a carbonium ion adjacent to a carbonyl group may occur without difficulty if the ion is stabilized by an adjoining aryl group.[7] We therefore chose α,β-epoxy-α-phenylpropiophenone (IIIa) for our initial studies in an effort to favor reaction path B (Fig. 1). The rearrangement of

(2) For previous papers in this series see THIS JOURNAL, (a) **76**, 1235 (1954); (b) **77**, 6525 (1955); (c) **78**, 2298 (1956); (d) **78**, 4394 (1956); (e) **79**, 1488 (1957).

(3) The cleavage of the oxirane ring and the attendant rearrangement may well be concerted processes. If this is the case, the positive charge would not reside entirely on the β-carbon atom as depicted in I. Studies to determine the relative charge distribution in the transition state are currently in progress.

(4) J. Hine, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y., 1956, p. 150.

(5) The failure of certain α-halo ketones to react with silver nitrate has been attributed to such destabilization [for example, see R. L. Shriner, R. C. Fuson and D. Y. Curtin, "The Systematic Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1956, p. 143].

(6) This reaction is analogous to the use of the quaternary salts of Mannich bases as precursors for unsaturated ketones in the Michael reaction [see J. H. Brewster and E. L. Eliel, *Org. Reactions*, **7**, 99 (1953)].

(7) The successful use of α-aryl α-halo ketones as alkylating agents in the Friedel–Crafts reaction [P. Ruggli, H. Dahn and J. Wegmann *Helv. Chim. Acta*, **29**, 113 (1946)] is in agreement with this idea.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

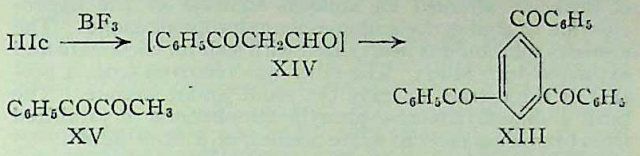
Digitized by Arya Samaj Foundation Chennai and eGangotri

the oxide IIIa in the presence of boron trifluoride etherate yielded the keto aldehyde VIIIa, the product expected if the reaction followed path B (Fig. 1). We were unable to isolate either of the diketones VIa or VIIa.

A previous example of an acid-catalyzed isomerization of an oxide analogous to IIIa has been reported[8]; the reaction of 1,2-dimesityl-2,3-epoxy-1-propanone (IX) with a mixture of acetic and hydriodic acids was found to yield an unknown product isomeric with the starting ketone. We have effected the same reaction by treatment of the oxide IX with boron trifluoride etherate. The product is acidic and has an infrared spectrum which is suggestive of an enolized β-dicarbonyl compound. Since the product does not resemble either of the known, isomeric enolized diketones X[9] or XI,[10] the compound was assigned the enolized keto aldehyde structure XII, an analog of the keto aldehyde VIIIa derived from IIIa. This assignment was confirmed when compound XII was synthesized by the reaction of the bromomagnesium enolate of desoxymesitoin (XIII) with ethyl formate.

We next turned our attention to α,β-epoxy-α-ethylpropiophenone (IIIb). Rearrangement of the epoxide IIIb *via* reaction path B (Fig. 1) would involve a tertiary cation adjacent to a carbonyl group as was the case with IIIa; however, the formation of such an ion from IIIb would not be favored by an adjoining phenyl ring. The isomerization of the epoxide IIIb proceeded much more slowly than isomerizations previously studied as might be expected if the reaction involved the formation of a relatively unstable carbonium ion. Best results were obtained when the rearrangement was effected in the presence of a benzene solution of gaseous boron trifluoride rather than with boron trifluoride etherate.[11] The only products which could be isolated from the isomerization were the keto aldehyde VIIIb and its degradation product, butyrophenone; neither of the diketones VIb and VIIb or compounds derived from them, the products expected from rearrangement *via* path A (Fig. 1), could be isolated from the reaction mixture.

We therefore investigated the behavior of α,β-epoxypropiophenone (IIIc). Reaction of this oxide IIIc with boron trifluoride yielded the triketone XIII as the only isolable product. The triketone XIII was presumably derived from the intermediate keto aldehyde XIV; when an authentic sample of the keto aldehyde XIV was subjected to the conditions of the rearrangement, only the triketone XIII was produced. The alternative product, the diketone XV which might result from the isomerization of the oxide IIIc, has been found to be stable to acids[12] and, consequently, is not the precursor of the triketone XIII.



In order to determine which of the reaction paths C or D (Fig. 2) was operative in the conversion of the oxide IIIc to the triketone XIII, the isomerization of the partially deuterated oxide XVI was studied. The fate of the deuterium label in each reaction path is outlined in Fig. 2; 47% of the deuterium present in the oxide XVI was retained in the product XIII. Consequently, we are led to believe that approximately half of the isomerization of the oxide IIIc is proceeding *via* reaction path C (Fig. 2) and the remainder *via* path D (Fig. 2).

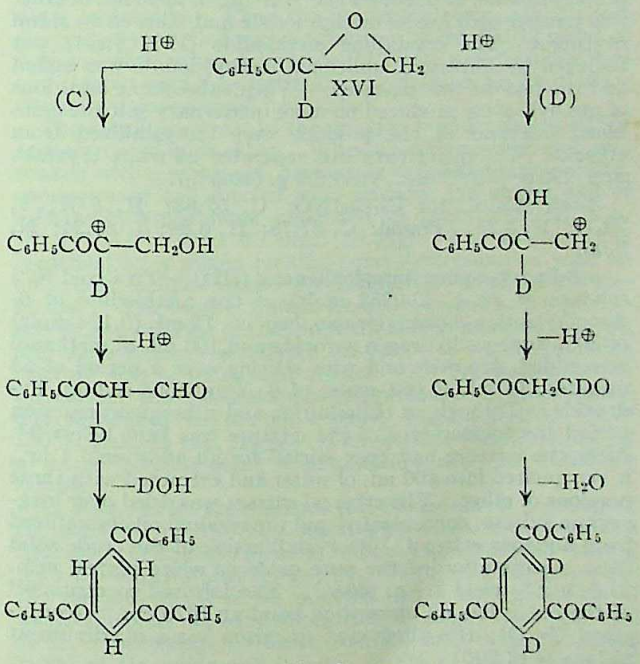


Fig. 2.

Our results suggest that the stability of a carbonium ion adjacent to a carbonyl group is approximately equivalent to the stability of a primary carbonium ion. The order of relative stabilities suggested by our present and previous[2] experiments is

The authors wish to acknowledge the assistance of Dr. R. C. Fuson who kindly supplied samples of desoxymesitoin and mesityl α-mesitylvinyl ketone for this study.

Experimental[13,14,15]

The Methiodide of β-Dimethylamino-α-phenylpropiophenone (Va).—The reaction of 25 g. (0.128 mole) of desoxybenzoin with a solution of 23 ml. of 25% aqueous dimethylamine and 11.1 ml. of 37% aqueous formaldehyde in 50 ml. of ethanol according to the directions of Denton and co-workers[16] afforded an aqueous solution of the hydrochloride of β-dimethylamino-α-phenylpropiophenone. The aqueous solution was neutralized with sodium carbonate and extracted with ether. The ether was removed from a portion of the extract to leave the crude amine ketone. The pure β-dimethylamino-α-phenylpropiophenone crystallized from petroleum ether as white needles, m.p. 82.0–82.8°.

Anal. Calcd. for $C_{17}H_{19}NO$: C, 80.57; H, 7.56; N, 5.53. Found: C, 80.49; H, 7.47; N, 5.40.

The ether extract was dried over magnesium sulfate, treated with excess methyl iodide and allowed to stand at 15° for 12 hr. The crude product, collected on a filter, was recrystallized from aqueous ethanol. The methiodide separated as white crystals, m.p. 182.8–183.8° dec., yield 23.8 g. (48.5% based on desoxybenzoin).

Anal. Calcd. for $C_{18}H_{22}INO$: C, 54.71; H, 5.62; I, 32.11; N, 3.54. Found: C, 54.60; H, 5.56; I, 32.31; N, 3.76.

The Methiodide of β-Piperidino-α-phenylpropiophenone.—A solution of 10.5 g. (0.035 mole) of β-piperidino-α-phenylpropiophenone, m.p. 90.8–91.8° (lit.[17] 91°), in 40 ml. of ether was treated with excess methyl iodide and allowed to stand overnight. The crystalline methiodide (17% yield) was removed by filtration, additional methyl iodide was added and the process was repeated. When subsequent additions of methyl iodide produced no more quaternary salt the combined fractions of the product were recrystallized from ethanol. The quaternary salt separated as white crystals, m.p. 192.8–193.6° dec., yield 6.0 g. (40.5%).

Anal. Calcd. for $C_{21}H_{26}INO$: C, 57.88; H, 6.01; I, 29.11; N, 3.21. Found: C, 57.78; H, 6.24; I, 29.24; N, 3.05.

α,β-Epoxy-α-phenylpropiophenone (IIIa).—To a cold (0°) mixture of 10 g. (0.0253 mole) of the methiodide of β-dimethylamino-α-phenylpropiophenone, 12 ml. (0.124 mole) of 30% aqueous hydrogen peroxide and 100 ml. of methanol was added, dropwise and with stirring over a period of 25 minutes, 14 ml. (0.084 mole) of 6 *N* aqueous sodium hydroxide. Throughout the addition and subsequent reaction period the temperature of the mixture was kept below 2°. After the mixture had been stirred for an additional 1 hr., it was poured into 400 ml. of water and extracted with three portions of ether. The ethereal extract was dried over magnesium sulfate, concentrated and the residual oil crystallized from aqueous ethanol. Recrystallization of the crude solid from hexane afforded the pure oxide as white plates, m.p. 29.6–30.6°, yield 3.7 g. (66%). The infrared spectrum[15,19] of the oxide has an absorption band at 1670 cm.$^{-1}$ (conjugated C=O); the ultraviolet spectrum has a maximum at 252 mμ (ε 13,600).

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39. Found: C, 80.18; H, 5.19.

Rearrangement of α,β-Epoxy-α-phenylpropiophenone (IIIa).—A solution of 260 mg. (0.00117 mole) of the oxide in 10 ml. of benzene was treated with 0.3 ml. (0.0024 mole) of boron trifluoride etherate and the resulting solution was allowed to stand at room temperature for 20 minutes. The reaction mixture was diluted with ether, washed with water and dried over magnesium sulfate. After the solvents had been removed, the residual oil was crystallized from hexane to give the **borofluoride complex of α-formyldesoxybenzoin** as yellow needles, m.p. 99.2–100° (lit.[20] 97–99°), yield 141 mg. (44%). In subsequent experiments the α-formyldesoxybenzoin was isolated as its copper complex, m.p. 223–224.5° (lit.[20] 220–221°), yield 65.3%, and, after treatment with phenylhydrazine as **1,4,5-triphenylpyrazole**, m.p. 211.2–212.2° (lit.[20] 210–211°), yield 75%. Each of the products was identified by a mixed melting-point determination with an authentic sample. As a control experiment a sample of the oxide IIIa was treated with phenylhydrazine under the same conditions which were employed to prepare 1,4,5-triphenylpyrazole from the crude isomerization product; none of the pyrazole could be isolated.

In an effort to isolate any benzyl phenyl diketone present as its quinoxaline, a crude rearrangement product was boiled with a solution of *o*-phenylenediamine dihydrochloride in ethanol. The only crystalline product which could be isolated was desoxybenzoin, m.p. 60–61° (lit.[21] 60°), yield 35%, which formed a 2,4-dinitrophenylhydrazone melting at 202–203.5° (lit.[22] 203°). All of our attempts to isolate dibenzoylmethane or one of its derivatives from the reaction mixture were unsuccessful.

Rearrangement of 1,2-Dimesityl-2,3-epoxy-1-propanone (IX).—Mesityl α-mesitylvinyl ketone [infrared absorption[19,23] 1665 cm.$^{-1}$ (conjugated C=O), 1625 cm.$^{-1}$ (conjugated C=C), 975 cm.$^{-1}$ (C=CH_2 adjacent to a carbonyl group)[23]] was converted to the epoxy ketone IX, m.p. 150.5–151.5° (lit.[8] 152–152.5°), by the procedure previously described.[8] The infrared spectrum[19,23] of the oxide has a band at 1700 cm.$^{-1}$ (C=O of a sterically hindered aryl ketone) but lacks the absorption at 975 cm.$^{-1}$ found in the corresponding unsaturated ketone. A mixture of 0.50 g. (0.0016 mole) of the oxide, 2 ml. (0.016 mole) of boron trifluoride etherate and 25 ml. of cyclohexane was stirred for 2 minutes, diluted with ether, washed with water and concentrated. The residual solid crystallized from ligroin (b.p. 90–120°) as white needles, m.p. 250–252°, yield 0.27 g. (54%). An additional crystallization sharpened the melting point of the keto aldehyde to 251–252°.

Anal. Calcd. for $C_{21}H_{24}O_2$: C, 81.78; H, 7.84; mol. wt., 308. Found: C, 81.76; H, 7.96; mol. wt., 245 (Rast).

An attempt to effect the same rearrangement in ether solution with boron trifluoride etherate resulted in isolation of the unchanged oxide (75% recovery).[11]

The infrared spectrum[19,25] of the enolized keto aldehyde has a broad intense band in the 3 μ region with its center at 2950 cm.$^{-1}$ (associated O–H); in the 6 μ region a band of medium intensity is found at 1630 cm.$^{-1}$ accompanied by a broad, intense band with its center at 1565 cm.$^{-1}$ (C=O and/or C=C of an enolized β-dicarbonyl compound). The product was shown to be identical with the sample, m.p. 250–253°, prepared by Fuson and co-workers[8] by means of a mixed melting-point determination. Although the compound dissolved readily in aqueous alkali, it was remarkably stable to cleavage. After a solution of the compound in 10% aqueous sodium hydroxide had been heated on a steam-bath for 1 hr., 98% of the unchanged, enolized keto aldehyde was recovered when the reaction mixture was acidified. The behavior of the compound was also anomalous in that an ethanolic solution of the product gave no color with ferric chloride.

1,2-Dimesityl-2-propen-3-ol-1-one (XII).—A solution of 280 mg. (0.001 mole) of desoxymesitoin and 1 ml. (0.001 mole) of a standard solution of ethylmagnesium bromide in 25 ml. of benzene was refluxed for 40 minutes and then treated with 3 ml. (0.037 mole) of ethyl formate. The resulting mixture was refluxed for 19 hr., diluted with ether and washed with aqueous ammonium chloride. After the

(13) All melting points are corrected and all boiling points are uncorrected.

Digitized by Arya Samaj Foundation Chennai and eGangotri

solvents had been removed from the organic layer, the residue was taken up in boiling methanol and the solution was decolorized with Norit, diluted with water and cooled. After the unchanged desoxymesitoin, m.p. 90–93°, recovery 182 mg. or 65%, had been removed, concentration of the mother liquor afforded 26 mg. of the crude enolized keto aldehyde, melting over the range 220–245°. The pure enolized dicarbonyl compound crystallized as white needles, m.p. 251–253°, yield 12 mg. (11% based on the unrecovered desoxymesitoin). The melting point of a mixture of the product with a sample obtained by rearrangement of 1,2-dimesityl-2,3-epoxy-1-propanone was not depressed.

The Methiodide of β-Dimethylamino-α-ethylpropiophenone (Vb).—The Mannich base hydrochloride was prepared from 40 g. (0.27 mole) of butyrophenone, 16.8 g. (0.56 mole) of paraformaldehyde and 49 g. (0.6 mole) of dimethylamine hydrochloride according to the general directions of Burckhalter and Fuson.[26] The paraformaldehyde and dimethylamine hydrochloride were added in two equal portions, the second portion being added after 4 hr.; a total reaction time of 16 hr. was employed. An aqueous solution of the Mannich base hydrochloride was neutralized with sodium carbonate and the amine was taken up in ether. The ethereal solution was dried over magnesium sulfate, treated with excess methyl iodide and allowed to stand for 12 hr. The methiodide separated as fine, white crystals, m.p. 188.8–189.8°, yield 59.3 g. (63%). The melting point of the product was not altered by recrystallization from an ethanol-ether mixture.

Anal. Calcd. for $C_{14}H_{22}INO$: C, 48.43; H, 6.40; I, 36.56; N, 4.03. Found: C, 48.47; H, 6.22; I, 36.58; N, 4.03.

α,β-Epoxy-α-ethylpropiophenone (IIIb). A. From the Methiodide Vb.—To a cold (−4°) solution of 58.8 g. (0.17 mole) of the quaternary salt and 81 ml. (0.84 mole) of 30% aqueous hydrogen peroxide in 500 ml. of methanol was added, dropwise and with stirring over a period of 20 minutes, 94 ml. (0.56 mole) of 6 *N* aqueous sodium hydroxide. The resulting mixture was stirred for 2 hr.; throughout the addition and subsequent reaction period the temperature of the mixture was kept at −2°. The reaction mixture was poured into water and the resulting mixture was extracted with ether. The extract was dried over magnesium sulfate and concentrated. The components of the extract were separated by repeated fractional distillation through a Holtzmann column. The α,β-epoxy-α-ethylpropiophenone (IIIb), a colorless liquid boiling at 60–61° (0.15 mm.), $n^{25}D$ 1.5249, amounted to 3.35 g. (11.2%). The infrared spectrum[19,27] of the oxide has a band at 1675 cm.$^{-1}$ (conjugated C=O); the ultraviolet spectrum has a maximum at 246.5 mμ (ε 11,600) with a minimum at 220 mμ (ε 2,210). The nuclear magnetic resonance spectrum of the oxide, determined as a pure liquid with a Varian Associates high-resolution nuclear magnetic resonance spectrometer, model V4300B, has the following peaks (expressed as cycles per second relative to the proton resonance of water): a triplet with its center at −174 sec.$^{-1}$ (CH_3 adjacent to CH_2); a singlet at −135 sec.$^{-1}$ (CH_2 adjacent to CH_3); a quadruplet with its center at −96 sec.$^{-1}$ (CH_2 of an oxide ring); and two multiple peaks centered around +90 sec.$^{-1}$ and +108 sec.$^{-1}$ attributable to the nuclear resonance of protons bonded to an aromatic ring.

Anal. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86. Found: C, 75.05; H, 6.86.

The α-ethylacrylophenone (IVb), collected in the initial fractions of the distillation, amounted to 11.24 g. (41.5%), b.p. 49–50° (0.15 mm.), $n^{25}D$ 1.5300 [lit.[26] b.p. 85° (5 mm.), $n^{25}D$ 1.5267]. The infrared spectrum[19,27] of the unsaturated ketone has a band at 1645 cm.$^{-1}$ (conjugated C=O) with a shoulder at 1625 cm.$^{-1}$ (conjugated C=C). The spectrum also exhibits a band at 975 cm.$^{-1}$ (C=CH_2 adjacent to a carbonyl group)[24] which is not present in the spectrum of the oxide. The ultraviolet spectrum of the unsaturated ketone has a maximum at 246 mμ (ε 10,000) with a minimum at 220 mμ (ε 6,650).[25] The nuclear magnetic resonance spectrum of the unsaturated ketone, determined as previously described, has the following peaks (relative to the proton resonance of water): a triplet with its center at −170 sec.$^{-1}$ (CH_3 adjacent to CH_2); a quadruplet with its center at −115 sec.$^{-1}$ (CH_2 adjacent to CH_3); a doublet (+7 and +18 sec.$^{-1}$) attributable to the two non-equivalent hydrogen atoms of the terminal methylene group; and a series of peaks centered around +92 sec.$^{-1}$ attributable to the nuclear resonance of protons bonded to an aromatic ring. Because of the discrepancy in refractive index values the composition of the unsaturated ketone was also determined.

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.46; H, 7.55. Found: C, 82.30; H, 7.52.

B. Epoxidation of α-Ethylacrylophenone (IVb).—A solution of 11.1 g. (0.069 mole) of the unsaturated ketone and 20 ml. of 30% aqueous hydrogen peroxide in 70 ml. of methanol was cooled to 0°, and 6 ml. (0.036 mole) of 6 *N* aqueous sodium hydroxide was added dropwise and with stirring. The resulting mixture was stirred for 3 hr. at room temperature, diluted with water and extracted with ether. After the extract had been dried and concentrated, distillation of the residue through a 30-cm. Podbielniak concentric tube fractionating column, model GE-117, afforded 6.91 g. (56.5%) of α,β-epoxy-α-ethylpropiophenone, b.p. 68.5° (0.4 mm.), $n^{25}D$ 1.5258. The infrared and ultraviolet spectra of the product are identical with the spectra of the oxide sample previously described.

Rearrangement of α,β-Epoxy-α-ethylpropiophenone (IIIb).—A solution of 309 mg. (0.00175 mole) of the oxide in 15 ml. of benzene was saturated with gaseous boron trifluoride and the resulting solution was allowed to stand for 3 hr. The reaction mixture was diluted with ether, washed with water and extracted with three portions of 5% aqueous sodium hydroxide. When the remaining ether solution was concentrated, boiled with a solution of 2 ml. (0.012 mole) of 6 *N* aqueous sodium hydroxide for 24 hr. and then acidified and treated with 2,4-dinitrophenylhydrazine, no 2,4-dinitrophenylhydrazone could be isolated.

The alkaline extract of the reaction mixture was acidified and extracted with ether. When the ethereal solution was shaken with a saturated, aqueous solution of cupric acetate, concentrated and diluted with pentane, the **copper salt of α-formylbutyrophenone** separated as green needles, m.p. 181.5–183.5°, yield 60 mg. (16.5%). The product was identified by a mixed melting-point determination with an authentic sample whose preparation is subsequently described. The mother liquors from the copper salt were dissolved in a solution of sodium hydroxide in aqueous ethanol, and the solution was refluxed for 1 hr. When the resulting mixture was acidified and treated with 2,4-dinitrophenylhydrazine, the **2,4-dinitrophenylhydrazone of butyrophenone** separated as orange needles, m.p. 190–191° (lit.[29] 190°), yield 64 mg. (14%). The product was identified by a mixed melting-point determination with an authentic sample.

In subsequent experiments the alkali-soluble fraction of the reaction mixture was boiled with a solution of sodium hydroxide in aqueous ethanol and then acidified and treated with 2,4-dinitrophenylhydrazine. With reaction times for the rearrangement of 20 minutes and 3 hr. the yields of butyrophenone 2,4-dinitrophenylhydrazone were 50 and 49%, respectively. When a solution of 270 mg. (0.00153 mole) of the oxide and 0.5 ml. (0.004 mole) of boron trifluoride etherate in 15 ml. of benzene was allowed to stand for 1.5 hr. and then worked up in the same manner, the yield of butyrophenone 2,4-dinitrophenylhydrazone was 40%. In no case could either acetophenone 2,4-dinitrophenylhydrazone or benzoic acid be isolated. Treatment of the reaction mixture from the rearrangement with either phenylhydrazine or *o*-phenylenediamine dihydrochloride failed to yield crystalline products.

As a control experiment, α,β-epoxy-α-ethylpropiophenone was treated first with a boiling solution of sodium hydroxide and then with 2,4-dinitrophenylhydrazine as described previously. No 2,4-dinitrophenylhydrazone could be isolated.

α-Formylbutyrophenone (VIIIb).—This β-keto aldehyde was prepared from 14.8 g. (0.1 mole) of butyrophenone, 7.5 g. (0.1 mole) of ethyl formate and 4.8 g. (0.2 mole) of sodium hydride by the standard procedure.[30] The product was

(26) J. H. Burckhalter and R. C. Fuson, THIS JOURNAL, **70**, 4184 (1948).

(27) Determined in a chloroform solution.

(25) The second band expected from the cross-conjugated system of the unsaturated ketone IVb is apparently masked by other absorption in the region 210–240 mμ. The oxide IIIb absorbs much less strongly in this region than does the unsaturated ketone IVb.

Digitized by Arya Samaj Foundation Chennai and eGangotri

separated from an ether solution of the organic components of the reaction mixture by extraction with a saturated, aqueous solution of sodium carbonate. The alkaline solution was acidified and extracted with ether. Evaporation of the ether followed by recrystallization of the residue afforded the pure keto aldehyde as white needles, m.p. 96–97°, yield 3.5 g. (20%). The infrared spectrum[19,25] has a broad band in the 3 μ region (associated O–H) as well as strong bands in the 6 μ region at 1645 and 1505 cm.$^{-1}$ (C=O and/or C=C of an enolized β-dicarbonyl compound). When the spectrum[19] of the product was determined in chloroform solution, two additional bands appeared in the 6μ region at 1675 cm.$^{-1}$ (conjugated C=O) and 1710 cm.$^{-1}$ (unconjugated C=O). Our product is, therefore, the **enol form of α-formylbutyrophenone.**

Anal. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86. Found: C, 74.95; H, 6.96.

The α-formylbutyrophenone sample, m.p. 86–87°, previously reported[31] is apparently the tautomer of the sample we have isolated.

A portion of the keto aldehyde was converted to its copper salt in the usual manner. **The copper salt of α-formylbutyrophenone** separated from an ether–pentane mixture as blue-green needles, m.p. 182.5–183.5°. The infrared spectrum[19,25] of the copper salt has broad absorption bands in the 6 μ region with their centers at 1585 and 1572 cm.$^{-1}$.

Anal. Calcd. for $C_{22}H_{22}O_4Cu$: C, 63.86; H, 5.32. Found: C, 63.94; H, 5.36.

Alkaline Cleavage of α-Formylbutyrophenone (VIIIb).—A solution of 1.0 g. (0.0057 mole) of the keto aldehyde and 2 ml. (0.012 mole) of 6 *N* aqueous sodium hydroxide in 20 ml. of ethanol was boiled under reflux until an acidified sample of the reaction mixture no longer gave a color with ferric chloride (1 hr.). The mixture was diluted with water and extracted with ether. Treatment of the residue from the ether solution with 2,4-dinitrophenylhydrazine yielded 1.62 g. (95%) of butyrophenone 2,4-dinitrophenylhydrazone, m.p. 190–191°.

1-Phenyl-1,3-pentanedione (VIb).—The reaction of 13.7 g. (0.114 mole) of acetophenone with 5.5 g. (0.228 mole) of sodium hydride and 23.3 g. (0.228 mole) of ethyl propionate in the usual manner[30] produced the β-diketone, b.p. 131–135° (6 mm.), n^{25}D 1.5820 [lit.[32] b.p. 120–122° (5 mm.), n^{20}D 1.5837], yield 12.4 g. (62%). The infrared spectrum[19,27] of the product has a broad band in the 6 μ region with its center at 1625 cm.$^{-1}$ (enolized β-diketone).

Alkaline Cleavage of 1-Phenyl-1,3-pentanedione (VIb).—A solution of 1.0 g. (0.0057 mole) of the diketone and 1.5 ml. (0.009 mole) of 6 *N* aqueous sodium hydroxide in 20 ml. of ethanol was refluxed until an acidified sample from the reaction mixture gave no color with ferric chloride (24 hr.). The mixture was diluted with water and extracted with ether. Evaporation of the ether followed by treatment with 2,4-dinitrophenylhydrazine yielded acetophenone 2,4-dinitrophenylhydrazone, m.p. 249–250° (lit.[33] 249–250°), yield 1.10 g. (65%). Acidification of the aqueous solution from the reaction mixture followed by appropriate manipulations afforded 0.10 g. (14.4%) of benzoic acid, m.p. 120–121°. Both products were identified by mixed melting point determinations with authentic samples.

Reaction of 1-Phenyl-1,3-pentanedione (VIb) with Boron Trifluoride.—A solution of 1.0 g. (0.0057 mole) of the diketone in 20 ml. of benzene was saturated with gaseous boron trifluoride, and the solution was allowed to stand for 2 hr. The benzene was removed and the residue crystallized from a hexane–ether mixture. **The borofluoride complex of 1-phenyl-1,3-pentanedione** separated as white needles, m.p. 68.4–69.2°, yield 638 mg. (50%). The infrared spectrum[19,27] of the product has a broad absorption band in the 6 μ region with its center at 1552 cm.$^{-1}$.

Anal. Calcd. for $C_{11}H_{11}BF_2O_2$: C, 59.00; H, 4.91; B, 4.82; F, 16.97. Found: C, 58.89; H, 5.09; B, 4.83; F, 16.76.

When a solution of 200 mg. (0.0009 mole) of the complex and 2.0 ml. (0.012 mole) of 6 *N* aqueous sodium hydroxide in 20 ml. of ethanol was refluxed for 24 hr. and the neutral fraction of the product treated with 2,4-dinitrophenylhydrazine as previously described, the yield of acetophenone 2,4-dinitrophenylhydrazone, m.p. 249–250°, was 180 mg. (67%). In a second control experiment a solution of 100 mg. of the borofluoride complex in 20 ml. of ether was extracted with three portions of 5% aqueous sodium hydroxide. Concentration of the ether solution left 60 mg. of the unchanged borofluoride complex, m.p. 67–69°. The alkaline extract was acidified and extracted with ether; treatment of the ethereal extract with saturated, aqueous cupric acetate yielded 33 mg. (28%) of the copper complex of 1-phenyl-1,3-pentanedione, m.p. 153–154° (lit.[32] 151°). The product was identified by a mixed melting-point determination with an authentic sample.

α,β-Epoxypropiophenone (IIIc).—A suspension of 3.0 g. (0.0094 mole) of the crude methiodide of β-dimethylaminopropiophenone,[34] m.p. 203–209°, and 5 ml. (0.052 mole) of aqueous 30% hydrogen peroxide in 55 ml. of methanol was cooled to 0°, and 6 ml. (0.036 mole) of 6 *N* aqueous sodium hydroxide was added dropwise and with stirring. The resulting mixture was stirred for 1 hr. at 0°, diluted with 150 ml. of water and extracted with 3 portions of ether. The ether extract was dried and concentrated to leave an oil which crystallized from an ether–petroleum ether mixture. The oxide separated as white plates, m.p. 52–53° (lit.[35] 53°), yield 0.78 g. (60.6%). The infrared spectrum[19,27] of the product has a band at 1675 cm.$^{-1}$ (conjugated C=O).

Rearrangement of α,β-Epoxypropiophenone (IIIc).—A solution of 0.1 g. (0.0007 mole) of the oxide in 25 ml. of benzene was saturated with gaseous boron trifluoride over a period of 2 minutes and then worked up in the usual manner. None of the copper salt of benzoylacetaldehyde could be isolated from the crude rearrangement product. The reaction product, **1,3,5-tribenzoylbenzene (XIII)**, crystallized from ethanol as white plates, m.p. 118–120° (lit.[36] 119°), yield 0.05 g. (56%). The infrared spectrum[19,25] of the compound has a band at 1685 cm.$^{-1}$ (conjugated C=O). When a benzene solution of the oxide was heated with 0.5 equivalent of boron trifluoride etherate for 15 minutes, the yield of the triketone XIII was 20%. As in the former case no benzoylacetaldehyde could be isolated.

Benzoylacetaldehyde (XIV).—The sodium salt of the keto aldehyde was prepared by the reaction of 60 g. (0.5 mole) of acetophenone with sodium hydride (12 g., 0.5 mole) and ethyl formate (45 g., 0.6 mole) in the usual manner.[30] Reaction of the crude sodium salt with cupric acetate afforded the **copper salt of benzoylacetaldehyde** which crystallized from an ether–pentane mixture as dark green needles, m.p. 212–213° dec., yield 110.7 g. (62%).

Anal. Calcd. for $C_{18}H_{14}O_4Cu$: C, 60.42; H, 3.92. Found: C, 60.61; H, 4.16.

A sample of benzoylacetaldehyde derived from 0.34 g. (0.0013 mole) of the copper salt was dissolved in ether and treated with 0.5 ml. (0.004 mole) of boron trifluoride etherate. The solution was refluxed for 15 minutes and then worked up in the usual way. None of the benzoylacetaldehyde could be recovered; instead 1,3,5-tribenzoylbenzene was isolated, m.p. 117–119°, yield 0.28 g. (80%). The compound was shown to be identical with the sample prepared by rearrangement of α,β-epoxypropiophenone both by a mixed melting-point determination and by comparison of the infrared spectra of the two samples.

Partially Deuterated α,β-Epoxypropiophenone (XVI).—A solution of 12 g. (0.1 mole) of acetophenone and 1 g. of sodium hydroxide in a mixture of 20 ml. of deuterium oxide and 20 ml. of ethanol was refluxed for 18 hr. The deuterium content of the recovered acetophenone was 21.92 atom per cent. deuterium or 1.75 gram atoms of deuterium per mole. The acetophenone was converted to the methiodide of β-dimethylaminopropiophenone and subsequently to α,β-epoxypropiophenone by the procedures described previously. The deuterium content of the epoxy ketone was 1.40 atom per cent. deuterium or 0.112 gram atom of deuterium per mole.

Rearrangement of Partially Deuterated α,β-Epoxypropiophenone (XVI).—A 1.0-g. (0.0067 mole) sample of the oxide was isomerized as previously described. The yield of par-

Reaction of Arenes with Silver Fluoride in Hydrogen Fluoride Solution

BY D. A. MCCAULAY AND A. P. LIEN

RECEIVED NOVEMBER 5, 1956

Silver fluoride, dissolved in anhydrous hydrogen fluoride, reacts with arenes to form a stable complex containing 3 moles of arene. The complex reverts to silver fluoride and arene as the hydrogen fluoride is removed by distillation. AgF–HF is therefore a useful solvent for separating arenes from other hydrocarbons. In contrast with other metal fluorides that complex with arenes, AgF in HF is a base; it inhibits rather than promotes such reactions as alkyl-group migration. The stability of the arene–silver fluoride complex is almost independent of the number and orientation of the alkyl groups on the ring. It differs from the σ-complexes formed by the action on arenes of HF plus other metal fluorides, such as BF_3, TiF_4, CbF_5, TaF_5, and acts more like a π-complex.

A few metal fluorides act as co-acids with liquid anhydrous hydrogen fluoride. A criterion used in previous work to establish such co-acid properties was whether the fluoride enabled a proton to add to a xylene molecule.[1] In the presence of a sufficiently strong co-acid, normally insoluble xylene accepts a proton and dissolves in the hydrogen fluoride. On the other hand, certain metal fluorides that are obviously bases in the hydrogen fluoride system also cause arenes to dissolve in this medium. Thus, Klatt[2] found that silver fluoride, which is soluble and ionizes in hydrogen fluoride probably according to the equation[3] can

$$AgF + HF \rightleftharpoons AgFH^+ + F^-$$

bring into solution up to four mole-equivalents of arene.

In the present study, batch extractions of hydrocarbon mixtures and petroleum fractions with AgF–HF have been used to elucidate the action of silver fluoride on arenes. Our objects were to determine how silver fluoride differs from the acidic fluorides and to learn whether it could be used to extract arenes from hydrocarbon mixtures, separate arenes from each other, or promote such reactions as alkylation and disproportionation.

Experimental

Silver fluoride, obtained from the Beta Research Laboratory, was dissolved in hydrogen fluoride and heated to 100° under vacuum to drive off any moisture present with the hydrogen fluoride. The hydrogen fluoride, a commercial grade of 99.6% purity supplied by the Matheson Co., was distilled before each experiment. The hydrocarbons, C.P. grades obtained from commercial suppliers, were used without further purification. The petroleum fractions used were typical straight-run and reformed West Texas naphthas.

The extraction runs were carried out in a 1.5-liter carbon–steel autoclave. Silver fluoride, hydrocarbon and a measured volume of hydrogen fluoride were added to the autoclave and stirred for 1 hr. After a settling period of 2 hr., the acid layer was withdrawn from the bottom of the autoclave into a polyethylene flask cooled in Dry Ice. In most cases, the extracted arenes were sprung by slowly adding water to the chilled acid phase. After a large excess of water had been added, the displaced arenes were decanted from the aqueous acid. The raffinate layer was drained from the autoclave. Both hydrocarbon products were then washed with ammonium hydroxide and were analyzed by appropriate means, such as refractive index measurement and infrared and ultraviolet absorption.

In a few experiments designed to show whether the silver fluoride could be regenerated and used again the technique differed. After the mixing step, the autoclave was heated to 50° and the hydrocarbon and hydrogen fluoride were distilled into an evacuated flask to recover the silver fluoride residue for re-use.

Extraction of Known Mixtures.—Four mixtures of known hydrocarbons were each extracted with an equal volume of hydrogen fluoride plus silver fluoride. The results are shown in Table I.

TABLE I

EXTRACTION OF ARENES FROM SYNTHETIC MIXTURES

Arene	Benzene	Xylene[a]	C_8-Alkylbenzenes[b]	
Moles AgF per mole arene	0.17	0.17	1.0	1.0

to 15. The exceptionally high selectivity of AgF–HF indicates that more than physical solution is involved; the amount extracted suggests that a coördination complex containing 3 moles of arene per mole of silver is formed. The excess 0.3 mole of benzene is probably extracted by physical solution. Xylene is known to be much less soluble in common solvents than benzene and, as expected, exactly 3 moles are extracted per mole of AgF. The excess one mole-equivalent observed by Klatt[3] could have resulted from working with pure arenes rather than with a heptane solution.

In the two runs with C_8-alkylbenzenes, two representative impurities were also present. One feed contained about 8% olefins, which alkylated the xylenes and were extracted as alkylbenzenes. The other feed contained about 1.5% propyl sulfide, which ended in the acid layer. In both these runs, excess AgF effected complete extraction. Also, the β-values jumped to well over 1000. Excess AgF changed the nature of the solvent and "salted out" the physically dissolved, uncombined hydrocarbon. The system AgF–HF is exceptional among solvents in that completeness and selectivity can be improved simultaneously.

The effect of hydrogen fluoride on extraction is summarized in Table II. Selectivity decreases as less hydrogen fluoride is used. Apparently, large amounts of arene–AgF complex change the nature of the solvent and increase the physical solubility of hydrocarbons in the acid phase. In the most concentrated solution, about 86 g. of AgF was present per 100 g. of hydrogen fluoride, whereas the measured solubility of AgF in hydrogen fluoride is only 33 g. per 100 g.[3] Because complexes form with arenes, much more than this amount of AgF goes into solution. Identical results were obtained when these runs were repeated after distilling off the HF and arenes under vacuum at 50°. Activity of the silver fluoride was unimpaired by the distillation step.

TABLE II
EFFECT OF HF CONCENTRATION

Extraction charge: 1 mole AgF, 6 moles arene, 7.5 moles *n*-heptane

HF, moles	111	18.5	7.4
Raffinate composition, moles			
Arene	2.97	2.93	2.77
n-Heptane	7.35	7.23	6.87
Acid-phase composition, moles			
HF	111.0	18.5	7.4
AgF	1.0	1.0	1.0
Arene	3.03	3.08	3.23
n-Heptane	0.17	0.27	0.63
Separation factor, β	50	28	13

Extraction of Petroleum Fractions.—Extraction experiments with one volume HF per volume of hydrocarbon and 1.0 mole of AgF per mole of arene were made also on two petroleum naphthas that contained a wide variety of arenes with boiling points up to 230°.

A high sulfur heavy naphtha, upon treatment with AgF–HF, formed a large amount of sludge, which interfered with phase separation. The sulfur compounds occurring in the naphtha—unlike propyl sulfide, which introduced no complication—evidently form an insoluble complex with silver fluoride. The naphtha was therefore desulfurized with HF alone before treatment with AgF–HF. No sludge formed and phase separation was good. As shown in Table III, all the arenes were extracted and the extract was almost 100% arene.

TABLE III
EXTRACTION OF LIGHT PETROLEUM STOCKS WITH HF–AgF

	Desulfurized heavy naphtha		Reformed light naphtha	
	Vol. % arene	$n^{20}D$	Vol. % arene	$n^{20}D$
Feed	23	1.4332	54.5	1.4477
Raffinate	0	1.4180	1.0	1.3873
Extract	99	1.4982	99.0	1.4968
% of aromatic removed	100		98	
Separation factor, β	>5000		4500	

A reformed naphtha was completely and selectively freed of arenes upon extraction with AgF–HF. All naturally occurring arenes boiling up to at least 230° can therefore be extracted from mixtures.

Separation of Arenes.—The possibility of separating close-boiling arenes from each other by extraction with AgF–HF was also investigated. Mixtures of two arenes in *n*-heptane solution were stirred with half a volume of hydrogen fluoride plus 1/6 mole AgF per mole of arene—enough to complex half of the arenes. The results are reported in Table IV. The separation factor, β, is equal to the equilibrium constant for the reaction in which both arenes compete for the silver ion

$$\text{Arene B}\cdot Ag^+ + \text{arene A} \rightleftarrows \text{arene A}\cdot Ag^+ + \text{arene B}$$

$$\beta = K_{eq} = [A\cdot Ag^+][B]/[B\cdot Ag^+][A]$$

It is therefore a measure of the relative stability of the two arene complexes with AgF–HF.

Complexes of AgF with *m*- and *p*-xylene are about equally stable, the *m*-xylene complex being slightly stronger. The difference in stability is too small to be used in a practical process for separating these two isomers.

TABLE IV
SEPARATION OF ARENES WITH AgF–HF

Feed				
Arene A	*p*-Xylene	*p*-Xylene		
Arene B	*m*-Xylene	Ethylbenzene		
Raffinate				
Vol. % A	13.5	5.5	12.1	17.4
Vol. % B	11.6	20.3	13.9	7.7
Ratio A to B	1.16	0.27	0.87	2.26
Extract				
Vol. % A	47.8	25.4	50.0	69.3
Vol. % B	47.2	69.5	41.3	22.8
Ratio A to B	1.01	0.37	1.21	3.04
Separation factor, β	0.87	1.35	1.39	1.35

The experiments comparing *p*-xylene and ethylbenzene at three different concentrations show, first, that the *p*-xylene complex is stronger by a factor of 1.35 and, second, that ethylbenzene itself is unreactive. The latter effect contrasts directly with the behavior of ethylbenzene in HF–BF_3, where extensive disproportionation occurs almost instantaneously, even at temperatures as low as 0°.[4] The difference in stability between the silver complexes of *p*-xylene and ethylbenzene can be made the basis of a process for separating ethylbenzene from the close-boiling xylenes. Separation by distillation, because of the low value of 1.05 for the relative volatility, requires about 150 stages; extraction with AgF–HF could give the same separation in about 20 stages.

Effect of AgF on Alkylation.—Because AgF can make arenes soluble in hydrogen fluoride, it should promote alkylation by providing intimate contact between catalyst and reactants. This supposition was tested by four experiments, reported in Table V, in which ethylene and an arene were stirred with 1.5 volumes of HF for 60 minutes at 15°. When added to a stirred mixture of *m*-xylene and hydrogen fluoride, ethylene alkylates *m*-xylene at a moderate rate. But, when enough AgF is present to bring the xylene into solution, the rate of alkylation decreases and only half as much ethylene reacts. Also, as demonstrated by the toluene runs, if the olefin instead of the arene is added to the AgF–HF first, alkylation stops completely. Therefore, despite providing a homogeneous reaction medium, AgF inhibits alkylation—probably by a combination of two effects: (a) lowering the acidity of the catalyst by raising fluoride concentration and (b) tying up both olefin and arene as unreactive complexes.

Conclusion

The differences between the behavior of AgF in hydrogen fluoride and that of other metal fluorides

[a] Unreacted ethylene appeared as ethyl fluoride.

(1) are summarized in Table VI. Silver fluoride acts as a base, decreases the acidity of the HF and inhibits acid-catalyzed reaction. The acidic fluorides markedly increase the hydrogen-ion concentration and thereby promote such acid-catalyzed reactions as alkylation and disproportionation. In forming complexes, the acidic fluoride coördinates with a fluoride ion and thereby assists a proton to add to the aromatic ring

$$\text{arene} + HF + BF_3 \longrightarrow \text{arene}\cdot H^+BF_4^-$$

Because the metal fluoride itself is not part of the arene cation, the tendencies of the various arenes to form a complex should be independent of the metal fluoride used. Such was actually observed with the acidic fluorides.

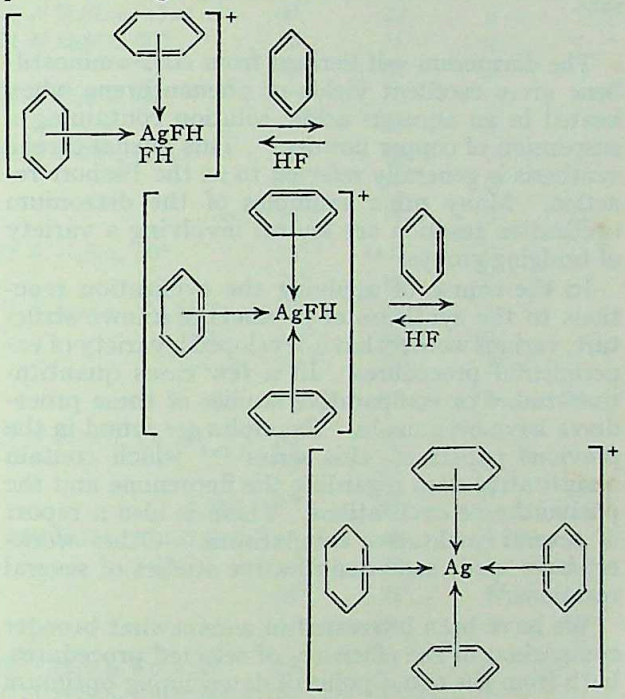
TABLE VI

BEHAVIOR OF METAL FLUORIDES IN HYDROGEN FLUORIDE

Property	AgF	BF_3, TiF_4, TaF_5, or CbF_5
Ionizes as	Base	Acid
Moles arene in complex	3	1
Benzene and toluene complexes	Stable	Unstable
Selectivity between *m*- and *p*-xylene	None	High
Catalytic activity		
Ethylbenzene disproportionation	Inactive	Promotes
Alkylation	Inhibits	Promotes

The arene cation is a σ-complex,[5] the stability of which is determined primarily by the number and orientation of alkyl groups on the ring.[6] The stability of the complex between arene and silver ion, however, is almost independent of the substituent groups. This cation therefore acts more like a π-complex; the silver ion combines loosely with the cloud of π-electrons around the ring.

Arenes and silver ion interact weakly[7] even in aqueous solution, but in anhydrous hydrogen fluoride the complex is many orders of magnitude more stable. Perhaps, because it is such a strong acid, hydrogen fluoride does not monopolize the vacant coördination positions around the silver ion but allows them to be filled by the arene to form complexes having the structures



The complex containing three molecules of arene is stable even at low arene concentrations, but it shows little tendency to take on an additional molecule. The reason for the sharp cut-off at three is not clear; perhaps steric requirements prevent more than three molecules from approaching within bonding distance.

The stability of the complex depends upon hydrogen fluoride concentration. As hydrogen fluoride is removed from solution, the complex dissociates and the arene separates as a distinct organic layer. Because a strong chemical bond is formed in solution, extraction with AgF–HF is highly selective, and because this bond is easily broken by removal of a low-boiling solvent, a separation process based upon this technique is practical.

Intramolecular Reactions. V. Factors Affecting the Yield in Diazonium Cyclization Reactions[1]

By DeLos F. DeTar and Thomas E. Whiteley[2]

Received August 30, 1956

A quantitative study of the effect of a series of reaction conditions on the product yields in the diazonium cyclization reaction shows that there is a great deal of individuality among the various diazonium salts. For the diazonium salts derived from *cis*-2-aminostilbene, from 2-amino-*sym*-diphenylethane and from 2-amino-3′-nitrobenzophenone, the best conditions are those of Pschorr, the use of a copper powder catalyst in dilute sulfuric acid. However, 2-(4′-methylbenzoyl)-benzenediazonium bisulfate and *o*-phenoxybenzenediazonium fluoborate gave a considerable amount of reduction product in the presence of copper powder. For these compounds the use of moderately concentrated sulfuric acid gave the best results.

The diazonium salt derived from *cis*-2-aminostilbene gives excellent yields of phenanthrene when heated in an aqueous acidic solution containing a suspension of copper powder.[3] This phenanthrene synthesis is generally referred to as the Pschorr reaction. Many other examples of the diazonium cyclization reaction are known involving a variety of bridging groups.[1,4,5]

In the course of applying the cyclization reactions to the synthesis of products of known structure, various workers have developed a variety of experimental procedures. In a few cases quantitative studies or comparative studies of these procedures have been made. Examples are found in the previous papers of this series[1,3b,6] which contain quantitative data regarding the fluorenone and the phenanthrene cyclizations. There is also a report of several qualitative comparisons.[7] Other workers have made semi-quantitative studies of several reactions.[8,9]

We have been interested in a somewhat broader comparison of the efficiency of selected procedures, both from the stand-point of determining optimum reaction conditions and from the standpoint of obtaining qualitative information about the mechanisms of the cyclization process. The purpose of the present work was to test out a series of typical cyclization procedures on a representative series of diazonium salts.

Among the large variety of cyclization procedures that have been described previously, the following general classes may be recognized: (1) The diazonium salt is heated in dilute acidic solution. Diazotized 2-aminobenzophenone gives a 65% yield of fluorenone under these conditions,[6] but diazotized *cis*-2-aminostilbene gives only about 30% of phenanthrene, due to a side reaction leading to indazole.[3b] (2) The diazonium salt is heated in dilute acidic solution in the presence of copper powder. These are the usual conditions for the Pschorr phenanthrene synthesis. (3) The diazonium salt is heated in alkaline solution. This procedure has given good results in the synthesis of 2-hydroxyphenanthrene-9-carboxylic acid[10] and with 2-methoxyphenanthrene-9-carboxylic acid[11] but gives low yields in the fluorenone series and in several other series.[6,7] (4) An aqueous ethanolic solution of the diazonium salt is treated with copper powder, or an aqueous solution is treated with hypophosphorous acid.[3a] The first variant gave an 85% yield of 2,3-methylenedioxyphenanthrene-9-carboxylic acid,[12a] and the second gave a 70% yield of 4,6-dimethylphenanthrene-9-carboxylic acid,[12b] but in other than the phenanthrene series such methods appear to lead to extensive replacement of the diazonium group with hydrogen with a serious diminution of the yield of cyclic product. (5) Miscellaneous methods have been reported such as treatment of an acetone suspension of the crystalline diazonium fluoborate with copper powder,[8] formation of the triazene by reaction of the diazonium salt with dimethylamine followed by treatment of a suspension of the triazene in an organic solvent with gaseous hydrogen chloride[8] and preparation of and decomposition of the N-nitrosoacetylamide.[8,13] In none of the reported examples were the yields by these miscellaneous methods any more attractive than those obtained by the first four procedures.

Since a considerable amount of information was already available regarding the fluorenone synthesis,[6-9] 2-(4′-methylbenzoyl)-benzenediazonium bisulfate was selected for a survey of the cyclization conditions. These included the use of a wide range of sulfuric acid concentrations, with and without copper catalysts, and a few examples of the use of other media such as sodium hydroxide, aqueous alcohol and glacial acetic acid. From this work six reaction conditions were selected for further investigation with four other diazonium salts, so chosen as to be representative of the various types used in the cyclization reaction. The results of this comparative study are summarized in Table I. The individual runs which have been averaged in Table I

and a number of others which represent additional reaction conditions are given in Tables II and III.

TABLE I

EFFECT OF CONDITIONS ON YIELD IN THE DIAZONIUM CYCLIZATION REACTION[a]

Diazonium salt from	Reaction conditions: 1 *N* H_2SO_4	1 *N* H_2SO_4 + Cu	1 *N* H_2SO_4 + CuCl	21 *N* H_2SO_4	21 *N* H_2SO_4 + Cu	21 *N* H_2SO_4 + CuCl
cis-2-Aminostilbene	36	94	94	46	60[b]	42
2-Amino-*sym*-diphenylethane	45	74	68	58	49	49
2-Amino-3'-nitrobenzophenone	40[b]	90	74[c]	53[b]	51	67
2-Aminodiphenyl ether	14[c]	20[d]	20[d]	27[c]	10[c,d]	17[c,d]
2-Amino-4'-methylbenzophenone	60	45[d]	46	74[e]	67	73[b]

[a] Entries are average percentage yield of cyclic product from crystalline diazonium salt, based on two runs unless otherwise indicated. The individual runs are presented in Tables II and III. Reaction temperatures from 25–90° or more all give the same product yield in the fluorenone series as can be seen from the data in Table II and from previous work. The averages for the yield of 3-methylfluorenone from diazotized 2-amino-4'-methylbenzophenone are for all runs under a given set of conditions regardless of temperature. For the first four compounds all cyclizations were carried out at 80°. The std. deviations given in Tables II and III were pooled: these are 3.8% for a single entry, 2.7% for averages of 2 (37 D.F.). Two averages which differ by 6% are significantly different at the 95% level. [b] Average of three values. [c] Single value. [d] Extensive reduction occurred. See Tables II and III. [e] Average of six values.

The reasons for the choice of the six reaction conditions listed in Table I are as follows: The use of dilute sulfuric acid, both with and without copper powder was, of course, mandatory, since these are the most commonly used cyclization conditions. The use of cuprous chloride was suggested by previous work.[1] There were also indications that the yields might be improved in more concentrated acid since the lower water concentration might reduce the yield of phenol and increase that of cyclic product. The 21 *N* acid was chosen as a suitable compromise, since 36 *N* acid led to diminished yields (Table II), apparently due to sulfonation. It also seemed desirable to test the effect of copper and cuprous chloride in the more concentrated acid. The low yields obtained with alkali and in aqueous ethanol indicated that there was little point in testing these conditions except perhaps with the phenanthrene synthesis.

The diazonium salts listed in Table I are representative of those used in the various cyclization reactions in that the cyclization of diazotized *cis*-2-aminostilbene typifies the Pschorr phenanthrene synthesis, that of diazotized 2-amino-*sym*-diphenylethane is representative of the two-atom bridge series, including the aporphine types,[14] the two 2-aminobenzophenones represent respectively a type which gives good yields of fluorenone in acidic solution in the absence of catalysts and one which does not. The salt from 2-aminodiphenyl ether is intended as a representative of the ethers and possibly of the N-alkyldiphenylamines.

The most surprising feature of the results reported in Table I is the extreme individuality exhib-

[k] 3.4 (2).

ited by the various salts. In view of this characteristic there is indeed some question as to how typical any given reaction may be.

With the diazonium salts derived from *cis*-2-aminostilbene, 2-amino-*sym*-diphenylethane and 2-amino-3′-nitrobenzophenone, the best results were obtained under the Pschorr conditions, copper powder in the presence of dilute sulfuric acid. With 2-(4′-methylbenzoyl)-benzenediazonium salts and 2-phenoxybenzenediazonium salts, the Pschorr conditions lead to appreciable reduction giving by-products which are difficult to remove. For these latter two salts the use of 21 *N* sulfuric acid alone gave the best results. In none of the cyclizations did cuprous chloride offer any advantage over the above conditions.

The reaction of the diazonium salts in the absence of catalysts probably involves SN1 cleavage of the C–N bond,[6] and the higher yields of cyclic product at the higher acid concentrations can be explained on the basis that there are fewer water molecules to react to give the phenolic by-product.

The results in the presence of cuprous chloride and of copper powder are more difficult to explain in detail. There is a considerable variation in the effectiveness of these catalysts at the two acid levels. The high phenanthrene yield with copper powder, cuprous chloride or with hypophosphorous acid and copper powder does suggest that some sort of free radical process may be involved under these conditions.

Experimental

The preparation of the following compounds has already been described: 2-amino-4′-methylbenzophenone,[6,15] 2-amino-3′-nitrobenzophenone,[6] *cis*-2-nitrostilbene,[3b,16] 2-aminodiphenyl ether,[7,17] 2-(3′-nitrobenzoyl)-benzenediazonium fluoborate,[6,18] the diazonium fluoborate of *cis*-2-aminostilbene,[3b] 3-methylfluorenone,[6] 4-methylbenzophenone,[19] 2-hydroxy-4′-methylbenzophenone,[6] 2-chloro-4′-methylbenzophenone,[6] mixtures of 2- and 4-nitrofluorenone,[6] dibenzofuran,[7] diphenyl ether,[19] *sym*-diphenylethane.[19]

***cis*-2-Aminostilbene Hydrochloride.**—*cis*-2-Nitrostilbene was reduced with ferrous hydroxide,[3a,b] but the amine was converted to its hydrochloride with concd. aq. hydrochloric acid; m.p. 201–203°.

2-Amino-*sym*-diphenylethane Hydrochloride.—*cis*-2-Nitrostilbene (3.68 g.) was hydrogenated in methanolic solution (180 ml.) with 0.36 g. of 10% palladium-on-charcoal. Dry hydrogen chloride was passed through an ether solution of the amine to give 3.8 g. of 2-amino-*sym*-diphenylethane hydrochloride, m.p. 189–190°.[3a] The absence of the strong peak at 796 cm.$^{-1}$ characteristic of *cis*-2-aminostilbene shows that reduction was complete.

2-Phenoxybenzenediazonium Fluoborate.—2-Aminodiphenyl ether was diazotized in hydrochloric acid and the fluoborate salt precipitated with fluoboric acid (82% yield). **The diazonium fluoborate of 2-amino-*sym*-diphenylethane** was similarly prepared in 50% yield.

2-(4′-Methylbenzoyl)-benzenediazonium Bisulfate.—2-Amino-4′-methylbenzophenone (1.0 g.) was dissolved in 12 ml. of glacial acetic acid, 2 ml. of methanol and 1 ml. of concd.

sulfuric acid. It was diazotized at 0° with 0.6 ml. of freshly distilled *n*-butyl nitrite. Ether was added until the mixture became turbid and, on rubbing, the diazonium salt crystallized. It was purified by solution in glacial acetic acid and precipitation with ether; yield 80%.

3-Nitrobenzophenone.[20]—This was prepared by the Friedel-Crafts reaction from *m*-nitrobenzoyl chloride; colorless crystals, m.p. 93.5–94.0°, after vacuum sublimation and recrystallization from ethanol. The reported m.p. is 94–95°.

Phenanthrene.—This was a colorless sample, m.p. 96–97°, prepared by Mr. Julian Pruitt.[21]

2-Hydroxy-3′-nitrobenzophenone.—This compound was isolated from the decomposition of 2-(3′-nitrobenzoyl)-benzenediazonium salts; m.p. 95.5–96.5°, reported m.p. 96–97°.[4]

2-Hydroxy-*sym*-diphenylethane. This was isolated by chromatography from decomposition mixtures; m.p. 81–82°, reported m.p. 83.5°.[22]

Gattermann Copper Powder.[23]—Zinc dust was added to a saturated aqueous solution of copper sulfate until the blue color began to fade. The copper powder was washed by decantation and allowed to stand in dilute hydrochloric acid until hydrogen no longer was evolved. It was then washed until chloride ion was absent in the wash water, filtered, washed with ethanol, with ether and dried *in vacuo*. The catalyst was freshly prepared for each run.

Cuprous Chloride.[24]—This also was freshly prepared for each run in 2-g. quantities by heating 20 ml. of a solution containing 312 g. of copper sulfate pentahydrate and 81 g. of sodium chloride per liter while adding 8 ml. of a second solution containing 138 g. of sodium bisulfite and 88 g. of sodium hydroxide per liter. The precipitated cuprous chloride was washed by decantation using freshly boiled water, then centrifuged and used without drying.

Kochi Cuprous Chloride Solution.[25]—To 15 ml. of acetone (purified with permanganate) was added 5 ml. of water, 0.6 g. of lithium chloride and 1.2 g. of cupric chloride dihydrate. Nitrogen was bubbled through to remove oxygen, and the mixture was then refluxed for 24 hr. The small amount of solid material was disregarded.

Procedure for Decomposition of the Diazonium Salts.—The same general technique was followed with all the reactions. A 150–350 mg. sample of the diazonium salts was mixed with 25 ml. of the reaction medium in a 125-ml. Erlenmeyer flask and allowed to stand, or heated, with occasional shaking until the spot test on filter paper moistened with sodium β-naphthoxide solution was no longer red. In the runs with copper or cuprous chloride approximately 2-g. amounts of these catalysts were used.

Isolation and Identification of Reaction Products from 2-(4′-Methylbenzoyl)-benzenediazonium Salts.—The cooled reaction mixture was extracted with five 15-ml. portions of methylene chloride.[26] The solution was evaporated, the residue dissolved in 5 ml. of benzene and introduced onto a column of alumina, 19 × 100 mm., of approximately grade 4.[27] A 50–50 mixture of benzene and pentane was then passed through the column and the first 40 ml. of solvent collected in a tared beaker (fraction 1). A further 40 ml. was collected but usually contained only a few mg. of dissolved material. A solution of 13% methanol in chloroform was then passed through the column and 40 ml. collected (fraction 2). In some runs, especially those in the presence of copper or of cuprous chloride, there was a small dark yellow band which remained on the column after the methanol–chloroform treatment. Solvents were removed at room temperature by evaporation using a desiccator equipped for continuous passage of a slow stream of dry dust-free air. The recovery of material from the chromatographic separation was usually 90–100%.

The decompositions carried out in sulfuric acid of various concentrations and at various temperatures gave a chromatographic first fraction which was almost pure 3-methylfluorenone as determined by m.p. (typically 64–66° as compared with 66.0–66.5° for the pure 3-methylfluorenone) and by the identity of the infrared spectra with those of the pure material. The chromatographic second fraction was checked in a few cases and proved to be pure 2-hydroxy-4′-methylbenzophenone, m.p. 60.5–61.5°.

The decompositions carried out in the presence of copper or of cuprous chloride gave a first fraction which was an oil-coated solid. The infrared curve had all the peaks present in 3-methylfluorenone–4-methylbenzophenone mixtures and no others. Since both of these products are expected, no attempt was made to separate them for further identification. The absence of 2-chloro-4′-methylbenzophenone was shown by the infrared curves.

The runs in 85 and 96% sulfuric acid gave low yields of extractable material; the aqueous layer was yellow. These results suggest that sulfonation was occurring at these acid concentrations.

The identity of the products present in the first chromatographic fraction was checked for all runs except for a few replicate runs carried out in the absence of catalysts.

The results of the product studies are summarized in Table II. In addition to these results, it was found that the reaction of 2-(4′-methylbenzoyl)-benzenediazonium bisulfate with the Kochi cuprous chloride solution in acetone gave 98.3 and 99.0% of 2-chloro-4′-methylbenzophenone.

Reaction Products from 2-(3′-Nitrobenzoyl)-benzenediazonium Salts.—The procedure was the same as the above except for use of grade 2 alumina as adsorbent and methylene chloride as eluent. The mixture of 2- and 4-nitrofluorenones was identified on the basis of the identity of the infrared peaks with those present in samples previously obtained. The proportions of isomers varied somewhat from one set of reaction conditions to another, but this point was not investigated. The 2-hydroxy-3′-nitrobenzophenone was also identified on the basis of its infrared curve.

The spectra of the first chromatographic fraction derived from certain runs in the presence of copper or of cuprous chloride had the peaks characteristic of 3-nitrobenzophenone in addition to those of the nitrofluorenone mixture.

The results of these runs are summarized in Table III.

Reaction Products from *o*-Phenoxybenzenediazonium Salts.—The reaction product from this diazonium salt was a black tar, and a large portion of the reaction mixture consisted of unidentified highly colored products. The dibenzofuran and the diphenyl ether were obtained in the first 40 ml. of benzene eluent using grade 1 alumina. They were identified and determined quantitatively by means of their infrared spectra. The results are summarized in Table III.

Reaction Products from the Diazonium Fluoborate of *cis*-2-Aminostilbene.—Since benzaldehyde was present in some of the runs in the absence of catalysts, the reaction mixture was treated with a small amount of hydrogen peroxide or of potassium persulfate in order to oxidize it to benzoic acid. The chromatographic separation was carried out with grade 4 alumina using benzene as the eluent. The progress could be followed by observing the column with long wave length ultraviolet light; the phenanthrene, the indazole and an unidentified strongly adsorbed component were all fluorescent. The first fraction in all runs consisted of phenanthrene; *cis*-stilbene was absent, for there was no adsorption at 700 or at 780 cm.$^{-1}$ which are strong peaks for *cis*-stilbene. The results are summarized in Table III.

Reaction Products from the Diazonium Fluoborate of 2-Amino-*sym*-diphenylethane.—The extractions were carried out with ether. The chromatographic separation utilized grade 2 alumina with benzene as eluent. Since a reference sample of 9,10-dihydrophenanthrene was not available, the first chromatographic fractions from runs in sulfuric acid (in the absence of catalysts) were used. The infrared spectra of these fractions showed that *sym*-diphenylethane and phenanthrene were both absent. 9,10-Dihydrophenanthrene has been prepared previously by the diazonium cyclization reaction.[5]

The infrared spectra of reactions run in the presence of copper had peaks at 810 and 733 cm.$^{-1}$ that were not accounted for by the 9,10-dihydrophenanthrene or by *sym*-diphenylethane. Phenanthrene has characteristic peaks at these positions. The presence of phenanthrene was verified by the appearance of characteristic ultraviolet peaks at 3295, 3375 and 3455 Å. The rather concentrated sample required cut off at 3200 Å. The phenanthrene concentration as estimated by the base-line technique agreed excellently with that estimated from the infrared curve. That the phenanthrene originated from the diazonium salt of 2-amino-*sym*-diphenylethane and not from that of *cis*-2-aminostilbene present as an impurity was established by the observation that phenanthrene was not produced in all runs.

Quantitative Spectrophotometric Analyses.—Infrared spectra were obtained in carbon disulfide solution in a fixed cell 0.106 mm. thick using a Perkin–Elmer model 21 spectrophotometer equipped with sodium chloride optics. For quantitative work, concentrations were adjusted to give peaks between 15 and 85% transmittance. The curve of the pure solvent was used to obtain the 100% transmission line, and a strong solvent absorption peak was used to give the 0% absorption value. Ultraviolet spectra were obtained with a Cary model 14 spectrophotometer using solvent in the reference beam. The absorbance curve of solvent *vs.* solvent was run after each solution.

A representative calibration analysis of known 3-methylfluorenone and 4-methylbenzophenone mixtures is given in Table IV. The results obtained with mixtures of the other compounds are comparable.

TABLE IV

INFRARED ANALYSIS OF KNOWN MIXTURES OF 3-METHYLFLUORENONE AND 4-METHYLBENZOPHENONE[a]

The Base-promoted Dehydrohalogenation of *cis*- and *trans*-2-Chlorocycloalkyl Aryl Sulfones[1]

BY HARLAN L. GOERING, DOUGLAS I. RELYEA AND KING L. HOWE[2]

RECEIVED JUNE 29, 1956

The base-promoted dehydrochlorination of *cis*-(I) and *trans*-2-chlorocyclohexyl aryl sulfones (II), and *cis*-(III) and *trans*-2-chlorocyclopentyl aryl sulfones (IV) in "80%" ethanol has been investigated. Rate constants and activation energies were determined for the least reactive of the four series of compounds, the *trans*-2-chlorocyclohexyl aryl sulfones. The other three series of compounds are too reactive to follow by the sampling technique used in the present work. For these compounds approximate relative reactivities were determined. In each of the four series of chlorocycloalkyl aryl sulfones I–IV, electron-withdrawing substituents in the aryl moiety increase the rate of dehydrochlorination. The following rate sequence for corresponding *p*-substituted 2-chlorocycloalkyl aryl sulfones was observed: *cis*-2-chlorocyclopentyl > *cis*-2-chlorocyclohexyl > *trans*-2-chlorocyclopentyl > *trans*-2-chlorocyclohexyl. The rate of elimination for *trans*-2-chlorocyclohexyl phenyl sulfone is essentially the same as that for *trans*-2-tosyloxycyclohexyl phenyl sulfone. The *trans*-2-chlorosulfones II and IV undergo *cis* elimination, evidently by a two-step process involving abstraction of the C_1-hydrogen followed by conversion of the resulting anion to the elimination product. The first step is rate determining and irreversible under the present conditions (*i.e.*, 80% ethanol containing 0.004 to 0.03 *M* sodium hydroxide). Presumably the *cis*-chlorosulfones I and III undergo a concerted *trans* dehydrohalogenation.

Introduction

In connection with a study[3,4] of the stereochemistry of radical additions, several *cis*-(I) and *trans*-2-chlorocyclohexyl aryl sulfones (II) and *cis*-(III) and *trans*-2-chlorocyclopentyl aryl sulfones (IV) were prepared. This paper describes the base-promoted dehydrochlorination of these four series of compounds in "80%"[5] ethanol. The effect of the β-sulfone group on the rate of dehydrohalogenation was of interest for comparison with the effect of β-halogen atoms observed in an earlier study.[6] The behavior of the *trans*-2-chlorocycloalkyl aryl sulfones was also of particular interest because of the recent observation by Bordwell and co-workers[7] that in similar systems the β-sulfone group activates the β-hydrogen so that *cis* elimination occurs rather than a concerted *trans* elimination.

Results

The chlorosulfones I-IV were obtained by oxidation (hydrogen peroxide or perbenzoic acid) of the corresponding sulfides. *trans*-2-Chlorocycloalkyl aryl sulfides were prepared by the *trans* addition[3,8] of the appropriate benzenesulfenyl chloride to cyclohexene or cyclopentene. The *cis*-chlorosulfides were obtained by the radical addition of the appropriate thiophenol to 1-chlorocyclohexene or 1-chlorocyclopentene.[3,4] *trans*-2-Tosyloxycyclohexyl phenyl sulfone, which was of interest for comparison of the rate of elimination with that of *trans*-2-chlorocyclohexyl phenyl sulfone, was prepared from the corresponding alcohol which in turn was obtained by oxidation of *trans*-2-hydroxycyclohexyl phenyl sulfide.[3]

The 2-chlorocycloalkyl aryl sulfones I-IV dehydrochlorinate rapidly at 0 to 10° in "80%" ethanol containing 0.004 to 0.03 *M* sodium hydroxide. That the reactions are indeed base-promoted is clear from the fact that the chlorosulfones do not solvolyze to a detectable extent in 24 hours at 25°, whereas in the presence of 0.03 *M* sodium hydroxide the least reactive compounds IIa and IIb are about 50% reacted in 2 hours at 10°.

The chlorosulfones dehydrochlorinate so rapidly that only for the least reactive series of compounds, the *trans*-2-chlorocyclohexyl aryl sulfones (II), could accurate rate constants be determined. The specific second-order rate constants (k) for this series of compounds and for *trans*-2-tosyloxycyclohexyl phenyl sulfone are shown in Table I. The reactions were quenched by rapidly delivering aliquots of reaction mixture into excess acid. The extent of reaction at the time of quenching was determined by either (a) titration with base to determine the amount of base consumed during the reaction (method A) or (b) Volhard titration of chloride ion (method B). The values of k given in Table I are the averages and mean deviations of six to ten values calculated by use of the appropriate equation for a second-order reaction. The reactions were followed to about 80% completion and no trends in k were observed. As shown in Table I, values of k were found to be reproducible.

The remaining three series of compounds (I, III and IV) dehydrochlorinate too rapidly even at 0° to be followed by conventional sampling techniques. Approximate relative reactivities for these compounds at 0° were determined from the lengths of time required for solutions 0.02 *M* in substrate and 0.01 *M* in sodium hydroxide in "80%" ethanol containing brom thymol blue to reach the same color as that of a slightly alkaline buffered solution of the indicator. From the relative reactivities thus obtained, together with the approximate second-order rate constant of 0.35 l. mole^{-1} sec.$^{-1}$ for the dehydrochlorination of *trans*-2-chlorocyclopentyl *p*-chlorophenyl sulfone (IVc) at 0°,[9] the reactivities of I, III and IV relative to *trans*-2-chlorocyclohexyl phenyl sulfone (IIa) can be calculated. The results are presented in Table II. As indicated in Table II, the relative reactivities measured in this way are reproducible to within 10%.

TABLE I

RATES OF SECOND-ORDER ELIMINATION FOR *trans*-2-CHLOROCYCLOHEXYL ARYL SULFONES AND *trans*-2-TOSYLOXYCYCLOHEXYL PHENYL SULFONE IN "80%" ETHANOL

trans-2-Chlorocyclohexyl- sulfone	Method[a]	Temp. °C.	RX 10^3M	NaOH 10^3M	10^3k, l. mole^{-1} sec.$^{-1}$	E_a, kcal.

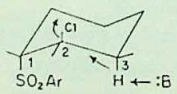
As shown in Table I electron-withdrawing substituents in the aryl moiety of *trans*-2-chlorocyclohexyl aryl sulfone (II) increase the rate of base-promoted dehydrochlorination. The kinetic data for the four members of this series give an excellent fit with the Hammett equation[10] and ρ at 0° is 1.42 ± 0.01. The data in Table II show that ρ is also positive for *cis*-2-chlorocyclohexyl aryl sulfone (I) and *cis*-(III) and *trans*-2-chlorocyclopentyl aryl sulfone (IV).

Discussion

In both the *cis* and *trans* isomers the β-sulfone group has a large accelerating effect on the rate of the base-promoted dehydrohalogenation. For example, *trans*-2-chlorocyclohexyl *p*-tolyl sulfone (IIb), the least reactive member of the least reactive series, is about 10^6 times as reactive as cyclohexyl chloride.[11] *cis*-2-Chlorocyclohexyl phenyl sulfone is about 10^9 times as reactive as cyclohexyl chloride.

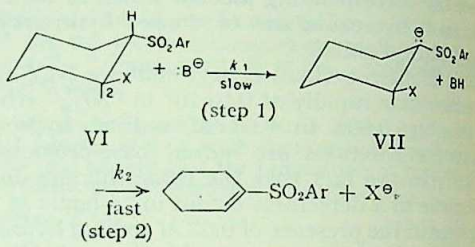
From the much greater reactivities of the *trans*-chlorosulfones than of cyclohexyl chloride it is apparent that a *cis* dehydrohalogenation is involved. Clearly the sulfone group in II could not accelerate a concerted *trans* elimination involving the C_3-hydrogen (V) or an S$_N$2 displacement (at C_2) by a factor of 10^6. In fact the sulfone group would be expected to retard the rates of these processes. The axial conformation (with chlorine in an axial position) is required for a concerted E2 elimination[6,12] and preferred for an S$_N$2 displacement.[13] Not only would the sulfone group tend to shift the conformational equilibrium toward the equatorial form (as compared to the conformational equilibrium for cyclohexyl chloride) which would retard the rate,[14] but in addition the axial sulfone group in the reactive conformation would retard both of these processes by shielding the C_3-axial hydrogen and the back side of C_2. The *cis* dehydrohalogenation of the *trans*-2-chlorocycloalkyl sulfones is not surprising and in fact would be expected in view of the observations by Bordwell, *et al.*,[7] that *cis* elimination is more rapid than *trans* if the *cis*-β-hydrogen is activated by a sulfone or similar group.



V

The most informative observation concerning the mechanism of the *cis* elimination is the nearly identical rates of elimination for *trans*-2-chlorocyclohexyl phenyl sulfone (IIa) and *trans*-2-tosyloxycyclohexyl phenyl sulfone (VI, X = $OSO_2C_6H_4CH_3$). Ordinarily, *p*-toluenesulfonates are much more reactive than the corresponding chlorides for second-order elimination reactions; *e.g.*, cyclohexyl *p*-toluenesulfonate[14] reacts with base—presumably the main reaction is an E2 elimination—more rapidly than cyclohexyl chloride[15] in absolute ethanol (75°) by a factor of 180.

The similar rates for IIa and the corresponding *p*-toluenesulfonate, the high reactivity of IIa and the effect of substituents on the rate are consistent with the two-step process illustrated below. This mechanism, which involves the removal of the β-proton by lyate ion ($:B^{\ominus}$) followed by conversion of the anion VII to product, has previously been suggested[16] for the dehydrohalogenation of β-benzene hexachloride.



Although certain details of this mechanism are not known, *e.g.*, the reactive conformation of the anion VII, etc., the present data show that step 1 is rate-determining and irreversible. Thus the second-order constants in Table I correspond to k_1 in step 1. Presumably the *trans*-2-chlorocyclopentyl aryl sulfones, which obviously undergo a *cis*-elimination, also react by this so-called E1cB[17] mechanism.

It is clear from the present and earlier[7] studies that in systems such as II, IV and VI, the β-sulfone group increases the acidity of the C_1-hydrogen (or in other words stabilizes the anion VII)[17] so that *trans* elimination does not compete with proton abstraction (step 1). It is interesting to note that a *trans*-β-halogen atom does not activate the *cis*-hydrogen atom sufficiently for *cis* elimination to be important as compared to *trans* elimination, *e.g.*, *trans*-1,2-dihalocyclohexanes give primarily 3-halocyclohexene as the initial product.[6] In systems where *trans* elimination is not possible (*e.g.*, β-benzene hexachloride) β-halogen atoms are sufficiently activating so that *cis* dehydrochlorination can be realized.[16] The latter observation, together with the fact that under certain conditions *trans*-1,2-dihalocyclohexanes give some 1-halocyclohexene[6,7] indicates that a *trans*-β-halogen is almost sufficiently activating for proton abstraction (*cis* elimination) to compete with the E2 reaction. This suggests that in the cyclohexyl system *cis* dehydrohalogenation will predominate if a *trans* substituent is present with a larger electron-withdrawing effect than that of a halogen atom.

The almost identical rates for IIa and the corresponding *p*-toluenesulfonate show that the leaving group is not involved in the rate-limiting step. This also shows that step 1 is irreversible. Undoubtedly k_2 in step 2 is larger for the *p*-toluene-

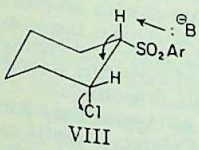
sulfonate than for the chloride by a factor of about 200. Thus if step 1 were reversible, step 2 would be in competition with this reverse reaction and the *p*-toluenesulfonate would undergo elimination faster than the chloride.

The observation that the first step in the *cis* elimination is irreversible in the present case suggests that the absence of deuterium exchange[18] does not necessarily rule out the possibility of a carbanion intermediate.[18] This observation also parallels that of Cristol and Fix[16c] that in the *cis* dehydrochlorination of benzene hexachloride, presumably by a two-step process similar to the one shown above, step 2 is 150 times as fast as the reverse of step 1.

Evidently the *cis*-chlorosulfones react by a concerted *trans* (E2) elimination (VIII). In the cyclohexyl system the *cis*-chlorosulfones are more reactive than the corresponding *trans* isomers by factors of 400 to 500. For the cyclopentyl system the factors are smaller, the *cis* isomers being more reactive than the corresponding *trans* isomers by factors of 40 to 50.



VIII

The large effect of the sulfone group in VIII on the rate of dehydrohalogenation is illustrated by comparing the rates for the *cis*-chlorosulfones I (Table II) with that for cyclohexyl chloride.[11] This comparison shows that the *trans* elimination in VIII is about 10^9 times faster than it would be if the sulfone group were replaced by hydrogen. The equatorial sulfone group in VIII has a considerably larger effect than a similarly located halogen atom; *cis*-1,2-dichlorocyclohexane dehydrohalogenates (to give 1-chlorocyclohexene) about 100 times faster than cyclohexyl chloride.[6] It is interesting to note that substituents in the aryl moiety have about the same effect in all four series of compounds.

Experimental

trans-2-Chlorocyclopentyl and *trans*-2-Chlorocyclohexyl Aryl Sulfides.—These series of compounds were prepared by the *trans* addition[3,5] of the corresponding sulfenyl chlorides to cyclopentene[19] and cyclohexene according to the general method of Lecher and Stocklin.[20] Benzene-, *p*-toluene- and *p*-chlorobenzenesulfenyl chloride were prepared by chlorinolysis of the corresponding thiophenols.[21] *p*-Nitrobenzenesulfenyl chloride was prepared by the chlorinolysis of 4,4′-dinitrodiphenyl disulfide.[22] The preparation of *trans*-2-chlorocyclohexyl phenyl sulfide was described in an earlier paper.[3] The properties of the *trans*-2-chlorocycloalkyl aryl sulfides prepared by this procedure are shown in Table III.

cis-2-Chlorocyclopentyl and *cis*-2-Chlorocyclohexyl Aryl Sulfides.—These series of compounds were prepared by the radical (photoinitiated) addition[3] of the corresponding thiophenol to 1-chlorocyclopentene[23] and 1-chlorocyclohexene,[3] according to the method described below for the preparation of *cis*-2-chlorocyclohexyl phenyl sulfide. A mixture of 77 g. (0.70 mole) of thiophenol (Eastman Kodak Co. White Label, redistilled) and 81.5 g. (0.70 mole) of 1-chlorocyclohexene in a Vycor flask was stirred for 10 days. During this period the solution was kept under nitrogen and irradiated with a Hanovia (type S100) mercury arc lamp placed 10 cm. from the reaction flask. Distillation of the reaction mixture gave 78 g. (49%) of crude ***cis*-2-chlorocyclohexyl phenyl sulfide**, b.p. 121–125° (0.5 mm.), $n^{25}D$ 1.5838, which solidified almost completely. After recrystallization from hexane the product melted at 38–39°.[24]

Anal. Calcd. for $C_{12}H_{15}ClS$: C, 63.56; H, 6.67. Found: C, 63.79; H, 6.78.

cis-2-Chlorocyclohexyl *p*-tolyl sulfide and *cis*-2-chlorocyclohexyl *p*-chlorophenyl sulfide were prepared in the same manner. In each case the crude reaction product, *i.e.*, product containing diaryl disulfide, was used for the preparation of the sulfones. The chlorosulfides were separated from the disulfide by chromatography using a column packed with Alcoa F-20 activated alumina. Pentane solutions of the crude products were passed through the column and the material was eluted with *n*-pentane. In each case the diaryl disulfide was eluted first and the disulfide was cleanly separated from the chlorosulfide.

The solid ***cis*-2-chlorocyclohexyl *p*-tolyl sulfide** remaining after evaporation of the pentane, melted at 34–35° (pentane).

Anal. Calcd. for $C_{13}H_{17}ClS$: C, 64.84; H, 7.11. Found: C, 65.23; H, 7.23.

Pure ***cis*-2-chlorocyclohexyl *p*-chlorophenyl sulfide**, m.p. 34.5–35.0° (pentane), was obtained in a similar manner.

Anal. Calcd. for $C_{12}H_{14}Cl_2S$: C, 55.18; H, 5.40. Found: C, 55.14; H, 5.62.

(21) H. Lecher, *ibid.*, **58**, 409 (1925).

(22) M. T. Bogert and A. Stull, "Organic Syntheses," Coll. Vol. I, John Wiley and Sons, Inc., New York, N. Y., 2nd ed., 1941, p. 220.

(23) 1-Chlorocyclopentene, b.p. 103.0–103.5°, $n^{25}D$ 1.4364, was prepared according to the method of E. A. Braude and W. F. Forbes, *J. Chem. Soc.*, 1755 (1951). Contrary to the report of these workers, this product was found to be unreactive toward aqueous alcoholic silver nitrate.

(24) The liquid sample of *cis*-2-chlorocyclohexyl phenyl sulfide described in reference 3, prepared by irradiation with a specially constructed high-intensity Hanovia lamp (type SC-2537) which was in contact with the reaction mixture, has been found to contain significant amounts of diphenyl disulfide. In the present work it has been found that less intense irradiation, *e.g.*, a Hanovia (type 30600) lamp placed 10 cm. or more from the reaction mixture, reduces considerably the formation of disulfide formed in the addition of thiophenol, *p*-thiocresol and *p*-chlorothiophenol.

[a] A = oxidation of sulfide with 30% hydrogen peroxide in acetic acid; recrystallization from acetic acid–water (2:1). B = Oxidation of sulfide with perbenzoic acid in chloroform; recrystallization from chloroform–hexane (1:9).

The *cis*-2-chlorocyclopentyl aryl sulfides were prepared in the same way.[4] These samples, which contained about 10% of the corresponding diaryl disulfides, were not purified further but were converted directly to the corresponding sulfones.

Conversion of Sulfides to Sulfones.—The *cis*- and *trans*-2-chlorocycloalkyl aryl sulfides were converted to the corresponding sulfones by oxidation with hydrogen peroxide in acetic acid[25] or perbenzoic acid in chloroform.[26] The properties of the sulfones, with the exception of *cis*- and *trans*-2-chlorocyclohexyl phenyl sulfone which were reported previously,[3] are shown in Table IV together with the analytical data.

***trans*-2-Tosyloxycyclohexyl Phenyl Sulfone.**—*trans*-2-Hydroxycyclohexyl phenyl sulfide[3] was oxidized with hydrogen peroxide in acetic acid (see above) to ***trans*-2-hydroxycyclohexyl phenyl sulfone**, m.p. 102–103° (aqueous acetic acid).

Anal. Calcd. for $C_{12}H_{16}O_3S$: C, 59.97; H, 6.71. Found: C, 59.72; H, 6.86.

A solution of 14.40 g. (0.060 mole) of *trans*-2-hydroxycyclohexyl phenyl sulfone in 60 ml. of dry pyridine was treated with 19.06 g. (0.100 mole) of *p*-toluenesulfonyl chloride. After standing for one week at room temperature the reaction mixture was decanted from the pyridine hydrochloride and the excess *p*-toluenesulfonyl chloride was hydrolyzed by addition of 20 ml. of water in small portions. The solution was poured into cold water and the mixture extracted with chloroform. The combined chloroform extracts were washed with 20% sulfuric acid and dried over sodium sulfate. Evaporation of the chloroform left 15 g. (63%) of light yellow solid, m.p. 115–116°. Recrystallization from acetone–pentane (15:85) gave pure *trans*-2-tosyloxycyclohexyl phenyl sulfone as white needles, m.p. 119.0–119.5°.

Anal. Calcd. for $C_{19}H_{22}O_6S_2$: C, 57.85; H, 5.62. Found: C, 58.13; H, 5.65.

Kinetic Experiments. Method A.—This method was used for determining the rates of elimination of the *trans*-2-chlorocyclohexyl aryl sulfones and *trans*-2-tosyloxycyclohexyl phenyl sulfone. A typical experiment was carried out as follows. A solution of an accurately weighed 0.6-g. sample of IIa in 75 ml. of "80%" ethanol[5] was thermostated at 9.95°. At zero time 50 ml. of 0.07305 *M* sodium hydroxide in "80%" ethanol (previously thermostated at 9.95°) was added and the resulting solution was rapidly and thoroughly agitated by swirling the reaction vessel in the thermostat. At appropriate time intervals (*ca.* every 10% reaction to 80% completion) 10-ml. aliquots were withdrawn and rapidly delivered into 5 ml. of 0.06041 *M* hydrochloric acid to stop the reaction. The percentage reaction at the time of sampling was determined by titration of the excess acid to the brom thymol blue end-point with 0.05594 *M* sodium methoxide in methanol. Specific second-order rate constants were calculated by use of the appropriate equation. Seven to ten values were determined for each kinetic experiment and the averages of these, together with the mean deviations, are given in Table I.

Method B.—In this method, the reaction was followed by titration of chloride ion. In a typical experiment, 0.37 g. of IIb in 75 ml. of "80%" ethanol was thermostated at 8.36°; 50 ml. of 0.02535 *N* sodium hydroxide in "80%" ethanol was weighed and thermostated in a tared stoppered flask. At zero time, the sodium hydroxide solution was quickly poured (in 1–2 seconds) into the flask containing the solution of sulfone and mixed thoroughly by swirling. The exact amount of sodium hydroxide solution used was determined by weighing the empty flask after the transfer. At appropriate time intervals, 10-ml. aliquots were withdrawn and rapidly delivered into 5 ml. of 3 *M* nitric acid at 0° to quench the reaction. The automatic pipet used for this purpose was wrapped with asbestos and kept in a large test-tube immersed in the thermostat. The amount of chloride ion in the nitric acid solution was determined by the Volhard method using 0.02 *M* standard silver nitrate and potassium thiocyanate solutions.

Determination of Approximate Relative Reactivities of *cis*- and *trans*-2-Chlorocyclopentyl and *cis*-2-Chlorocyclohexyl Aryl Sulfone.—The dehydrochlorinations of these chlorosulfones were too fast to follow by the method described above. Approximate relative reactivities for these compounds at 0° were determined from the relative lengths of time required for solutions 0.02 *M* in substrate and 0.00845 *N* in sodium hydroxide in "80%" ethanol containing brom thymol blue to reach the same color as that of a slightly alkaline buffer solution containing the indicator. The buffer solution was prepared by mixing 9 ml. of 0.1 *N* sodium hydroxide, 10 ml. of 0.1 *M* potassium dihydrogen phosphate, 1 ml. of water and 20 ml. of absolute ethanol; 15 ml. was then placed in an 8″ × 1.25″ test-tube and 2 drops of 0.05% brom thymol blue indicator (in ethanol) was added to give a bluish-green reference color. In a typical experiment a solution of 0.0777 g. (0.300 mmole) of *cis*-2-chlorocyclohexyl phenyl sulfone in 10.00 ml. of "80%" ethanol was prepared in an 8″ × 1.25″ test-tube and 2 drops of 0.05% brom thymol blue indicator was added and the solution thermostated at 0°. At zero time, 5 ml. of 0.02535 *M* sodium hydroxide in "80%" ethanol, previously thermostated at 0°, was added with an automatic pipet. The automatic pipet used for this purpose was wrapped with asbestos and stored in a large test-tube immersed in ice. The test-tube was tightly stoppered and swirled. The color of the solution gradually changed from a rich blue to green, and finally to yellow. The time at which the color of the solution first became indistinguishable from the bluish-green color of the reference buffer solution was found to be 12±3 seconds.

A New Synthesis of α-Nitroesters[1,2]

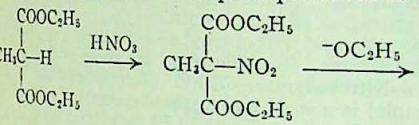
BY NATHAN KORNBLUM, ROBERT K. BLACKWOOD AND JACK W. POWERS

RECEIVED SEPTEMBER 17, 1956

A simple new synthesis of α-nitroesters which involves treating α-haloesters with sodium nitrite in the presence of phloroglucinol is described; 66 to 91% yields of pure α-nitroesters are obtained.

While α-nitroesters have been prepared on a number of occasions, none of the methods employed can be characterized as genuinely useful.[3] For example, while the reaction of α-iodoesters with silver nitrite gives 77–84% yields of α-nitroesters,[4] it suffers from important drawbacks. The readily available α-bromoesters react so slowly that they cannot be used and, so, must first be converted to α-iodoesters. Even with α-iodoesters the reaction is so slow, despite the use of a 100% excess of silver nitrite, as to be impractical for the preparation of any but low molecular weight, straight chain, α-nitroesters.[4]

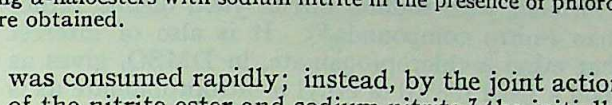
Nitration of malonic esters and subsequent alkaline degradation as, for example, in eq. 1 has been used, but the isolation of pure products is difficult



$$CH_3\overset{\displaystyle -}{C}(COOC_2H_5)_2\text{—}NO_2 + (C_2H_5O)_2CO \quad (1)$$

and the yields are low (15–22%).[5]

As pointed out previously[6] the reaction of organic halides with sodium nitrite requires a solvent which will dissolve both reactants; this immediately rules out most common solvents. Dimethylformamide (DMF) not only has the requisite solvent properties but, in addition, the reaction in this medium is very rapid so that processes which destroy the initially produced nitroparaffin and alkyl nitrite do not have a chance to intrude.[6,7] When, however, an attempt was made to carry out the reaction of equation 2, none of the α-nitroester could be isolated even though the α-bromoester was consumed rapidly; instead, by the joint action of the nitrite ester and sodium nitrite,[7] the initially produced α-nitroester was very quickly converted into the α-oximinoester.



$$RCHCOOC_2H_5 \xrightarrow[DMF]{NaNO_2} RCHCOOC_2H_5 + RCHCOOC_2H_5 \quad (2)$$
(Br) (NO₂) (ONO)

It transpires, however, that simply by adding phloroglucinol to the reaction mixture the formation of oximinoesters is prevented and pure α-nitroesters are obtained in excellent yields (Table I). The phloroglucinol functions as a scavenger for nitrite esters and is especially effective for this purpose. That this attribute of phloroglucinol is involved is shown by the production of ethyl α-nitroisobutyrate in 78–91% yields without phloroglucinol being present (eq. 3). Here the α-nitroester being devoid of α-hydrogen cannot undergo

$$(CH_3)_2\text{—}C(Br)\text{—}COOC_2H_5 \xrightarrow{NaNO_2} (CH_3)_2\text{—}C(NO_2)\text{—}COOC_2H_5 \quad (3)$$

the nitrosation reaction which converts α-nitroesters to α-oximinoesters.[7]

It also has been found that the reaction can be conducted in dimethyl sulfoxide (DMSO); in fact, DMSO is somewhat superior to DMF in the α-nitroester synthesis (*cf.* Table I). This superiority appears to derive principally from the distinctly greater solubility of sodium nitrite in DMSO; less solvent is needed and shorter reaction times are required.[8]

TABLE I

SYNTHESIS OF α-NITROESTERS FROM α-BROMOESTERS

Ethyl α-nitroester	Reaction time,[c] hr. In DMSO	Reaction time,[c] hr. In DMF	Yield, % In DMSO	Yield, % In DMF
Propionate[a]	1.5	2	66	62
Butyrate	1.5	2.5	83	70–75
Valerate	1.5	...	87	..
Caproate	1	5	76	74
Isobutyrate[b]	5	44	91	78
Isovalerate	75	150	75	67
α-Phenyl-α-nitroacetate	..	2.5	..	70

[a] From ethyl α-chloropropionate a 68% yield of ethyl α-nitropropionate was obtained (solvent DMSO; reaction time 48 hr.). A run employing ethyl α-iodopropionate in DMF gave a 62% yield of ethyl α-nitropropionate after 2 hr. [b] No phloroglucinol employed. [c] DMF solutions *ca.* 0.5 molar in RBr and *ca.* 0.8 molar in $NaNO_2$. DMSO solutions *ca.* 1.2 molar in RBr and *ca.* 2 molar in $NaNO_2$.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Irrespective of whether DMSO or DMF is used, the reaction of α-haloesters with sodium nitrite is carried out at room temperature and, as the data of Table I show, it makes readily available a wide variety of α-nitroesters. Especially noteworthy is the preparation, in excellent yield, of ethyl α-nitroisobutyrate (eq. 3), since *t*-alkyl halides on treatment with sodium nitrite yield olefins rather than *t*-nitro compounds.[6,9] It is also of interest that ethyl α-chloropropionate, in DMSO, gives as good a yield (68%) of ethyl α-nitropropionate as is obtained from the α-bromoester.[10]

In only one instance does the new α-nitroester synthesis fail. If ethyl bromoacetate is treated with sodium nitrite in the usual way, a very rapid reaction ensues, but no ethyl nitroacetate can be isolated.[11]

α-Nitroesters possessing an α-hydrogen are relatively strong acids. They dissolve slowly in aqueous sodium bicarbonate, the rate of solution being a function of the molecular weight of the ester; in aqueous sodium carbonate they dissolve after a few minutes and, with 10% aqueous sodium hydroxide, they go into solution almost instantaneously. From the salts the α-nitroesters are readily regenerated (at least from sodium carbonate solution) by aqueous acetic acid and urea.[12]

Table II shows the apparent pK_A values of several α-nitroesters and nitroparaffins in 50% aqueous ethanol.[13]

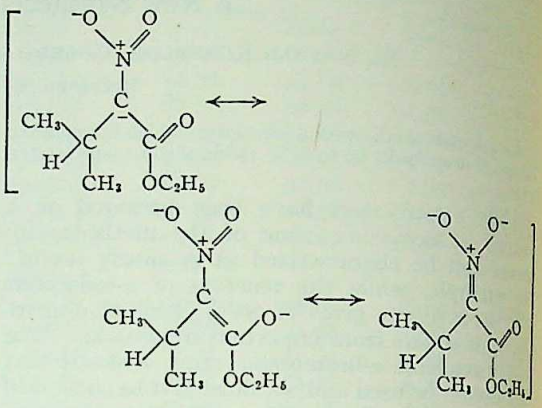
TABLE II

APPARENT pK_A VALUES IN 50% AQUEOUS ETHANOL

Compound	Apparent pK_A
Ethyl α-nitropropionate	7.5
Ethyl α-nitrobutyrate	7.6
Ethyl α-nitrocaproate	7.7
Ethyl α-nitroisovalerate	9.0
Ethyl α-nitro-α-phenylacetate	6.9
1-Nitrobutane	10
2-Nitrobutane	9.4
Phenylnitromethane	8.2
Benzoic acid	5.7[a]

[a] F. G. Bordwell and G. D. Cooper, THIS JOURNAL, 74, 1058 (1952), report an apparent pK_A of 5.73.

Straight chain, secondary α-nitroesters are about 100 times stronger acids than 2-nitrobutane. It is also noteworthy that ethyl α-nitroisovalerate is distinctly less acidic than any of the other α-nitroesters. This may well be a case of steric inhibition of resonance.



Experimental

Reagents.[14]—N,N-Dimethylformamide (DMF, du Pont technical grade), phloroglucinol dihydrate (Ringwood technical grade) and dimethyl sulfoxide (DMSO, Stepan Chemical Co.) were used as received.[15] The α-bromoesters were commercial products which were rectified and only material of constant b.p. and $n^{20}D$ was used. Ethyl α-bromo-α-phenylacetate ($n^{20}D$ 1.5360) was specially prepared by Fairfield Laboratories. Sodium nitrite was an analytical grade.

The preparation of ethyl α-nitrobutyrate exemplifies the DMF procedure and that of ethyl α-nitrovalerate typifies the DMSO procedure. Reaction times are given in Table I.

Ethyl α-Nitrobutyrate.—Ethyl α-bromobutyrate (58.5 g., 0.30 mole) is poured into a stirred mixture of 600 ml. of DMF, 36 g. of sodium nitrite (0.52 mole) and 40 g. (0.32 mole) of anhydrous phloroglucinol (or 52 g. of phloroglucinol dihydrate; *cf.* footnote 15) in a 1-l. three-necked flask equipped with a sealed stirrer. The flask is stoppered, immersed in a water-bath maintained at room temperature, and stirring is continued for 2.5 hr. The reaction mixture is then poured into 1.2 l. of ice-water layered over with 300 ml. of diethyl ether. After separation of the upper layer, the aqueous phase is extracted four more times with 100-ml. portions of ether. The combined extracts are washed with four 100-ml. portions of water and then dried over anhydrous magnesium sulfate. The mixture is filtered with suction, the magnesium sulfate is washed with four 25-ml. portions of ether and these are combined with the filtrate. Using a small column, the ether is removed under reduced pressure, heat being supplied by a bath whose temperature is gradually raised to *ca.* 60°. The residual yellow liquid is transferred to a 100-ml. flask, the column is attached and the remaining solvent is removed under reduced pressure. Rectification of the residue yields 2–3 g. of forerun in the range 33–71° (1 mm.) which is followed by 34–36 g. (70–75%) of colorless ethyl α-nitrobutyrate (b.p. 71° (1 mm.), $n^{20}D$ 1.4233).

In the preparation of ethyl α-nitro-α-phenylacetate, the procedure was modified in that the crude product was not rectified; instead it was dissolved in aqueous sodium carbonate, regenerated with aqueous acetic acid and urea[12] and, finally, distilled.

The reaction is not critically dependent on conditions. Thus, using ethyl α-bromopropionate, the same yield of ethyl α-nitropropionate was obtained at 0° and at 25°.

(9) N. Kornblum and R. K. Blackwood, THIS JOURNAL, 78, 4037 (1956).

(10) It is probable that α-chloroesters in DMF will also give excellent yields of α-nitroesters despite the somewhat longer reaction times which will be required.

(11) Precisely what happens has yet to be determined. Even lowering the reaction temp. to −20°, a device which is successful in the preparation of phenylnitromethane from benzyl bromide (ref. 6), fails to produce a trace of ethyl nitroacetate [W. M. Weaver, unpublished work].

(12) N. Kornblum and G. E. Graham, THIS JOURNAL, 73, 4041 (1951).

(13) The apparent pK_A values in Table II are *ca.* 1.5 units higher than pK_A's determined in water. Thus, in water, benzoic acid has pK_A 4.20 [R. A. Benkeser and H. R. Krysiak, THIS JOURNAL, 75, 2424 (1953)]; *cf.* also G. W. Wheland and J. Farr, *ibid.*, 65, 1433 (1943).

(14) We thank the du Pont Co., the Ringwood Chemical Corporation and the Stepan Chemical Co. for generous gifts of DMF, phloroglucinol and DMSO, respectively.

(15) With ethyl α-nitrobutyrate, ethyl α-nitrovalerate and ethyl α-nitrocaproate, the yields were not altered (*cf.* Table I) by using phloroglucinol rendered anhydrous by heating for 3 hr. at 110° and DMSO which had been dried by standing over calcium hydride for several days. As regards reactions conducted in DMF, while all but one of the preparations summarized in Table I were carried out with anhydrous phloroglucinol, it is extremely probable that phloroglucinol dihydrate is equally effective. In experiments using ethyl α-bromopropionate and ethyl α-iodopropionate, phloroglucinol dihydrate gave 60–62% yields of ethyl α-nitropropionate, whereas with anhydrous phloroglucinol the yields were 62%.

May 20, 1957

Extension of the reaction time at 25° from 2 hr. to 17 hr. gave no loss in yield.

In reactions employing ethyl α-bromopropionate and ethyl α-iodopropionate, the use of half the amount of anhydrous phloroglucinol (20 g.) gave only 3 to 5% less ethyl α-nitropropionate. Other nitrate ester scavengers may be employed, but phloroglucinol seems to be far and away the most effective at destroying the nitrite ester formed along with the α-nitroester. Thus use of resorcinol (in the same molar concentration as an otherwise identical experiment using phloroglucinol) led to only a 25% yield of the α-nitropropionate along with an 8% yield of ethyl α-oximinopropionate. Furthermore, the rectified product, in spite of having correct refractive index, was highly colored.

In the conversion of ethyl α-bromoisobutyrate to the α-nitroester, the same yield (78%) was obtained in the presence and in the absence of phloroglucinol.

Ethyl α-Nitrovalerate.—Ethyl α-bromovalerate (60.9 g., 0.3 mole) is poured into a solution of 250 ml. of dimethyl sulfoxide (DMSO), 36 g. of sodium nitrite (0.52 mole) and 52 g. of phloroglucinol dihydrate (0.32 mole) in a 500-ml. three-necked flask equipped with a sealed stirrer. The flask is stoppered, immersed in a water-bath maintained at room temperature and stirring is continued for 1.5 hr. A slurry forms after *ca.* 0.5 hr., and, if necessary, a small amount of DMSO is added to facilitate stirring. The reaction mixture is then poured into 600 ml. of ice-water layered over with 200 ml. of diethyl ether. After separation of the upper layer, the aqueous phase is extracted four more times with 75-ml. portions of ether. The combined extracts are washed with four 100-ml. portions of water and then dried over anhydrous magnesium sulfate.

Using a small column the ether is removed at atmospheric pressure and the residual yellow liquid is rectified. This gives 44.2 g. (87% yield) of colorless ethyl α-nitrovalerate; b.p. 62° (1 mm.), $n^{20}D$ 1.4266.

TABLE III

PHYSICAL CONSTANTS OF α-NITROESTERS

Ethyl α-nitroester	B.p. °C.	B.p. Mm.	$n^{20}D$	Literature[a] B.p. °C.	Mm.	$n^{20}D$
Propionate	55	1	1.4209	75	9	1.4210

Found: C, 44.8, 44.6; H, 7.01, 7.11; N, 8.72. [d] *Anal.* Calcd. for $C_7H_{13}NO_4$: C, 48.0; H, 7.50; N, 8.00. Found: C, 47.9; H, 7.51; N, 8.03. [e] *Anal.* Calcd. for $C_{10}H_{11}NO_4$: C, 57.5; H, 5.30; N, 6.70. Found: C, 57.5; H, 5.48; N, 6.79.

Relative Reaction Rates in DMF and in DMSO.—In one arm of a two-armed flask was placed 50 ml. of 0.05 *N* ethyl α-bromobutyrate solution (0.488 g.) and in the other was placed 50 ml. of a solution which was 0.05 *N* in $NaNO_2$ (0.173 g.) and 0.05 *N* in anhydrous phloroglucinol. The flask was immersed in a constant temperature bath (25°), and after the two solutions had come to temperature they were mixed. Aliquots (5 ml.) were withdrawn, run into dilute sulfuric acid and titrated for bromide ion with 0.05 *N* $AgNO_3$. The following is a typical result and shows that the reaction of α-bromoesters with sodium nitrite occurs at essentially the same rate in DMF and in DMSO.

Time, min.	0.05 *N* $AgNO_3$ ml. DMSO	DMF
1	0.25	0.31
5	0.80	0.90
10	1.18	1.38
20	1.58	1.73
35	1.87	1.91
50	2.00	2.02
∞	2.50	2.50

The Reaction of Ethyl α-Bromopropionate with Sodium Nitrite in DMF without Phloroglucinol.—Ethyl α-bromopropionate (0.3 mole) was treated with sodium nitrite in DMF as described above except that no phloroglucinol was present. After 5.5 hr. the reaction mixture was worked up in the usual way. After removal of the ether 24.4 g. of a pale green, partly crystalline, residue remained. This, when treated with petroleum ether, gave 9.2 g. (24% yield) of ethyl α-oximinopropionate, m.p. 93.5–94°, mixed m.p. with authentic ethyl α-oximinopropionate, 94–94.5°. Concentration of the petroleum ether mother liquors left a green oil which, when rectified at 1 mm., gave no ethyl α-nitropropionate; it was not investigated further.

The Reaction of Ethyl α-Bromobutyrate with Sodium Nitrite in DMSO without Phloroglucinol.—Ethyl α-bromobutyrate (0.14 mole) was treated with sodium nitrite in DMSO as described above, except that no phloroglucinol was present. After 15 minutes the reaction mixture was worked up in the usual way. Distillation gave a 65% yield of ethyl α-oximinobutyrate, m.p. 59°, lit.[16] m.p. 58–60°.

pK_A Determinations.—The apparent pK_A values given in Table II were determined at 25° by a procedure analogous to that of Bordwell and Cooper.[17] A Beckman *p*H meter equipped with calomel and glass (sodium) electrodes and calibrated with standard buffers at *p*H 9.16 and 7.00 was employed. Solutions of the various nitro compounds (*ca.* 0.01 *M*) in 50% (by volume) aqueous ethanol were titrated with aqueous sodium hydroxide (0.0967 *N*). An equal volume of absolute ethanol was added simultaneously from a second buret. The *p*H value at half-neutralization was taken as the pK_A value. With the weaker acids several minutes were required before a constant, equilibrium reading could be obtained. In no case was more than 5 min. required and, in general, the time interval was inversely proportional to the acid strength. Since no special potassium glass electrode was employed, apparent pK_A values above 9 must necessarily be only approximate, due to the electrode error above *p*H 9.

aci-Nitroalkanes. II. The Mechanism of the Nef Reaction[1]

BY M. FREDERICK HAWTHORNE

RECEIVED AUGUST 2, 1956

The kinetics of the acid-catalyzed solvolysis of seven *sec-aci*-nitroalkanes has been determined in a nitrogen atmosphere at 0° in 80% by volume methanol by the use of a newly developed spectrophotometric microanalytical method for *aci*-nitroalkanes. All kinetics were conducted with approximately 1×10^{-3} *M* *aci*-nitroalkane solutions. In each case the reaction was found to be first order in both *aci*-nitroalkane and hydrogen ion and reproducible to ±15%. Spectrophotometric product analyses for nitroalkanes indicated that, with the possible exception of nitrocyclobutane, no detectable amounts of nitroalkane were regenerated under kinetic conditions. Product isolation experiments indicated that each of the *aci*-nitroalkanes studied gave excellent yields of the corresponding ketones (isolated as 2,4-dinitrophenylhydrazones) on hydrolysis under conditions similar to those of the kinetic experiments and very little if any pseudonitrole. The *sec-aci*-nitroalkane reactivity sequence cyclohexyl > cyclobutyl > 2-propyl > 1-cyclopropylethyl > cyclopentyl > dicyclopropylmethyl > cycloheptyl was observed and when coupled with the first-order dependence of reaction rate on both hydrogen ion and *aci*-nitroalkane concentrations, leads to the conclusion that the rate-determining step of the Nef reaction is most probably the nucleophilic attack of solvent on the unsaturated carbon atom of the conjugate acid of the *sec-aci*-nitroalkane. The near average reactivity of the cyclopropyl-substituted nitroalkanes is discussed. The ultraviolet absorption spectra of the anions of these latter nitroalkanes show a marked shift of their absorption maxima to longer wave lengths when compared with the absorption spectra of anions of other representative *sec*-nitroalkanes.

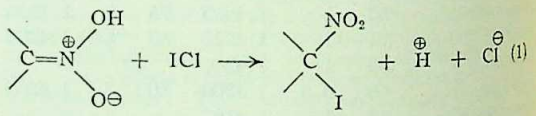
Although the hydrolysis of *aci*-nitroalkanes (Nef reaction) often has been utilized as a synthetic method for the preparation of carbonyl compounds[2] and a mechanism recently has been proposed,[3] no kinetic studies of this reaction have been reported. Because of this lack of quantitative information, the present investigation was initiated in an effort to bring the mechanism of this reaction more sharply into focus and to secure additional information with regard to the stereoelectronic requirements of *aci*-nitroalkanes.

Secondary nitroparaffins were chosen for study since diverse members of this series are easily prepared by the trifluoroperoxyacetic acid oxidation of the corresponding oximes[4] and the hydrolysis of their *aci*-isomerides has been shown[2,3] to produce the corresponding ketones in high yield. Nitrocycloalkanes received particular attention since their kinetic examination coupled with the recent generalizations of Brown, Brewster and Shechter[5] provided a tool which was used to specify the probable course of the reaction.

Kinetic Method

In order to examine the rates of the acid-catalyzed hydrolysis of *sec-aci*-nitroalkanes, certain experimental requirements were necessarily imposed on any method chosen. These include: (1) the use of low *aci*-nitroalkane concentrations which would minimize the importance of bimolecular side reactions which might occur between *aci*-nitroalkane molecules, (2) the generation of the anions of the nitroalkanes in an atmosphere containing no oxygen,[6] (3) a method for the instantaneous addition of strong acid to the nitroalkane anion solution with a minimum temperature increase and the ultimate production of a predetermined hydrogen ion concentration, (4) an analytical method for the determination of *aci*-nitroalkane at low concentrations and in the presence of a moderate concentration of strong acid.

These requirements were met and the rates of acid-catalyzed hydrolysis of seven *sec-aci*-nitroalkanes were determined at 0° in 80% by volume methanol using a spectrophotometric adaptation of the classical halometric determination of *aci*-nitroalkanes[7] described by equation (1).



(1)

Each rate run was carried out under nitrogen. Approximately 1×10^{-3} *M* concentrations of *aci*-nitroalkanes were generated in a stirred reactor in the presence of known hydrogen ion concentrations by the addition of a known and excess amount of concentrated hydrochloric or perchloric acid to a solution of nitroalkane anion.[8]

The nitroalkane anion was prepared under nitrogen in the reactor from a known volume of standardized dilute sodium hydroxide solution in 80% methanol and approximately 3 mg. of nitroalkane.

In essence, the analytical method consisted of the rapid addition of an aliquot of reaction mixture to a known and excess amount of iodine monochloride in aqueous methanol solution followed by the addition of a small portion of an intimate mixture of N,N,N′,N′-tetramethyl-*p*-phenylenediamine dihydrochloride and sodium acetate. The excess iodine monochloride rapidly and quantitatively reacted as

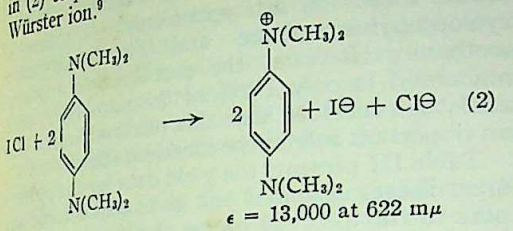
in (2) to produce an intensely blue solution of the Würster ion.[9]



(2)

ϵ = 13,000 at 622 mμ

The spectrophotometric determination of the amount of Würster ion produced allowed the calculation of the instantaneous concentration of *aci*-nitroalkane present in the aliquot taken. Since the stoichiometry of (1) is cleanly observed, each *aci*-nitroalkane examined was in this manner given an effective extinction coefficient of 2.6×10^4 at 622 mμ.

Results

Each *sec-aci*-nitroalkane examined in the manner described above gave acceptable first-order plots with the determined first-order rate constant reproducible to ±15% and proportional to the hydrogen ion concentration. The instantaneous rate expression is then defined by (3).

$$v = k[H^+]\ [aci\text{-nitroalkane}] \qquad (3)$$

Figure 1 is a typical first-order plot obtained with *aci*-nitrocyclohexane and Fig. 2 illustrates the

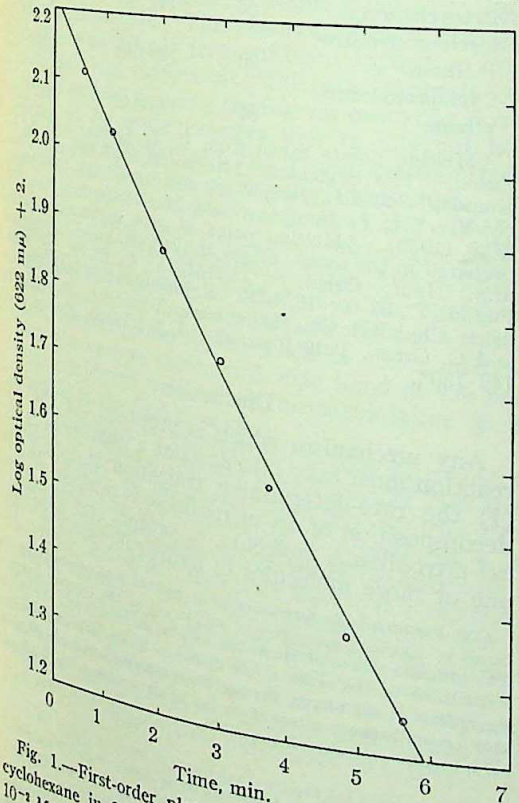


Fig. 1.—First-order plot of the solvolysis of *aci*-nitrocyclohexane in 80% methanol at 0.0° containing 4.4 × 10^{-1} *M* hydrochloric acid.

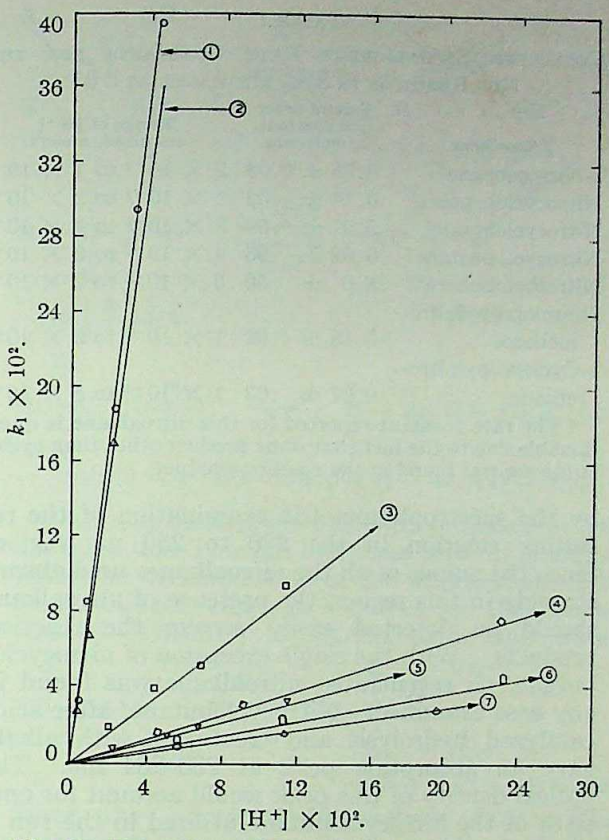

Fig. 2.—Dependence of pseudo first-order rate constant on hydrogen ion concentration for: nitrocyclohexane, 1; nitrocyclobutane, 2; 2-nitropropane, 3; nitrocyclopentane, 4; 1-cyclopropylnitroethane, 5; dicyclopropylnitromethane, 6; and nitrocycloheptane, 7.

fit of all the data obtained to equation 3. It should be noted that within experimental error all of the lines in Fig. 2 pass through the origin. This observation rules out the occurrence of a kinetic term of the form 4 which would result if *aci*-nitro-

$$v = k'[aci\text{-nitroalkane}] \qquad (4)$$

alkane were tautomerizing to the nitroalkane at a significant rate.[10]

Table I summarizes the second-order rate constants obtained in the hydrolysis of *aci*-nitrocyclobutane, -cyclopentane, -cyclohexane, -cycloheptane, 2-*aci*-nitropropane, *aci*-nitrocyclopropylethane and *aci*-nitrodicyclopropylmethane. With the exception of nitrocyclohexane and 2-nitropropane, all the parent nitroalkanes were prepared by the peroxytrifluoroacetic acid oxidation of the corresponding oximes.[4] The two cyclopropyl compounds reported here were each obtained in approximately 40% yield.

Product analyses were carried out in every case for both regenerated nitroalkane and for the ketone product of the Nef reaction. The analytical procedure applied to the former possible product was based on the treatment of the reaction mixture with strong base in a nitrogen atmosphere followed

(9) L. Michaelis, M. P. Schubert and S. Granick, THIS JOURNAL, 61, 1981 (1939).

(10) R. G. Pearson and R. L. Dillon, *ibid.*, 72, 3574 (1950), have shown that in the case of nitroethane this tautomerization reaction is observed kinetically as the reaction of nitroalkane anion with general acids, $RNO_2^- + HA \rightarrow RHNO_2 + A^-$. The kinetic isolation of the acid-catalyzed hydrolysis of *aci*-nitroalkane at relatively high acid concentrations is to be expected on the basis of the difference in transition state composition of the two competing processes.

TABLE I

COLLECTED SECOND-ORDER RATE CONSTANTS FOR THE NEF REACTION IN 80% METHANOL AT 0.0°

Nitroalkane	Second-order rate constant, l./mole-min.	Range of $[H^+]$ examined, mole/l.
2-Nitropropane	0.78 ± 0.08	2×10^{-2} to 1×10^{-1}
Nitrocycloheptane	0.14 ± .02	5×10^{-2} to 2×10^{-1}
Nitrocyclohexane	8.9 ± .50	3×10^{-3} to 4×10^{-2}
Nitrocyclopentane	0.32 ± .05	4×10^{-2} to 2×10^{-1}
Nitrocyclobutane[a]	8.0 ± .50	3×10^{-3} to 2×10^{-2}
Dicyclopropylnitromethane	0.18 ± .02	1×10^{-1} to 3×10^{-1}
1-Cyclopropylnitroethane	0.27 ± .03	1×10^{-1} to 5×10^{-1}

[a] The rate constant reported for this nitroalkane is questionable due to the fact that some product other than cyclobutanone was found in the reaction product.

by the spectrophotometric examination of the resulting solution in the 220 to 250 mμ region. Since the anions of all the nitroalkanes used absorb strongly in this region, the presence of nitroalkane should be detected easily among the reaction products. With the single exception of nitrocyclobutane, no regenerated nitroalkane was found in any case examined. Nitrocyclobutane, after acid-catalyzed hydrolysis and treatment with alkali, gave an absorption peak at 230–234 mμ. The optical density of this peak would account for one-sixth of the nitrocyclobutane utilized in the run if the extinction coefficient of the product were the same as that of the nitrocyclobutane anion. It appears that nitrocyclobutane does not give the Nef reaction quantitatively under the conditions employed. That the material responsible for the 230–234 mμ peak in the products was not due to nitrocyclobutane, which escaped the initial treatment with hydroxide ion, was shown by the fact that this absorption was independent of the time allowed for the initial ionization reaction.

Table II summarizes the absorption maxima of the nitroalkane anions employed in this study. The striking bathochromic shift observed on the introduction of α-cyclopropyl rings into a *sec*-nitroalkane lends considerable support to the concept of the unsaturated character of cyclopropyl groups.[11]

TABLE II

THE ULTRAVIOLET ABSORPTION SPECTRA OF NITROALKANE ANIONS IN 80% METHANOL

Parent nitroalkane	λ_{max}, mμ	$\epsilon_{max} \times 10^{-4}$[a]
2-Nitropropane	227	1.06
Nitrocycloheptane	234	1.15
Nitrocyclohexane	237	1.20
Nitrocyclopentane	230	1.13
Nitrocyclobutane	234	1.17
Dicyclopropylnitromethane	248	1.17
1-Cyclopropylnitroethane	240	1.25

[a] Values dependable to only ±5%.

The second product analysis employed involved the execution of the rate experiments at somewhat higher (*ca.* 0.07 *M*) *aci*-nitroalkane concentrations and the isolation of the resulting ketone as its 2,4-dinitrophenylhydrazone. In these runs, a fleeting blue intermediate always was observed. Pseudonitrole formation was noted only in the cases of cyclopropylnitroethane and dicyclopropylnitromethane. However, the pseudonitrole produced amounted to only 1–2% of the nitroalkane used, and it is concluded that this reaction did not play an important role in the kinetic studies.[12]

Table III presents the yield data for the series of nitroalkanes examined and gives considerable support to the assumed course of the reaction. The somewhat lower yield of 2,4-dinitrophenylhydrazone obtained from nitrocyclobutane may be due to the incomplete separation of the ketone as the solid derivative. However, as stated above, spectrophotometric examination of an alkaline solution of the reaction products of nitrocyclobutane did show absorption in the 230 mμ region, and it is conceivable that the Nef reaction may here take another course and produce correspondingly less cyclobutanone.

TABLE III

COLLECTED PRODUCT ANALYSIS DATA FOR THE NEF REACTION IN 80% METHANOL AT 0.0°

Parent nitroalkane	Crude ketone 2,4-dinitrophenylhydrazone Yield, %	M.p., °C.	M.p. pure 2,4-dinitrophenylhydrazone, °C.

Discussion

Any mechanism which is proposed for the Nef reaction must take into account a number of facts: (1) the rate-determining transition state for the decomposition of *aci*-nitroalkane is composed of an *aci*-nitroalkane molecule, a proton and probably one or more molecules of hydroxylic solvent. (2)

(12) Pseudonitrole formation is at present best accounted for in terms of spurious quantities of nitrite ion in the reaction mixture. The ultimate source of nitrite ion may be an impurity in the parent nitroalkane or the result of air oxidation of the nitroalkane anion. Regardless of the source, the reaction producing pseudonitrole probably occurs between nitrosonium ion or its precursor, $H_3{}^+ONO$ and *aci*-nitroalkane or nitroalkane anion.

$$RNO_2H + NO^{\oplus} \longrightarrow R(NO_2)(NO) + H^{\oplus}$$

Such a process would make a much smaller contribution to the over-all course of *aci*-nitroalkane decomposition in the low concentration kinetic experiments than the preparative experiments due to its second-order character.

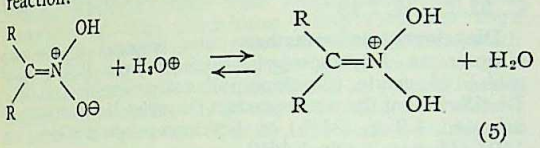
The reactivity sequence, *aci*-nitrocyclohexane > -nitrocyclobutane > -nitropropane > -nitrocyclopentane > -1-cyclopropylnitroethane > -dicyclopropylnitromethane > -nitrocycloheptane is observed. (3) A blue intermediate having an appreciable lifetime is produced. (4) *aci*-Nitroalkanes having enhanced resonance stabilization do not normally give the Nef reaction[3] or do so only very slowly.

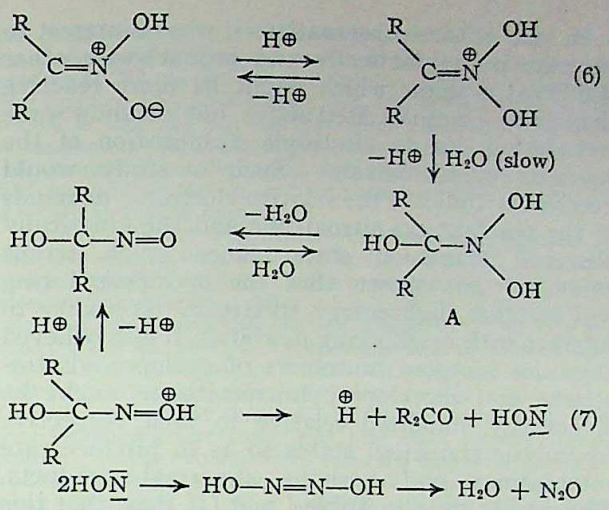
The bare fact that the first slow step of the Nef reaction involves a protonated *aci*-nitroalkane molecule immediately suggests the possibility that equilibrium (5) plays an important role in the reaction.



(5)

Thus, the conjugate acid of the *aci*-nitroalkane molecule which is produced in this equilibrium would have an electron-deficient carbon atom attached to nitrogen and would be labile to nucleophilic attack at this carbon atom. This tentative conclusion is further strengthened by the consideration of the relative rates of reaction found in the nitrocycloalkane series as follows: Brown, Brewster and Shechter[5] have recently summarized a great deal of reactivity data which leads to the postulate that a 5-ring having an exocyclic double bond is always extremely stable relative to its 6-ring counterpart. This observation is rationalized by these authors in terms of bond opposition interactions. On somewhat different grounds one would expect a 4-ring having an exocyclic double bond to be quite reactive due to internal bond angle deformation and the 7-ring system should appear much as the cyclopentyl derivative. The fact that at 0° *aci*-nitrocyclohexane is hydrolyzed 27 times faster than *aci*-nitrocyclopentane and 11 times faster than *aci*-nitropropane, and *aci*-nitrocyclobutane is nearly as reactive as the cyclohexyl compound (this latter result should be accepted with caution, *vide supra*) leads to the conclusion that the carbon–nitrogen double bond of the reactive conjugate acid of an *aci*-nitroalkane is destroyed in the first slow step.

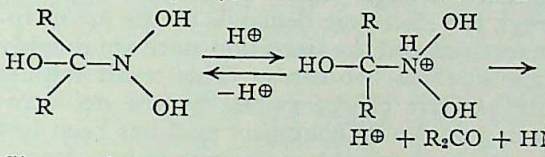
The question of the role of the blue intermediate which is observed during a preparative Nef reaction cannot be answered definitely at this time. However, the very fact that it persists at a detectable concentration level while *aci*-nitroalkane is being destroyed[13] indicates that it is a relatively stable species. Since the intense blue color of these intermediates strongly suggests the presence of a nitroso group, they may be tentatively formulated[2] as α-hydroxynitrosoalkanes which may arise as in (6) and decompose to ketone and nitrous oxide by one of many possible paths such as (7).[14]



(6)

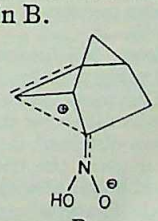
(7)

A similar mechanism has been proposed by van Tamelen and Thiede,[3] but these authors prefer to write the decomposition of the intermediate A by acid-catalyzed cleavage followed by the conversion of $HN(OH)_2$ to nitrous oxide and water.



Since the α-hydroxynitrosoalkane intermediate postulated above may be in mobile hydrolytic equilibrium with A, these paths are presently indistinguishable.[15]

The reluctance of highly resonance stabilized *aci*-nitroalkanes to undergo the Nef reaction has been discussed previously in terms of stabilization of the reactant. Notable examples of this class of nitroalkanes are α-phenylnitroethane[16] and phenylnitromethane which give hydrolytically stable *aci*-nitro tautomers on acidification of their anions with strong mineral acids.[17] Similarly, Wildman and Saunders[18] report that the 5-nitrobicyclo-[2,2,1]2-heptenes fail to undergo the Nef reaction and these authors attribute this inertness to the stabilization of the *aci*-nitrotautomer by the 1,3-interaction shown in B.



B

(13) In the preparative experiments carried out in this study the acid concentration was such as to give the calculated half life of the *aci*-nitroalkane a duration of only a few minutes in the slowest cases. The blue intermediate often was found to persist in these same experiments for as long as two to four minutes.

(14) D. C. Iffland and G. X. Criner, *Chemistry & Industry*, 176 (1956), has described compounds obtained by the reaction of lead tetraacetate with ketoximes and believed to be α-acetoxynitroso alkanes. Acid hydrolysis of these materials yields the corresponding ketone presumably *via* an α-hydroxynitroso intermediate. M. F. Hawthorne and R. D. Strahm have found that the second-order silver ion catalyzed solvolysis of 1-chloro-1-nitrosocyclohexane in aqueous acetonitrile produces cyclohexanone in 90% yield, nitrous oxide and no hydroxylamine. This reaction sequence most likely passes through 1-hydroxy-1-nitrosocyclohexane and will be described in detail in the following paper of this series.

(15) Additional processes may be proposed such as the acid-catalyzed dimerization of the α-hydroxynitrosoalkane followed by the elimination of HON=NOH and two molecules of ketone.

In view of these observations it was of interest to examine both kinetically and product-wise other stabilized systems which might be more reactive than those examples cited above, but yet show some retardation due to electronic stabilization of the reactant *aci*-nitroalkane. Such a study would necessarily indicate the relative electronic demands of the reactant *aci*-nitroalkane and the kinetically observed transition state. Since much recent evidence[10] has shown that the cyclopropyl ring will stabilize high energy species by its ability to interact with neighboring *p*-orbitals, it was believed that the *aci*-nitro tautomers of cyclopropylnitroethane and dicyclopropylnitromethane might be sufficiently stabilized relative to their respective hydrolytic transition states so as to produce rate retardations and perhaps abnormal products. The results given in Table I and III show that this is not the case since the rates of hydrolysis of these two *aci*-nitroalkanes are no less than would be expected on the basis of steric hindrance to the attack of solvent and the corresponding ketones are obtained in high yield. It therefore appears as though the electronic demands of the *aci*-nitroalkane reactant and the transition state are roughly the same in these two cases. This result implies that the positive charge gained by the *aci*-nitroalkane in going to its conjugate acid has been lost to the attacking solvent in the succeeding transition state. In the cases of α-phenylnitroethane and phenylnitromethane the increased stability of the *aci*-nitrotautomers may shift the rate-determining transition state so far toward products that the positive charge of the reactant *aci*-nitrotautomers is almost wholly held by nucleophilic solvent in the transition state.[19] The unsaturation afforded the system by the phenyl group would thus stabilize the reactant species but would not appreciably stabilize the rate-determining transition state and a rate retardation would result.

Experimental[20]

2-Nitropropane was obtained from Mathieson, Coleman and Bell, Inc., and distilled through a 50–75 plate center-rod distillation column at atmospheric pressure. After a small forerun, the center portion of the material was taken; b.p. 119.5°, n^{20}D 1.3940.

Nitrocyclohexane from Mathieson, Coleman and Bell, Inc., was fractionated using a Helipak packed column of *ca.* 20 plates efficiency at 15 mm. A center portion boiling at 102° and n^{20}D 1.4619 was taken for use.

Nitrocyclobutane was obtained in 32% yield from 5.0 g. of cyclobutanone oxime using the trifluoroperoxyacetic acid method of Emmons and Pagano[4] with a disodium acid phosphate acid scavenger. The crude product was twice distilled through a Holzman column[21] at 40 mm.; b.p. 78–79°, n^{20}D 1.4429.[22]

Nitrocyclopentane,[23] b.p. 90° (40 mm.) and n^{20}D 1.4518, was prepared as previously described.[4]

Nitrocycloheptane,[23,24] b.p. 101° (15 mm.) and n^{20}D 1.4721, was prepared as previously described.[4]

1-Cyclopropylnitroethane.—To 7.4 g. (0.075 mole) of crude cyclopropylmethyl ketoxime was added 200 ml. of pure acetonitrile, 2.0 g. of dry urea and 78 g. of disodium acid phosphate. The mixture was brought to reflux with stirring, and a trifluoroperoxyacetic acid solution prepared from 5.5 ml. (0.20 mole) of 90% hydrogen peroxide and 34.0 ml. (0.24 mole) of trifluoroacetic anhydride in 50 ml. of acetonitrile was added slowly over a 1-hr. period. Stirring and refluxing was continued for one additional hour. The mixture was cooled, poured into one liter of water and extracted with ether three times. The combined ether extracts were washed three times with water, dried over magnesium sulfate and concentrated to an oil under a small column. The residual oil was fractionated with a Holzman column giving 3.5 g. (42%) of 1-cyclopropylnitroethane, b.p. 70° at 22 mm., n^{15}D 1.4338.

Anal. Calcd. for $C_5H_9NO_2$: C, 52.16; H, 7.88. Found: C, 52.30; H, 7.98.

Dicyclopropylnitromethane was prepared in the same manner as 1-cyclopropylnitroethane from 12.5 g. (0.10 mole) of crude dicyclopropylketoxime melting at 67°.[25] Distillation of the crude product through a Holzman column[21] afforded 4.9 g. (35%) of dicyclopropylnitromethane, b.p. 110° (15 mm.), n^{15}D 1.4619.

Anal. Calcd. for $C_7H_{11}NO_2$: C, 59.55; H, 7.85. Found: C, 59.87; H, 8.00.

Kinetic Procedure.—All kinetic measurements were made at 0° by the use of a 4-liter Dewar flask cryostat containing a well-stirred mixture of ice and water. The reaction vessel was a 150-ml. wide-neck test-tube shaped flask having a Tru-bore stirrer powered by a variable-speed direct current motor. A nitrogen inlet and outlet were attached to the apparatus as was a tightly-stoppered sampling port. "Prepurified" grade nitrogen was supplied directly from the tank through a pressure regulator. Stopcocks on the gas line were arranged in such a manner as to allow rapid sweeping of the system or maintenance of a few millimeters of positive pressure in the closed system. This nitrogen pressure was maintained during each run and prevented the admittance of air when aliquots of reaction mixture were removed through the open sampling port.

The procedure is as follows: The system was thoroughly flushed with nitrogen, and 200 ml. of 0.060 *N* sodium hydroxide in 80% methanol was introduced under nitrogen through the open sampling port. Exactly 0.003 ml. (essentially 3 mg. of each compound investigated) of nitroalkane was added to the sodium hydroxide solution in the same manner. The port was then closed with a rubber stopper and the solution briefly stirred with the attached stirrer. This reaction mixture was allowed to stand under nitrogen for 1 hr. to ensure complete conversion of the nitroalkane to its sodium salt. The reaction vessel was then immersed in the ice–water cryostat, 50 ml. of 80% methanol added and the solution brought to 0° during a 20-minute period. To initiate the Nef reaction, a small accurately measured volume (0.025 to 1.00 ml.) of 12.00 *N* hydrochloric acid was rapidly introduced beneath the surface of the reaction mixture while the solution was vigorously stirred. The use of extremely dilute solutions minimized the effect of heat of neutralization on the temperature of the reaction system. At intervals, 2.00-ml. aliquots of reaction solutions were removed through the sampling port by the use of an automatic pipet. The pipet previously had been cooled to 0° by immersion in a methanol-bath which in turn was cooled by ice and water. The contents of the pipet were discharged into a 10-ml. volumetric flask containing 3 ml. of *ca.* 4×10^{-4} *M* iodine monochloride in 80% methanol. The color of the iodine monochloride faded instantaneously, and the time of delivery was taken as the time of the point. About 20 mg. of an intimately ground mixture of equal weights of sodium acetate and N,N,N′,N′-tetramethyl-*p*-phenylenediamine was added to the flask, the flask shaken to effect conversion to Würster's blue, the solution made up to volume with 80% methanol and the optical density determined at 622 mμ with a Beckman model DK-1 recording spectrophotometer. Preliminary experiments with accurately titrated iodine monochloride solutions gave a value of 1.3×10^4 for the extinction coefficient of Würster's blue at that wave length. Optical density values were within 5% of the theoretical

values calculated on the basis of complete conversion of nitroalkane to anion and complete reaction of the resulting *aci*-nitro tautomer. Acid concentrations present in each run were calculated on the basis of negligible ionization of the *aci*-nitroalkane and by the relationship

$$[H^+] = \frac{N(\text{ml. } N \text{ normal acid used}) - 2.00\ (N \text{ of base used})}{52.0}$$

In each run an acceptable first-order constant was obtained from log (optical density) *vs.* time plots. Figures 1 and 2 present the data obtained from one nitrocyclohexane run and from all runs with all nitroalkanes, respectively. Table I summarizes all second-order rate constants.

Spectrophotometric Measurements.—The ultraviolet absorption spectra of the nitroalkane anions recorded in Table II were determined in 80% methanol using a model DK-1 Beckman spectrophotometer and 1-cm. stoppered silica absorption cells. The nitroalkane anion solutions were prepared under nitrogen as described above and diluted with 50 ml. of solvent at room temperature in the reactor. Aliquots of these solutions were further diluted and immediately examined. Since the density of each nitroalkane examined was within a few per cent. of unity, the concentrations of nitroalkanes employed were calculated on the assumption that the 0.003 ml. of nitroalkane introduced was equal to 3 mg. of material. For this reason the extinction coefficients may be accurate only to ±5%.

Reaction products were analyzed for regenerated nitroalkane by making a run as described above and withdrawing no aliquots. The reaction mixture was then warmed to room temperature, and 5 ml. of 19 *N* (saturated) sodium hydroxide solution was added under nitrogen. After 1 to 2 hr. the spectrum of the basic reaction mixture was scanned using suitably diluted 19 *N* sodium hydroxide in the solvent cell. Only nitrocyclobutane showed absorption in the 230 mμ region. In two such experiments with this compound, the concentration of nitroalkane present in the basic solution before acidification was such as to give an optical density reading at 234 mμ of 0.91 after suitable dilution. After the Nef reaction had been carried out, the optical density observed at 232–234 mμ was 0.16 when concentrations were normalized to that or the original nitroalkane anion solution. About one-sixth of the nitrocyclobutane either survived the Nef reaction or the reaction produced a small amount of strongly absorbing impurity.

Ketone Isolation Procedure.—One-half gram samples of each nitroalkane were dissolved in 4.0 ml. of 2.5 *N* sodium hydroxide in 80% methanol in the reactor under nitrogen and at room temperature. After 0.5 hr., 50 ml. of 80% methanol was added and the solution cooled to 0° for 0.5 hr. Exactly 3.0 ml. of 12 *N* hydrochloric acid was added and the solution was stirred for 0.5 hr. In every case examined, acidification led to the immediate formation of a blue color. In each case, except those of 1-cyclopropylnitroethane and dicyclopropylnitromethane, this blue color rapidly disappeared. In the two abnormal cases the blue color persisted and finally disappeared as pseudonitrole separated from solution. Filtration of these solutions afforded about 5–10 mg. of unstable white solid which turned blue on solution in warm methylene chloride. A control experiment showed that 1-nitrosonitrocyclohexane was stable under these reaction conditions and indicates that pseudonitroles would have been isolated if they had been produced in other cases.

In every case the reaction mixture was placed on the steam-bath and warmed to 60°. At this point a slurry of 1 g. of 2,4-dinitrophenylhydrazine in 100 ml. of 6 *N* hydrochloric acid was added and the solution stirred and heated for 20 minutes, cooled to room temperature and filtered. The crude crystalline derivatives were washed with warm water, dried, weighed and melting points determined. Table III summarizes the yield data.

aci-Nitroalkanes. III. The Solvolysis of α-Chloronitrosocycloalkanes in the Presence of Electrophilic Silver Ion

BY M. FREDERICK HAWTHORNE AND R. DONALD STRAHM

RECEIVED SEPTEMBER 4, 1956

1-Chloronitrosocyclohexane and 1-chloronitrosocyclopentane are rapidly converted to cyclohexanone and cyclopentanone, respectively, in essentially quantitative yields when treated with silver perchlorate in 20:30:50 (by volume) ethanol:water:acetonitrile at 50.0°. The rates of these reactions were determined under the above conditions by titration of liberated hydrogen ion. The rate equation in each case is of the form $d[H^+]/dt = k[Ag^+][\text{chloronitrosocycloalkane}]$ with the second-order rate constant, k, equal to 2.0 and 5.0 × 10^{-2} l. mole^{-1} min.^{-1} for 1-chloronitrosocyclohexane and 1-chloronitrosocyclopentane, respectively. No hydroxylamine, nitrogen, nitric oxide or nitrogen dioxide was produced and nitrous oxide was identified by gas chromatography. Silver chloride is produced in quantitative yield. It is suggested that these transformations probably proceed *via* the α-hydroxynitrosocycloalkanes which are in turn produced by the nucleophilic attack of water upon the α-carbon atom. This proposed path is in accord with recent proposals concerning the mechanism of the Nef reaction.

Because of our previous interest in the mechanism of the Nef reaction[1] and the probable relationship of the chemistry of α-hydroxynitrosoalkanes to that reaction, it was of interest to seek a more direct route to such materials and to determine their mode of decomposition in acidic aqueous media.

Piloty and Stock[2] long ago reported the synthesis of 2-nitro-2-nitrosopropane by the reaction of silver nitrite with 2-bromo-2-nitrosopropane in ethereal solution. This silver ion assisted displacement of bromide ion by nitrite ion probably proceeded by way of a concerted termolecular displacement reaction such as those recently characterized by Kornblum and Hardies[3] and by Hammond and Hawthorne.[4] It thus appeared probable that the similar treatment of 1-chloronitrosoalkanes with silver ion in the presence of water and in the absence of nucleophilic anions might yield α-hydroxynitrosoalkanes.

Two reactions of this type have been studied from the viewpoint of reaction kinetics and product analysis.

Results

In order to test this hypothesis 1-chloronitrosocyclopentane and 1-chloronitrosocyclohexane were prepared[5] as recently described. Both materials could be stored in the dark at Dry Ice temperatures for long periods of time without decomposition. Preliminary solubility measurements indicated that these materials would dissolve in quantity in aqueous solvent systems only if this solvent contained ethanol. For this reason a ternary solvent system prepared from 2 volumes of ethanol, 3 volumes of water and 5 volumes of acetonitrile was utilized in the kinetic and product experiments.

The kinetics of the reaction of each of the 1-chloronitrosocycloalkanes with silver perchlorate was determined in the dark at 50.0° by titration of the hydrogen ion produced during each run. In every case the kinetics were of the form (2) and each kinetic experiment was carried to about 50% reaction. Initial silver perchlorate concentrations

$$d[H^{\oplus}]/dt = k_2[Ag^{\oplus}][\text{1-chloronitrosocycloalkane}] \quad (2)$$

were varied four-fold (*ca.* 0.1 to 0.4 *M*) in each case while the initial 1-chloronitrosoalkane concentration was always near 0.2 *M*. Control experiments based on the spectrophotometric determination of the 1-chloronitrosoalkanes in the 620 mμ region proved that these materials were thermally and photochemically stable under the conditions of the kinetic experiments. Figure 1 gives a typical second-order plot obtained for both the cyclohexane and cyclopentane derivatives at the same initial concentration of reactants, and Table I records a summary of all the rate data obtained.

TABLE I

RATES OF SILVER ION ASSISTED SOLVOLYSES OF 1-CHLORONITROSOCYCLOHEXANE AND -PENTANE IN 50:30:20 ACETONITRILE, WATER, ETHANOL (VOLUME) AT 50.0

Initial concentrations, mole/l. [Chloronitrosoalkane]	[$AgClO_4$]	Second-order constant, l./mole-min. × 10^2
0.200[a]	0.099	2.06
.199[a]	.159	1.84
.200[a]	.300	2.03
.199[a]	.310	2.11
.199[a]	.416	2.30
.200[b]	.305	4.92
.200[b]	.149	4.97
.201[b]	.164	4.87
.201[b]	.100	4.97
.207[b]	.400	5.23

[a] 1-Chloronitrosocyclohexane, mean $k_2 = 2.07 \pm 0.23 \times 10^{-2}$ l./mole-min. [b] 1-Chloronitrosocyclopentane, mean $k_2 = 5.08 \pm 0.16 \times 10^{-2}$ l./mole-min.

It is seen from these results that the cyclopentane derivative is approximately 2.5 times as reactive as the cyclohexane derivative under these experimental conditions.

Several reactions were carried out under kinetic conditions and the products examined. It was found that both the cyclopentyl and cyclohexyl derivatives gave quantitative yields of silver chloride and 85 and 92% yields of the corresponding ketone (isolated as 2,4-dinitrophenylhydrazones), respectively. The reaction mixtures were found to evolve no gas during the reaction. Similarly, no nitrogen dioxide or nitric oxide was observed in either case as evidenced by the absence of brown fumes above the reaction mixture. Hydroxylamine was shown to be absent by treating a portion of the reaction mixtures with an acidic solution of ferric chloride[6] followed by titration of the resulting ferrous ion with standard potassium permanganate solution. In no case was more than a trace of ferrous ion produced. Vapor phase chromatography[7] of a portion of each reaction mixture at −78° gave a single large peak for a soluble gas present in high concentration and with the characteristic retention time of nitrous oxide. Although these latter experiments were not quantitative in nature, the complete absence of other nitrogen-containing compounds in the reaction mixture supports the view that nitrous oxide is the only nitrogenous product.

Discussion

The fact that the reaction of silver perchlorate with 1-chloronitrosocyclohexane and 1-chloronitrosocyclopentane in aqueous ethanolic acetonitrile obeys the kinetic equation 1 over a range of silver salt concentrations leads to the conclusion that silver ion functions as the electrophilic reagent, solvent as the nucleophile[8] and that perchlorate ion is not kinetically involved.[9] Furthermore, the fact that the cyclopentane derivative is 2.5 times as reactive as the cyclohexane derivative under the same conditions lends considerable support to the idea that a displacement reaction on carbon is the rate-determining process.[10]

Granted that an α-hydroxynitrosoalkane is formed *in situ* as the product of this rate-determining displacement reaction, the reaction products arising from the decomposition of this intermediate may be rationalized in terms of the reaction sequence 3 which was proposed as an integral portion of the Nef reaction sequence.

Further evidence for reaction sequence 3 is to be found in the recently reported work of Iffland and Criner.[11] These authors report that cyclohexanone oxime reacts readily with lead tetraacetate to produce a blue liquid which appears to be 1-acetoxnitrosocyclohexane. Hydrolysis of this ma-

(7) We are indebted to Dr. Charles B. Colburn for performing these experiments.

(8) Although a mixed solvent was used in the kinetic and product experiments, the approximately 4:1 mole ratio of water to ethanol present in that solvent mixture would probably make water the dominant product-determining nucleophile in these reactions. It should be pointed out that if ethanol is the nucleophile which initially attacks the substrate, the product which seems likely to arise from this attack may revert, by acid-catalyzed hydrolysis, to the products formed by the direct attack of water.

(9) The observed kinetics do not distinguish between this situation and that situation which would exist if silver perchlorate were completely associated and both silver ion and perchlorate ion entered into the rate-determining transition state. This latter situation is most improbable due to the ionizing power of the solvent mixture.

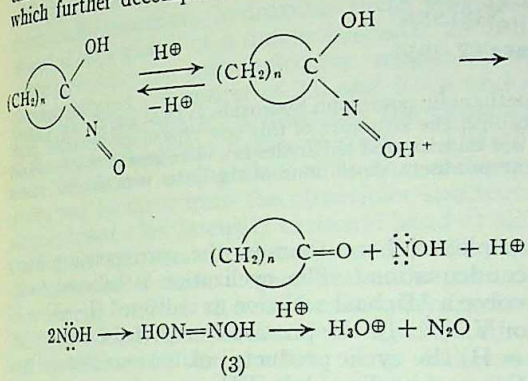
terial in aqueous acid media produces a quantitative yield of cyclohexanone. It seems reasonable to assume that the first step of this hydrolysis is the formation of 1-hydroxynitrosocyclohexane which further decomposes as in 3. Although the



(3)

authors did not isolate or identify nitrous oxide, its presence in the reaction products is indicated.

Experimental[12]

1-Chloronitrosocyclopentane was prepared in 75% yield by the method of Muller, Fries and Metzger[5] and fractionated with a 20-plate Heli-pak column at 15 mm., b.p. 42° and $n^{20}D$ 1.4570 (lit.[5] $n^{20}D$ 1.4570).

1-Chloronitrosocyclohexane was prepared and distilled in a like manner[5] at 15 mm., b.p. 55°, $n^{20}D$ 1.4630 (lit.[5] $n^{20}D$ 1.4629).

Acetonitrile was obtained from the Union Carbide and Carbon Co. and distilled from phosphorus pentoxide, b.p. 80°.

Ethanol was Union Carbide and Carbon C.P. absolute ethanol and the water used in the kinetic experiments was de-ionized conductivity water.

Silver perchlorate was chemically pure and obtained from the G. Frederick Smith Chemical Co. It was vacuum dried over phosphorus pentoxide before use.

Kinetic measurements were carried out in 10-ml. volumetric flasks which had been blackened with several coats of black paint. All kinetic measurements were carried out at 50.0 ± 0.01° in a solvent prepared by mixing 2 volumes of ethanol and 3 volumes of water with 5 volumes of acetonitrile. The following procedure was employed: an estimated amount of anhydrous silver perchlorate was placed in a 100-ml. volumetric flask and dissolved in *ca.* 100 ml. of solvent. Aliquots of this solution were taken and titrated for silver using standard ammonium thiocyanate and ferric alum indicator in dilute nitric acid. A predetermined weight of chloronitrosocycloalkane was weighed into a blackened 100-ml. volumetric flask and thermostated at 50.0°. The proper volume of standard silver perchlorate solution which had been previously thermostated was added and the reaction initiated by solution of the chloronitrosoalkane and the time noted. Several 10.0-ml. aliquots of reaction mixture were immediately transferred to thermostated 10-ml. volumetric flasks. At various time intervals a sample flask was withdrawn, its contents washed into 20 ml. of distilled water covered by 10–15 ml. of hexane. The hexane completely separated the blue nitroso compounds from the aqueous phase and allowed the produced acid to be titrated to the brom thymol blue end-point with standard, 0.10 *N* sodium hydroxide. The resulting acid titer was used in the calculation of the instantaneous concentrations of silver perchlorate and chloronitrosoalkanes, and these values were treated as in Fig. 1. In every case the reactions were carried to at least 50% completion. Spectrophotometric control experiments carried out at 620 mμ and in the reaction solvent at 50.0° showed that not more than 1–2% of chloronitrosoalkane decomposed during the course of the longest kinetic run. In one kinetic experiment it was found that the acid titer agreed with the quantity of silver chloride to within 2% at 50% reaction.

(12) All melting and boiling points are uncorrected.

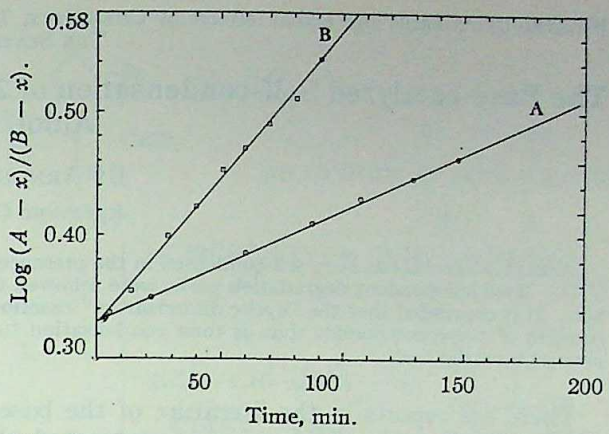


Fig. 1.—Second-order plot of the reaction of 0.100 *M* silver perchlorate with 0.20 *M* 1-chloronitrosocyclohexane, A, and 0.20 *M* 1-chloronitrosocyclopentane, B.

Product analyses were carried out for silver chloride, hydroxylamine, ketone and nitrous oxide in the following manner: after the disappearance of blue color a reaction mixture originally prepared from 70 ml. of 0.40 *M* silver perchlorate and made up to 0.20 *M* with chloronitrosoalkane was filtered with a tared sintered glass funnel of medium porosity. The silver chloride so collected was washed with ethanol and then ether and air-dried. In every case the yield of silver chloride was found to be quantitative to within 1–2%.

The filtrate and combined washings were treated with a slight excess of aqueous 5% sodium chloride solution, to precipitate excess silver ion and the solid separated by filtration. The volume of the final filtrate (*ca.* 150 ml.) was determined and the solution divided into two equal portions. The first portion was treated with 2.5 g. of 2,4-dinitrophenylhydrazine hydrochloride and 5 ml. of concentrated hydrochloric acid and then heated for 1 hr. on the steam-bath. The mixture was then cooled to room temperature and the precipitated 2,4-dinitrophenylhydrazone separated by filtration, washed copiously with warm 5% aqueous hydrochloric acid followed by water and then air-dried. In this manner crude cyclopentanone and cyclohexanone 2,4-dinitrophenylhydrazones melting at 138–142°[13] and 156–160°,[13] respectively, were obtained in 85 and 92% yields, respectively.

The remaining half of the filtrate was reduced to *ca.* 20 ml. by low pressure evaporation and 1 g. of ferric ammonium sulfate and 5 ml. of concentrated sulfuric acid added. The resulting solution was refluxed for 5 minutes and immediately titrated with standard 0.1 *N* potassium permanganate solution. A permanent pink color was obtained on the addition of only 0.20 ml. of 0.0832 *N* permanganate showing the absence of hydroxylamine.[6]

Nitrous oxide was found to be present in a reaction mixture before work-up by placing 0.10 ml. of the solution on an infusorial earth gas chromatographic column having ethanol as a liquid phase. A chromatogram was obtained on this column using helium carrier gas and at −78°. Only a single peak was obtained and this had the characteristic retention time of nitrous oxide.[7] The absence of brown fumes and the lack of pressure increase during every experiment show that nitrous oxide was the only nitrogen-containing gaseous product.

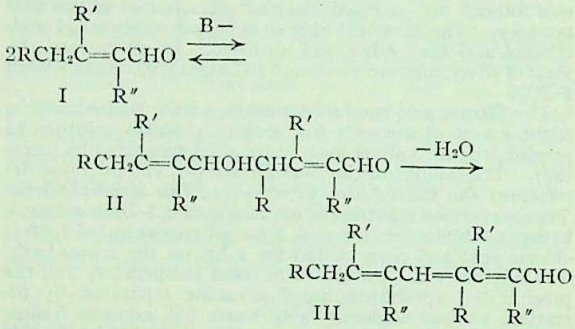
The Base-catalyzed Self-condensation of 2-Ethyl-2-hexenal. I. Formation of a Cyclic Aldol, $C_{16}H_{28}O_2$[1]

BY ARNOLD T. NIELSEN[2]

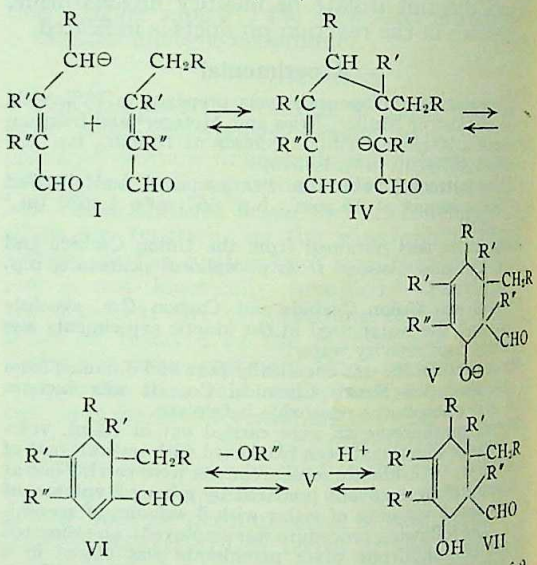
RECEIVED OCTOBER 22, 1956

2-Ethyl-2-hexenal has been self-condensed in the presence of methanolic potassium hydroxide to yield a cyclic aldol dimer VIII. Two independent degradation paths were followed to establish the structure of this new type of condensation product. It is concluded that the "cyclic dimerization" reaction of α,β-unsaturated aldehydes is a more general base-catalyzed reaction of these compounds than is their condensation to linear products, since none of the latter were obtained in the present investigation.

There are reports in the literature of the base-catalyzed self-condensation of α,β-unsaturated aldehydes to either cyclic or linear products. The latter compounds are believed to arise from an aldol condensation, involving carbonyl attack at the γ-carbon, which generally produces a conjugated trienal III.[3-5] A weakly basic catalyst (usually piperidine acetate) is employed in this reaction, the intermediate aldol II seldom being isolated because of its ease of dehydration. Mixed condensations of this type, employing two different aldehydes, also have been reported.[3,4b,6]



Cyclic condensation products have been obtained from crotonaldehyde,[3,4b,7] 3-methyl-2-butenal[3,8] and citral,[3] stronger basic catalysts being employed here than in the corresponding linear condensation. The cyclization is believed to involve a Michael addition as indicated (I → V → VI or VII).[8] In the previously reported examples (R′ = H) the cyclic products isolated were dienals (type VI), not cyclic aldols (VII).



In the present work the self-condensation of 2-ethyl-2-hexenal, in the presence of methanolic potassium hydroxide catalyst, has been investigated. Although no previous study of this condensation had been reported at the time this work was initiated, there appeared independently, subsequent to our first report,[9] patents disclosing some of these preliminary results.[10] The present paper presents a more detailed study of the reaction. The base-catalyzed self-condensation of 2-ethyl-2-hexenal was also studied recently by Häusermann.[11] However, with the elevated temperatures which he employed, the condensation products obtained were different from those reported herein.

On the basis of previously reported work one would expect 2-ethyl-2-hexenal to self-condense

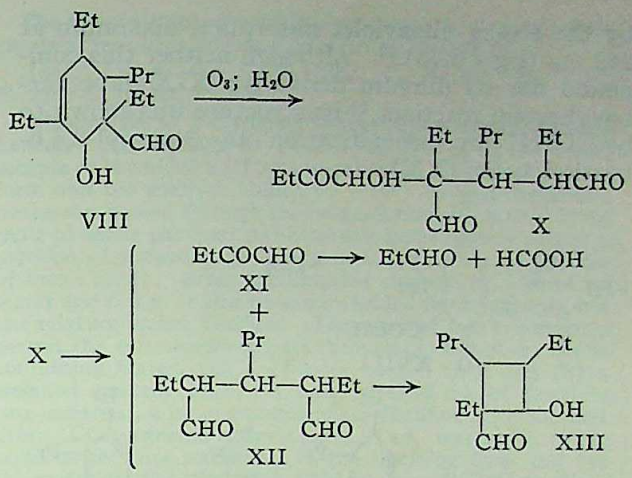
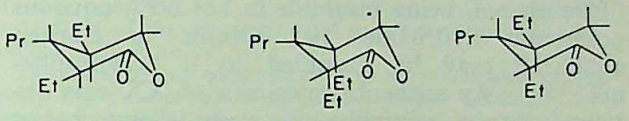
initially to either a linear or a cyclic aldol dimer (II or VII). It was found, however, that unlike other α,β-unsaturated aldehydes previously studied, it failed to react in the presence of weak bases. On the other hand, when treated with aqueous methanolic potassium hydroxide, there was produced a 40% yield[12] of a dimer, $C_{16}H_{28}O_2$, as indicated by analysis and molecular weight data. Strong infrared absorption at 3.0 and 5.9 μ and a Zerewitinoff determination indicated the presence of one hydroxyl and one carbonyl group. The absence of olefinic conjugation with the carbonyl group was apparent from the ultraviolet spectrum which showed a low intensity carbonyl band at 320 mμ but no maximum in the region 200–270 mμ. The compound formed a monoöxalomonophenylhydrazone and a 2,4-dinitrophenylhydrazone and gave a Schiff aldehyde reaction. Quantitative hydrogenation and bromination data indicated the presence of only one olefinic double bond. Reduction with lithium aluminum hydride gave a glycol, $C_{16}H_{30}O_2$ (IX), also having one double bond. The above data are in agreement with a cyclic aldol structure for the dimer (*i.e.*, VIII; VII, R′ = H, R = R″ = Et); such a compound cannot, of course, dehydrate to VI.

Since no cyclic aldol had been reported previously as a product of the self-condensation of an α,β-unsaturated aldehyde, it was felt that additional evidence in support of structure VIII was required, particularly in view of the limited number of examples of this cyclization reaction.[3,4b,7,14] Such evidence was first obtained by ozonolysis of the dimer to yield the following products[15]: formic acid (38%), propionic acid (30%), propionaldehyde (8%), carbon dioxide (3%) and a neutral, steam-volatile compound, $C_{12}H_{22}O_2$ (XIII), (*ca.* 30% yield, crude). The latter substance showed strong infrared absorption at 2.9 and 5.8 μ assigned to one hydroxyl and one carbonyl group, respectively; a Zerewitinoff determination supported this assignment. The ozonolysis products readily can be rationalized on the basis of structure VIII by the equations shown. Under the reaction conditions the intermediate X (not isolated) is cleaved, by dealdolization, to 2-ketobutanal (XI) and the dialdehyde XII which readily cyclizes to the aldol XIII.[16–18]



Aldol XIII when treated with methanolic potassium hydroxide led to the lactone XIV, a compound previously reported by Häusermann.[11,19,20]



XIV XIVa XIVb

By direct titration with 0.5 *N* sodium hydroxide XIV was easily saponified to regenerate its precursor, the anion of 2,4-diethyl-5-hydroxy-3-propylpentanoic acid (XV). Oxidation of XV with permanganate led to a high melting *meso* isomer of 2,4-diethyl-3-propylpentanedioic acid (XVI), m.p. 151–151.5°,[21] which was found, by mixture melting point determination, to be identical with an authentic sample of this acid kindly provided by Dr. Häusermann.[11]

Because the ozonolysis gave products somewhat indirectly derived from VIII, more direct evidence for the presence of a six-membered ring was sought by chromic acid oxidation. This reaction produced equal molar amounts of carbon dioxide and a neutral compound $C_{15}H_{26}O$. The same product was obtained by oxidizing VIII with permanganate and decarboxylating the crude acid (XVII) formed thereby. The presence of one double bond in the product was demonstrated by quantitative hydrogenation. That this bond was conjugated with a carbonyl group was indicated

(12) The maximum yield (40%) was obtained using 0.6 mole-equivalent of potassium hydroxide per mole of aldehyde (25°, 30 minutes reaction time); under these same conditions, shorter or longer reaction periods gave a lowered yield. At the longer reaction times (1–2 hr.) large amounts of an acidic compound, $C_{16}H_{30}O_3$, were produced (ref. 13). Increasing or decreasing the reaction temperature or alkali concentration did not increase the yield.

(13) A. T. Nielsen, THIS JOURNAL, **79**, 2524 (1957).

(14) The structure of the product has been established in two of the three reported cases of self-condensation to a cyclic dienal, *viz.*, 3-methyl-2-butenal[3a] and crotonaldehyde.[7] The reaction has perhaps not been recognized as a general one because of the paucity of examples (*cf.* ref. 8).

(15) Yields in parentheses are based on the assumption that one mole-equivalent of each compound is formed from VIII.

(16) The formation of a four-membered cyclic aldol is believed to be favored by the buttressing effect of adjacent alkyl substituents; (a) R. C. Fuson in H. Gilman, "Organic Chemistry," 2nd Ed., Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 81; (b) S. Winstein and E. Grunwald, THIS JOURNAL, **70**, 828 (1948).

(17) Under the conditions of the experiment, none of the 2-ketobutanal was isolated, since it decomposed, apparently completely, into formic acid and propionaldehyde. For similar cleavages of 2-hydroxy aldehydes *cf* (a) R. Pummerer, O. Guyot and L. Birkofer, *Ber.*, **68**, 480 (1935); (b) C. Harries and H. O. Türk, *Ann.*, **374**, 338 (1910) and (c) W. G. Young, A. C. McKinnis, I. D. Webb and J. D. Roberts, THIS JOURNAL, **68**, 293 (1946); refs. b and c refer to ozonolysis experiments.

(18) Only an 8% yield of propionaldehyde was obtained (as its 2,4-dinitrophenylhydrazone), since the major portion was oxidized to propionic acid (30% yield); T. E. Friedemann (*J. Biol. Chem.*, **73**, 331 (1927)) observed pyruvaldehyde to be very rapidly oxidized by hydrogen peroxide at *p*H 7 or less to formic and acetic acids.

(19) See H. Meerwein, *Ber.*, **53**, 1829 (1920), for other examples of disproportionation of 1,5-dialdehydes.

(20) The dialdehyde XII should readily equilibrate to the most stable conformation in the presence of base, thus leading to the equatorial form XIV. The alternate structure (XIVa) which could lead to a *meso*-acid may be considered unstable relative to XIV. The possibility of epimerization at the position alpha to the carbonyl group occurring readily as a result of the mild saponification conditions (direct titration with 9.5 *N* sodium hydroxide) appears unlikely; the lactone structure XIVb (which would lead to racemic XVI in the absence of epimerization) is therefore excluded.

(21) The racemic isomer melts at 98–99° (ref. 13).

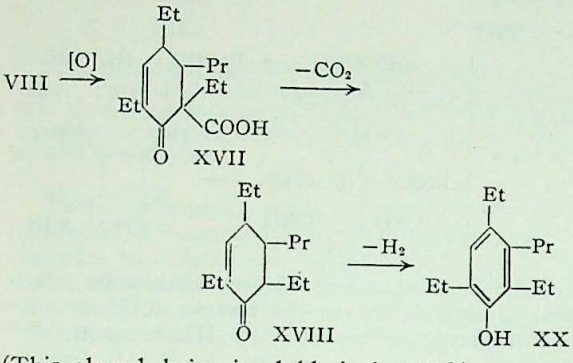
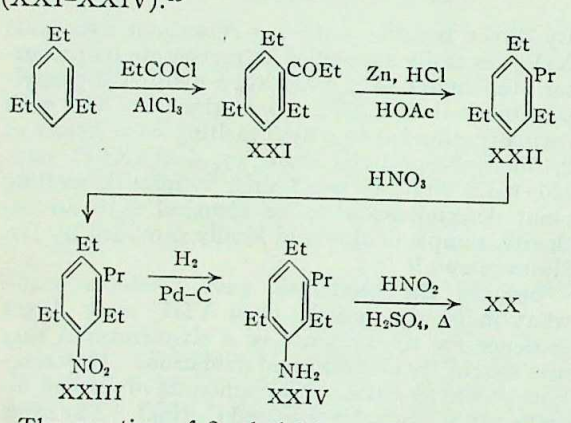
by the strong ultraviolet absorption maximum at 242 mμ (log ε 3.75).[22] Although neither this compound nor its dihydro derivative XIX gave carbonyl-group reactions,[23] its structure was shown to be XVIII by aromatization to 3-propyl-2,4,6-triethylphenol (XX).



(This phenol, being insoluble in hot 50% aqueous potassium hydroxide, but soluble in Claisen alkali,[24,25] may be classified as a "cryptophenol."[26,27]) An authentic specimen of XX was obtained by an unambiguous route shown below (XXI–XXIV).[28]



The reaction of 2-ethyl-2-hexenal to form VIII provides the first reported example of the dimerization of an α,β-unsaturated aldehyde to yield a cyclic aldol which is incapable of dehydration; in previously reported cases cyclization has always led to cyclic dienals.[8] It should be emphasized that 2-ethyl-2-hexenal, unlike its lower homologs, failed to yield any linear condensation product. Thus, it would appear that the "linear aldol condensation" discussed above is limited to suitably unhindered aldehydes (I, R, R′ and R″ no larger than methyl); also, it requires a milder basic catalyst than the corresponding condensation to cyclic products. The position of the equilibrium I ⇄ II evidently is determined to some extent by steric factors. In cases where the formation of II is unfavorable, the "cyclic dimerization" is realized (assisted by the formation of a six-membered ring) and would appear to be possible for all examples, including higher homologs of 2-ethyl-2-hexenal having γ-hydrogens, and to be a typical, general reaction of these compounds.

Experimental[29]

2-Ethyl-2-hexenal.—Preliminary experiments indicated that purified, freshly distilled, samples of 2-ethyl-2-hexenal were required for maximum yields of condensation products. Traces of peroxide or acidic impurities in the aldehyde had no effect on the reaction, but in larger amounts these substances caused much resin formation with resulting lowered yields of condensation products. Peroxide-free 2-ethyl-2-hexenal was prepared by the self-condensation,[30] in a nitrogen atmosphere, of peroxide-free butanal, b.p. 70–72° (690 mm.), $n^{25}D$ 1.3770.[31] The pure 2-ethyl-2-hexenal obtained (71% yield) was distilled under nitrogen; b.p. 81° (34 mm.), $n^{25}D$ 1.4504. It was found to contain no peroxide[32] and 0.1% of an acidic impurity[33] by direct titration with 0.1 *N* sodium hydroxide It was found unnecessary, however, to employ this highly purified material, since samples of aldehyde which had been purified by the following procedure gave equally good results. A 423-g. sample of Carbide 2-ethyl-2-hexenal[34] was washed successively with five 100-ml. portions of *N* sodium hydroxide solution and then with *N* hydrochloric acid and water. After drying over anhydrous magnesium sulfate in a nitrogen atmosphere, the aldehyde was distilled *in vacuo* under nitrogen; b.p. 67° (18 mm.), yield 368 g.; peroxide and acidic impurities were 0.6 and 0.3%, respectively.[32,33]

Self-condensation of 2-Ethyl-2-hexenal: Preparation of 2-Hydroxy-6-propyl-1,3,5-triethyl-3-cyclohexene-1-carboxaldehyde (VIII).—2-Ethyl-2-hexenal (160 g., 1.27 moles), purified by the alkali extraction procedure described above, was freshly distilled, under nitrogen, directly into the reaction flask. A solution of 48 g. of potassium hydroxide (85% assay, 0.73 mole) in 25 ml. of water and 65 ml. of methanol was then added during 1.5 minutes with vigorous stirring while a nitrogen atmosphere was maintained and the temperature held at 25° by ice-bath cooling. The color quickly changed to orange while the alkali was being added, and after a total reaction time of 30 minutes (temp. 25°), 500 ml. of water was added rapidly to the mixture with stirring. The oily layer which formed was separated, the aqueous layer extracted four times with ether and the extracts combined with the main portion. The ether solution was washed with water and dried over magnesium sulfate.

After distilling the ether on the steam-bath, the residue was distilled *in vacuo* to yield the following fractions: (1) 56 g., b.p. 60–61° (14 mm.), 2-ethyl-2-hexenal (35% recovery); (2) 72 g. (45%), b.p. 114–115° (0.12 mm.), $n^{25}D$ 1.4885, crude aldol VIII; (3) residue, 8 g. Redistillation of fraction 2 gave 63.5 g. (40% yield) of pure VIII, b.p. 114–116° (0.16 mm.), $n^{25}D$ 1.4893.

Anal. Calcd. for $C_{16}H_{28}O_2$: C, 76.14; H, 11.18; mol. wt., 252.4. Found: C, 76.27; H, 11.39; mol. wt., 250, 253.[35]

The aqueous alkaline solution above, remaining after extraction with ether, was acidified with concd. hydrochloric acid. The oil which formed was separated and the aqueous part extracted three times with ether. The ether extracts and the oil were combined and dried over magnesium sulfate. After distilling the ether, the residue was distilled to give (1) 1.4 g., b.p. 85–142° (0.25 mm.); (2) 9.2 g., b.p. 142–155° (0.25 mm.), $n^{25}D$ 1.4764 and 1.0 g. of residue.

Attempts were made to increase the yield of VIII by varying the experimental conditions. It was found that, under the conditions of the above experiment, either longer or shorter reaction periods gave lower yields of VIII. At shorter reaction times than 30 minutes, larger amounts of unreacted 2-ethyl-2-hexenal were recovered; at longer reaction times (1–2 hr.) less unreacted aldehyde was recovered; but greater amounts of acidic material were obtained. Higher reaction temperatures or alkali concentrations produced a less pure aldol in lowered yield, whereas lower temperatures or alkali concentrations made necessary a prolonged reaction time without increasing the yield.[13]

Quantitative hydrogenation of a 0.5-millimole sample of the aldol VIII at 689 mm. and 23° (acetic acid solvent containing a few drops of concd. hydrochloric acid, 5% palladium–charcoal catalyst) resulted in absorption of 1.00 mole-equivalent of hydrogen in 300 minutes, after which time hydrogenation continued extremely slowly (*ca.* 0.065 mole-equivalent per hour). On quantitative bromination with a 5% solution of bromine in carbon tetrachloride, 1.07 mole-equivalents of bromine were absorbed, with some hydrogen bromide evolution. A Zerewitinoff determination showed 1.03 active hydrogens and 1.04 additional mole-equivalents of methylmagnesium iodide reacted. The compound gave a positive Schiff aldehyde test. A sample of the aldol, b.p. 132–135° (0.5 mm.), $n^{25}D$ 1.4894, showed a broad ultraviolet maximum at 320 mμ (log ε 2.1), a minimum at 270 mμ (log ε 1.85) (95% ethanol solvent). There was no maximum in the range 200–270 mμ. The infrared spectrum showed bands at 3.0m, 3.5, 3.6, 5.9, 6.9, 7.3m, 9.4m, 9.75 and 13.0 μ.

The oxalomonophenyldihydrazone[36] separated from dilute aqueous ethanol or from ligroin as a cream-colored amorphous powder, m.p. 95–97°. The derivative was contaminated with a small amount of less soluble impurity which could not be removed by crystallization.

Anal. Calcd. for $C_{24}H_{26}N_4O_3$: C, 67.26; H, 8.47. Found: C, 68.6; H, 8.9.

A 2,4-dinitrophenylhydrazone derivative was prepared, m.p. 40–62°. It could not be purified to constant melting point by recrystallization.

6-Hydroxymethyl-5-propyl-2,4,6-triethyl-2-cyclohexen-1-ol (IX).—To a solution of 1.1 g. (0.029 mole) of lithium aluminum hydride in 80 ml. of ether was added, with stirring, a solution of 13.0 g. (0.0515 mole) of the aldol VIII dissolved in 35 ml. of dry ether, during 30 minutes[37]; stirring was continued for 10 minutes longer. The solution was then treated successively with 45 ml. of water and 50 ml. of 10% sulfuric acid. The ether layer was separated, washed with water and dried over magnesium sulfate. After distilling the ether there was obtained 9.7 g. (74% yield) of the extremely viscous glycol, b.p. 133–135° (0.36 mm.), $n^{25}D$ 1.4930[38]; infrared bands at 2.78m, 2.92m, 3.40, 3.48, 6.05w, 6.85, 7.26, 8.1w, 8.67w, 9.20w, 9.68, 10.02, 10.60w, 11.20w, 11.52w and 11.95w μ (chloroform solvent).

Anal. Calcd. for $C_{16}H_{30}O_2$: C, 75.53; H, 11.89. Found: C, 75.49; H, 12.12.

On quantitative hydrogenation of the glycol (under conditions identical with those employed with the above aldol VIII) 0.95-mole-equivalent of hydrogen was absorbed in 120 minutes, after which time hydrogenation ceased. A Zerewitinoff determination indicated 1.98 active hydrogens and an additional 0.1 mole-equivalent of methylmagnesium iodide reacted.

(38) Hall and Tuerck (ref. 10) reduced the aldol VIII to an unsaturated glycol, $C_{16}H_{30}O_2$, by hydrogenation with Raney nickel catalyst, 74% yield, b.p. 149–151° (2 mm.), $n^{20}D$ 1.4966, bis-3,5-dinitrobenzoate m.p. 178°. Attempts to prepare a 3,5-dinitrobenzoate of the above glycol resulted in the formation of a gum which failed to crystallize.

The bis-*p*-nitrophenylurethan was prepared as pale yellow crystals from high boiling ligroin, m.p. 76.5–78.5°.

Anal. Calcd. for $C_{30}H_{38}N_4O_8$: C, 61.84; H, 6.57. Found: C, 62.29; H, 6.9.

Ozonolysis of 2-Hydroxy-5-propyl-2,4,6-triethyl-3-cyclohexene-1-carboxaldehyde (VIII).—A 25.3-g. (0.10 mole) sample of the aldol VIII was dissolved in 100 ml. of chloroform and the solution chilled to −15°; oxygen containing ozone was passed through the cold solution at a rate of 0.014 mole of ozone per hour until the exit gases rapidly caused a solution of potassium iodide to turn red (8 hr.; 0.11 mole of ozone used). After distilling the chloroform, 150 ml. of water and 6.6 g. of zinc dust were added to the ozonide and the mixture steam distilled. The receiver was arranged to permit the exit vapors to pass through (1) a washing bottle containing water, (2) a Drierite packed tube and (3) a weighed Ascarite tube. A total of 4040 ml. of distillate was collected, a large amount of oil distilling with the first liter. Concentrated sulfuric acid, 10 ml., was added to the aqueous mixture remaining in the distilling flask and the steam distillation continued, 2350 ml. of additional distillate being collected; very little oil distilled with the last portion of water collected. Throughout the distillation, aliquot portions of the distillate, taken at intervals, were titrated with 0.1 *N* sodium hydroxide to determine the rate of distillation of water-soluble acid; of the total acid collected (0.068 mole) 65% of this amount (0.044 mole) distilled after adding the sulfuric acid.

The Ascarite tube gained 0.14 g. in weight, corresponding to a 3.2% yield of carbon dioxide. A blank determination showed such minute amounts of carbon dioxide in the steam which was used that no correction of this value was necessary.

The total combined aqueous steam distillate obtained was found to contain 0.068 mole of water-soluble acid; aliquot samples of the distillate were analyzed as follows: Formic acid was determined quantitatively by a modification of the procedure of Reid and Weihe.[39] The total amount obtained was found to be 0.038 mole (56% of the total water-soluble acid).

One aliquot portion of the distillate was neutralized with dilute sodium hydroxide solution, evaporated to dryness, diluted with water and acidified with sulfuric acid. In order to decompose the formic acid, the solution was refluxed with mercuric oxide until no more carbon dioxide was evolved. The acid which remained gave Duclaux numbers 12.2, 11.9, 11.5 on distillation (reported[40] for propionic acid, 11.9, 11.7, 11.3). The *p*-phenylphenacyl ester of this acid, m.p. 102.5°, showed no depression in melting point when mixed with an authentic sample of *p*-phenylphenacyl propionate, m.p. 102–103°.

The original distillate was found to contain 0.0079 mole of total carbonyl compounds. (Carbonyl analysis was made by reaction of an aliquot sample with hydroxylamine hydrochloride and titration of the liberated hydrochloric acid with 0.1 *N* sodium hydroxide.) An aliquot portion was neutralized with dilute sodium hydroxide and this solution refluxed gently while nitrogen was passed slowly through it. The exit gases when passed into a solution of 2,4-dinitrophenylhydrazine in dilute phosphoric acid formed an orange precipitate, m.p. 153–155°, after recrystallization from dilute ethanol. This compound showed no depression in melting point when mixed with an authentic sample of propionaldehyde 2,4-dinitrophenylhydrazone, m.p. 154–155°.

Thus from the ozonolysis of VIII there were produced a 38% yield of formic acid, 30% propionic acid, 8% propionaldehyde, 3% carbon dioxide and 30% (crude) of the aldol XIII (see below). The remainder of the ozonolysis products were 1.4 g. of steam-volatile oil produced after acidification of the zinc salts with sulfuric acid, 5.7 g. of neutral and 2.9 g. of acidic, non-steam-volatile, undistillable residue. The total weight of ozonolysis products obtained was 22.7 g. (from 25.3 g. of VIII).

1,3-Diethyl-2-hydroxy-4-propylcyclobutanecarboxaldehyde (XIII).—In the above ozonolysis experiment, the oil which distilled before adding the sulfuric acid was separated and the aqueous part extracted twice with ether, the ether

extracts being combined with the main portion. After drying and distilling the ether, there was obtained on distillation a forerun, 0.7 g., b.p. 72–78° (0.3 mm.); 6.3 g. of crude compound XIII, b.p. 78–113° (0.3 mm.); and 1.1 g. of residue. On redistillation 3.7 g. (19% yield) of the light yellow, nearly odorless aldol was produced, b.p. 84–92° (0.3 mm.), $n^{25}D$ 1.461–1.463.

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18; mol. wt., 198.3. Found: C, 72.46; H, 10.99; mol. wt. (Rast), 194, 195.

The infrared spectrum showed bands at 2.90m, 3.38, 3.45, 3.64w, 5.80, 6.85, 7.30, 7.90m, 8.05m, 9.1, 10.4 and 12.90m μ.

A Zerewitinoff determination showed 0.72 active hydrogen and 1.37 mole-equivalents additional methylmagnesium iodide reacted. Oxidation of the compound with alkaline or acid potassium permanganate under various conditions failed to yield a compound which could be isolated in pure form.

2,4-Diethyl-3-propyl-1,5-pentanolactone (XIV).—To a solution of 15.3 g. (0.077 mole) of XIII in 100 ml. of methanol was added, in small portions, a solution of 24 g. of potassium hydroxide (85%) in 60 ml. of methanol and 20 ml. of water (temperature, 10–15°). The orange solution which formed was allowed to stand 24 hr. at 3°, 24 hr. at room temperature (solution became dark red) and then refluxed gently for 1 hr. The methanol was then distilled and the residue diluted with 500 ml. of water. The resulting mixture was extracted five times with ether to remove neutral material. The aqueous solution remaining was acidified with hydrochloric acid and extracted three times with ether. The resulting ether solution of acidic material was extracted with saturated sodium bicarbonate solution, *N* hydrochloric acid and water and dried over magnesium sulfate. Distillation gave: (1) 1.9 g., b.p. 140–152° (10 mm.), $n^{25}D$ 1.4617; (2) 2.6 g. (17%) of XIV, b.p. 152–156° (10 mm.), $n^{25}D$ 1.4613; (3) 1.5 g., b.p. 161–164° (9 mm.), $n^{25}D$ 1.4636; and 2.0 g. of residue. (Häusermann[11] reported b.p. 147–149° (11 mm.), $n^{18}D$ 1.4660 for XIV.) The infrared spectrum of fraction 2, above, showed bands at 3.53, 3.60, 5.85, 6.90, 7.30, 7.95, 8.15m, 8.45, 8.75, 8.95, 9.50m, 10.60w and 13.0w μ.

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18; mol. wt., 198.3. Found: C, 72.77; H, 11.13; sapn. equiv., 199.

The dried ether solution above, containing neutral material, was distilled to yield the following fractions: 1.4 g., b.p. 120–135° (13 mm.), $n^{25}D$ 1.4702; 2.3 g., b.p. 135–145° (13 mm.), $n^{25}D$ 1.4808; and 1.5 g. of residue; these fractions were not investigated further.

2,4-Diethyl-3-propylpentanedioic Acid (XVI).[11]—A small sample of fraction 2 above (XIV) was saponified, by direct titration, with 0.5 *N* sodium hydroxide; the resulting solution was treated with potassium permanganate to yield the acid XVI, m.p. 151–151.5°, after one recrystallization from water (lit.[11] m.p. 149–150°).[21] When this material was mixed with an authentic sample (m.p. 151–151.5°), kindly provided by Dr. Häusermann, the melting point was not depressed.

5-Propyl-2,4,6-triethyl-2-cyclohexen-1-one (XVIII).—A solution of 33 g. (0.33 mole) of chromic anhydride in 40 ml. of water and 40 ml. of acetic acid was added during 1 hr., with stirring, to a solution of 61.3 g. (0.244 mole) of VIII. The temperature was maintained below 25° during the addition. After 3.5 hr., the solution was warmed to 70–80° and the stirring continued for 25 additional hr. A slow stream of nitrogen was continuously passed through the apparatus, the exit gases being conducted through a purifying train and finally through an Ascarite packed tube. The Ascarite tube gained in weight 2.21 g., corresponding to a 20.6% total yield of carbon dioxide; the yield was *ca.* 19% in 15 hr.

After adding 340 ml. of 6 *N* sodium hydroxide solution and extracting with ether, the ether extracts were washed with water, *N* sodium hydroxide solution, water and dried. After distilling the ether, the residue was fractionally distilled to yield 11.2 g. (20.7% yield) of the unsaturated ketone XVIII, having a faint fruity odor, b.p. 94–96° (0.2 mm.), $n^{25}D$ 1.4829; 29.0 g., b.p. 113–140° (0.20 mm.), partly oxidized and unchanged material; and 7.2 g. of residue. From the alkaline aqueous portion remaining after the ether extractions there was isolated, after acidification, 4.6 g. of a viscous oil which gave off carbon dioxide when heated strongly. The yield of crude ketone and of carbon dioxide could be increased to 50% by using a 75% excess of chromic anhydride; however, in this case, the ketone could not be obtained in a pure state by redistillation, and the use of a smaller excess of oxidizing agent was found to be more desirable.

A 12.5-g. sample of VIII, suspended in a solution of 100 ml. of 5 *N* sulfuric acid and 20 ml. of acetic acid was stirred with 11 g. of potassium permanganate for 2.5 hr. at 25°. After adding sodium bisulfite to dissolve the manganese dioxide, the oxidation product was separated into neutral and acidic portions in the usual manner. The acid product was a viscous oil, 3.7 g., containing crude 2-oxo-6-propyl-1,3,5-triethyl-3-cyclohexene-1-carboxylic acid (XVII). [No attempt was made to characterize this acid, since it decarboxylated so readily; on warming slightly on the steam-bath it rapidly evolved carbon dioxide.] Distillation of this material gave 1.0 g. of the neutral, unsaturated ketone XVIII, b.p. 120–127° (0.5 mm.), $n^{25}D$ 1.4807, and 1.6 g. of residue. The neutral fraction from the oxidation was distilled to yield 0.8 g., b.p. 60–130° (0.8 mm.); 3.6 g., b.p. 130–139° (1.0 mm.), $n^{25}D$ 1.4859; and 1.9 g. of residue.

The ketone XVIII was found to react with bromine in carbon tetrachloride solution very slowly without evolution of hydrogen bromide. Quantitative hydrogenation of a small sample in isoamyl alcohol solvent containing a few drops of hydrochloric acid (platinum catalyst, 25°, 690 mm.) showed 0.9 mole-equivalent of hydrogen absorbed in 1.5 hr., after which time hydrogenation continued very slowly (1.0 mole-equivalent total absorbed in 3 hr.). The ultraviolet spectrum showed maxima at 242 mμ (log ϵ 3.75) and 293 mμ (log ϵ 2.79) and a minimum at 281 mμ (log ϵ 2.76) (95% ethanol solvent). Attempts to prepare a carbonyl derivative of this ketone, using a variety of carbonyl reagents, failed, the original reactants being recovered in each case; infrared bands at 2.90w, 3.40, 3.50, 5.82m, 5.98, 6.85, 7.28m, 11.10w and 11.50 μ.

Anal. Calcd. for $C_{16}H_{26}O$: C, 81.02; H, 11.79; mol. wt., 222.4. Found: C, 80.26; H, 11.48; mol. wt., 227, 228.5.[25]

3-Propyl-2,4,6-triethylcyclohexanone (XIX).—An 11.6-g. sample of the above unsaturated ketone XVIII (0.052 mole) dissolved in a solution of 50 ml. of acetic acid, 10 ml. of water and 1 ml. of concd. hydrochloric acid was hydrogenated at 690 mm. (0.87 g. of platinum oxide and 4 g. of 5% palladium-on-charcoal catalysts) until one mole-equivalent of hydrogen was absorbed (64 hr.). After filtering the catalyst, the filtrate was diluted with 350 ml. of water and extracted with ether. The ether extracts were washed with *N* sodium hydroxide solution, then with water and dried. After distilling the ether, the residue was distilled to yield 0.7 g., b.p. 80–89° (0.6 mm.); 4.7 g. of crude XIX, b.p. 88–93° (0.35 mm.), $n^{25}D$ 1.4668; 2.8 g., b.p. 94–95° (0.2 mm.), $n^{25}D$ 1.4700; and 0.7 g. residue. Redistillation of the second fraction gave 2.6 g., b.p. 78–82° (0.17 mm.), $n^{25}D$ 1.466, having a faint sweet odor, which was used for elemental analysis; infrared bands at 3.0w, 3.40, 3.48, 5.83, 6.85, 7.27, 8.85w and 9.10w μ.

Anal. Calcd. for $C_{15}H_{28}O$: C, 80.29; H, 12.58. Found: C, 79.91; H, 12.39.

Attempts to prepare a carbonyl derivative of this ketone failed, the original reactants being recovered in each case.[23]

2,4,6-Triethyl-3-propylphenol (XX) from XVIII.—A 0.70-g. (3.16 millimoles) sample of 5-propyl-2,4,6-triethyl-2-cyclohexen-1-one (XVIII) was refluxed with 0.35 g. of 5% palladium–charcoal catalyst for 1 hr., during which time 0.71 mole-equivalent of hydrogen was collected. After filtering, the residue was distilled through a small Emich tube, to yield 0.32 g. (45%) of the yellow phenol, b.p. 262–266° (690 mm.), $n^{25}D$ 1.506–1.510. Redistillation gave a sample which was used for analysis, $n^{25}D$ 1.5086. The compound rapidly became dark orange in the presence of air, but could be stored under nitrogen without change. The ultraviolet spectrum showed a broad maximum at 281 mμ (log ϵ 3.22) (95% ethanol solvent); infrared bands at 2.87, 3.47, 3.53, 5.95w, 6.22w, 6.37w, 6.87, 7.30m, 7.70m, 7.93, 8.25, 8.45, 9.05 (shoulder), 9.15–9.20, 9.40m, 10.1w, 11.4m, 11.6m and 12.1m μ.

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.69; H, 11.21.

The phenol was insoluble in 50% aqueous potassium hydroxide solution but soluble in Claisen alkali.[24,25] It re-

Digitized by Arya Samaj Foundation Chennai and eGangotri

acted with sodium metal but gave a negative ferric chloride test in alcohol. The infrared spectrum showed some absorption at 5.95 μ which was absent in the authentic sample of XX (see below) and which is believed to be due to the presence of a small amount of carbonyl compound (XIX or XVIII) which could not be removed by distillation; in all other respects the two samples were spectroscopically identical.

The phenylurethan derivative was prepared by refluxing a solution of 0.44 g. of the above phenol XX from the condensation, 4 ml. of phenyl isocyanate and 5 ml. of pure diethylene glycol dimethyl ether for 22 hr. After distilling the solvent and excess phenyl isocyanate, the residue was extracted with boiling hexane and filtered hot to remove insoluble material. From the filtrate, by fractional crystallization from hexane, there was obtained 0.14 g. of the crude crystalline derivative, m.p. 111–119°. Three recrystallizations from petroleum ether gave long white needles, m.p. 120–121°; when mixed with an authentic sample of 2,4,6-triethyl-3-propylphenol phenylurethan derivative, m.p. 122–122.5° (see below), the melting point was not depressed. When the ether solvent was omitted from the procedure, no derivative could be isolated.

Anal. Calcd. for $C_{22}H_{29}NO_2$: C, 77.84; H, 8.61. Found: C, 77.77; H, 8.59.

2,4,6-Triethylpropiophenone (XXI).—To a solution of 58.7 g. (0.362 mole) of purified 1,3,5-triethylbenzene (b.p. 101° (21 mm.), $n^{25}D$ 1.4934[41]) and 37.2 g. (0.40 mole) of freshly distilled propionyl chloride, b.p. 76–78°, in 50 ml. of dry tetrachloroethane was added, with stirring, during 1 hr., 66 g. (0.50 mole) of anhydrous aluminum chloride (temp. 26–35°). After addition of approximately one-third of the aluminum chloride, the solution became deep red in color. The solution was held at 40° with continuous stirring for 30 minutes after addition of the aluminum chloride. It was then poured into 400 g. of ice and stirred until all of the complex was dissolved. The oil was separated with the aid of ether and washed successively with *N* sodium hydroxide, *N* hydrochloric acid and water. After drying over magnesium sulfate and distilling the solvents, there was obtained 12 g., b.p. 80–109° (5 mm.), containing mainly unreacted 1,3,5-triethylbenzene (20% recovery) and 60 g. (77%) of colorless, odorless 2,4,6-triethylpropiophenone, b.p. 109–110° (4 mm.), $n^{25}D$ 1.5040, and 1.0 g. of residue; infrared bands at 3.42, 5.90, 6.20, 6.35, 6.90, 7.10, 7.28, 7.48, 7.57 (shoulder), 7.90m, 8.25, 8.68, 9.30, 9.47, 9.88, 10.56, 11.48, 12.40m, 12.69m, 13.15m and 13.84w μ.

The Perrier modification[42] gave a low yield of the propiophenone compound in addition to higher boiling material believed to contain much diacylated product.

Anal. Calcd. for $C_{15}H_{22}O$: C, 82.51; H, 10.16. Found: C, 82.27; H, 10.07.

The ketone failed to react with 2,4-dinitrophenylhydrazine under forcing conditions.

2-Propyl-1,3,5-triethylbenzene (XXII).[43]—A solution of 39.8 g. (0.182 mole) of the ketone XXI in 400 ml. of acetic acid was added dropwise, during 4.5 hr., to a refluxing mixture of 750 g. of amalgamated zinc and 150 g. of water, while, starting simultaneously, 2500 ml. of concd. hydrochloric acid was added during 7.5 hr.; refluxing was continued 14 hr. after addition of the hydrochloric acid was complete. The mixture was then steam distilled and 2 l. of distillate collected. The distillate was extracted three times with ether and the combined ether extracts washed with *N* sodium hydroxide solution and water and dried over magnesium sulfate. Distillation gave the following fractions: (1) 8.1 g., b.p. 78–85° (6 mm.), $n^{25}D$ 1.4931; (2) 3.6 g., b.p. 92–101° (4 mm.), $n^{25}D$ 1.4930; (3) 15.3 g., b.p. 101–108° (5 mm.), $n^{25}D$ 1.4976; (4) 2.2 g. residue.

Fractions 1 and 2 were combined, distilled from sodium at 760 mm. (b.p. 216–230°) and then *in vacuo* to yield 7.0 g., b.p. 101–102° (21 mm.), $n^{25}D$ 1.4932, of 1,3,5-triethylbenzene (24% yield). The infrared spectrum of this sample was identical with that of an authentic sample of 1,3,5-triethylbenzene; infrared bands at 3.47, 5.62w, 5.70w, 6.23, 6.88, 7.28, 7.58, 8.60w, 9.35, 9.45, 11.35, 11.6, 12.1w, 12.80w and 14.20 μ.

Fraction 3, distilled from sodium at 760 mm., b.p. 252–254°, and redistilled *in vacuo*, gave 10.0 g. (27% yield), b.p. 134–136° (21 mm.), $n^{25}D$ 1.4960, of 2-propyl-1,3,5-triethylbenzene; infrared bands at 3.48, 6.20m, 6.90, 7.28, 7.60w, 9.20w, 9.35m, 9.50, 11.10w, 11.30m, 11.50, 12.90w and 13.7w μ. (The strong band at 14.20 μ found in 1,3,5-triethylbenzene is absent.)

Anal. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 87.60; H, 11.96.

Nitration of 2-Propyl-1,3,5-triethylbenzene.—To 2-propyl-1,3,5-triethylbenzene (3.06 g., 0.015 mole) was added dropwise, with stirring, a mixture of 2 ml. of fuming nitric acid and 6 ml. of concd. nitric acid during 50 minutes (temperature 3–4°). Stirring was continued at 5° for 5 hr. and then at 24° for 30 minutes. The mixture was then poured into ice-water and extracted with ether. The ether extract was washed four times with water, dried over magnesium sulfate and the ether distilled. Distillation of the residue gave 1.8 g. of crude 1-nitro-3-propyl-2,4,6-triethylbenzene (XXIII), b.p. 117–120° (0.50 mm.), and 1.2 g. of residue. A redistilled sample which was used for analysis had b.p. 109–112° (0.25 mm.), $n^{25}D$ 1.5140; infrared bands at 3.48, 5.95, 6.25m, 6.58, 6.88, 7.30, 7.82, 8.30m, 8.60m, 9.23m, 9.50, 10.50w, 11.37, 12.27, 12.75m and 13.55w μ.

Anal. Calcd. for $C_{15}H_{23}NO_2$: C, 72.25; H, 9.30; N, 5.62. Found: C, 74.97; H, 9.45; N, 4.15.

The poor elemental analysis suggests that the compound probably decomposed on distillation or on standing.

3-Propyl-2,4,6-triethylaniline (XXIV).—A 2.50-g. sample of the above crude nitro compound, dissolved in 100 ml. of acetic acid, was hydrogenated at 50 pounds pressure in the presence of 5.0 g. of 10% palladium–charcoal catalyst until the theoretical amount of hydrogen was absorbed (3 hr.). After filtering the catalyst, the acetic acid was evaporated *in vacuo* leaving a mass of brown crystals. These were suspended in benzene and dry hydrogen chloride gas was passed through the mixture; a few ml. of ethanol was then added and the volatile materials evaporated *in vacuo*. Trituration of the residue with petroleum ether gave 1.4 g. (26% from hydrocarbon XXII) of white crystalline 3-propyl-2,4,6-triethylaniline hydrochloride (neut. equiv. calcd. for $C_{15}H_{26}ClN$: 255.8; found, 255 (by direct titration with 0.1 *N* sodium hydroxide)). Reduction of the nitro compound with tin and hydrochloric acid also was successful and gave a 22% over-all yield of the hydrochloride (from XXII).

The above hydrochloride (1.4 g.) when treated with *N* sodium hydroxide gave an oil which was extracted with ether, dried and distilled under nitrogen to yield 0.5 g. (11% yield from XXII), b.p. 101–102° (0.35 mm.), $n^{25}D$ 1.5265, of 3-propyl-2,4,6-triethylaniline; infrared bands at 2.95w, 3.40, 3.47, 6.15, 6.86, 7.28m, 7.75m, 8.25w, 9.20w, 11.36 and 12.1w μ.

Anal. Calcd. for $C_{15}H_{25}N$: C, 82.13; H, 11.49. Found: C, 82.04; H, 11.49.

3-Propyl-2,4,6-triethylphenol (XX) from 3-Propyl-2,4,6-triethylaniline.—3-Propyl-2,4,6-triethylaniline (0.90 g., 4.1 mmoles) when treated with 10 ml. of 2 *N* sulfuric acid, formed a precipitate of the corresponding sulfate, soluble on warming. To a cold stirred suspension of the finely divided sulfate was added a solution of 0.28 g. (4.1 mmoles) of sodium nitrite in 2 ml. of water (temperature 5–10°). After 20 minutes a gummy solid had formed; 45 ml. of 12 *M* sulfuric acid was then added to the mixture, causing the temperature to rise to 90°. After warming on the steam-bath for a few minutes, the mixture was cooled and allowed to stand 2 hr. at room temperature. The red oil which formed was extracted three times with petroleum ether, the extracts washed with water and sodium bicarbonate solution and dried, under nitrogen, over magnesium sulfate. Dry hydrogen chloride was passed into the solution to precipitate a small amount of black material. The mixture was filtered and the filtrate distilled *in vacuo* under nitrogen through a short column to yield, in addition to 0.30 g. of residue and holdup, 0.24 g. (27%) of 3-propyl-2,4,6-triethylphenol, b.p. 96–98° (0.4 mm.), $n^{25}D$ 1.5181–1.5193; λ_{max} 282 mμ, (log ϵ 3.31); infrared bands at 2.87m, 3.47, 3.52, 6.10w, 6.25w, 6.37w, 6.85, 7.30m, 7.70m, 7.93, 8.25, 8.45, 9.05m (shoulder), 9.15–9.20, 9.40m, 10.1w, 11.41, 11.62m and 12.1m μ.

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.80; H, 10.98.

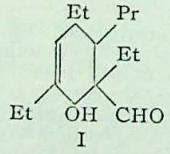
The Base-catalyzed Self-condensation of 2-Ethyl-2-hexenal. II. Formation of a Glycol, $C_{16}H_{30}O_2$, and a Lactone, $C_{16}H_{30}O_3$[1]

BY ARNOLD T. NIELSEN[2]

RECEIVED OCTOBER 22, 1956

The aldol dimer I of 2-ethyl-2-hexenal undergoes an intramolecular disproportionation in the presence of methanolic potassium hydroxide to form 5,7-dihydroxy-3-propyl-2,4,6-triethyl-1,5-heptanolactone (III). In the presence of 2-ethyl-2-hexenal, I also undergoes a Cannizzaro reaction leading to the glycol II, 2-ethyl-2-hexenoic acid and butyric acid. A mechanism for the formation of III in a preferred conformation is discussed.

2-Ethyl-2-hexenal has been shown to self-condense in the presence of aqueous methanolic potassium hydroxide to yield the cyclic dimer I.[3] It has been observed that the yield of I decreases rapidly as the reaction time is increased while, simultaneously, other products are formed, including a C_{16}-lactone III, a C_{16}-glycol II and 2-ethyl-2-hexenoic and butyric acids (Fig. 1).



I

The preparation of compounds I, II and III has been reported previously,[4,5] although no structures were suggested by Anseln and Nickl or Hall and Tuerck.[5] Häusermann[6] also has studied the self-condensation of 2-ethyl-2-hexenal but under more vigorous reaction conditions (25–50% aqueous sodium hydroxide, *ca.* 200°, 22 hr.) than those of the present investigation. He isolated, among other products, butyric and 2-ethyl-2-hexenoic acids, 2,4-diethyl-3-propyl-1,5-pentanolactone and a C_{16}-glycol, to which no structure was assigned. No C_{16}-lactone was reported by him. There are scattered reports in the literature of the formation of high molecular weight glycols and lactones from various saturated and unsaturated aliphatic aldehydes, in the presence of basic catalysts.[4-7] In most cases, however, the structures of these condensation products have not been established.

The glycol II, formed in 10–30% yields, was found to be identical with the lithium aluminum hydride reduction product of the aldol I.[3] It is believed to have been formed by a Cannizzaro reaction involving reduction of I and oxidation, principally of butanal[8] and 2-ethyl-2-hexenal to butanoic and 2-ethyl-2-hexenoic acids.[9] The linear

(8) Butanal must be formed mainly by hydration of 2-ethyl-2-hexenal to butyraldol, followed by dealdolization. Evidence for formation of butanal from 2-ethyl-2-hexenal (alkaline catalyst) has been reported previously; S. G. Powell and A. T. Nielsen, THIS JOURNAL, **70**, 3627 (1948); Y. Sprinzak, *ibid.*, **74**, 2116 (1952).

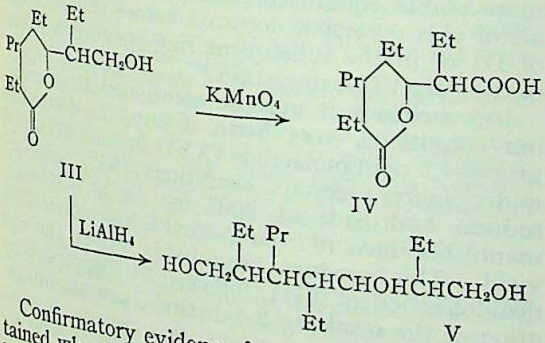
(9) The aldol I, itself, is apparently not an important oxidizing agent in this reaction since it was found to be converted solely into lactone III under the milder conditions of the reaction (Fig. 1). However, under more vigorous reaction conditions where the yield of II is higher, some I may be oxidized, leading to a larger amount of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

relationship between the mole-per cent. yield of II and these acids supports this view (Table I, Experimental part).

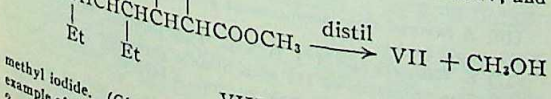
The third major product obtained from the reaction of 2-ethyl-2-hexenal with alkali was shown by elemental analysis, molecular weight and saponification equivalent determinations to be $C_{16}H_{30}O_3$ (40–56% yield). Strong infrared absorption at 2.98 μ, the formation of a monoacetate derivative and the Zerewitinoff determination indicated the presence of one free alcoholic hydroxyl group. Oxidation of III with permanganate led to a monocarboxylic acid lactone, $C_{16}H_{28}O_4$ (IV), in 75% yield, indicating the hydroxyl group to be primary. Compound III was insoluble in hot aqueous *N* sodium hydroxide solution but could be converted into its carboxylate anion with hot aqueous alcoholic *N* sodium hydroxide (saponification equivalent determination). This observation, and the presence of strong infrared absorption at 5.85 μ, support a six-membered lactone structure. Failure of III to react with bromine in carbon tetrachloride or potassium permanganate in acetone and, particularly, failure to absorb hydrogen under conditions favorable for facile hydrogenation of I and II, as well as the empirical formula and spectral data, suggest the absence of olefinic unsaturation in the molecule. Reduction of III with lithium aluminum hydride led to a crystalline triol V, $C_{16}H_{34}O_3$ (58%), m.p. 96.5–97.5°. A Zerewitinoff determination supports the triol assignment as does the intense infrared band at 2.97μ and the absence of carbonyl absorption in the 5.5–6.0μ region; compound V failed to react with lead tetraacetate or periodic acid. On the basis of the above preliminary evidence structure III was proposed for the lactone, IV for the corresponding acid and V for the triol.



Confirmatory evidence for structure III was obtained when VII, the methyl ester of IV (obtained by reaction of IV with diazomethane or of its monosilver salt VI with methyl iodide),[10] was

undistillable acid residue (*cf.* Table I) and proportionately less butyric and 2-ethyl-2-hexenoic acids.

(10) Ester VII was also obtained by demethanolation, during distillation, of the dimethyl ester VIII. The latter compound was obtained from the corresponding disilver salt, prepared from IV, and methyl iodide. (*Cf.* E. Oberreit, *Ber.*, **29**, 1998 (1896), for a similar example of thermal demethanolation in the case of methyl 4-hydroxy-2-propylpentanoate.)



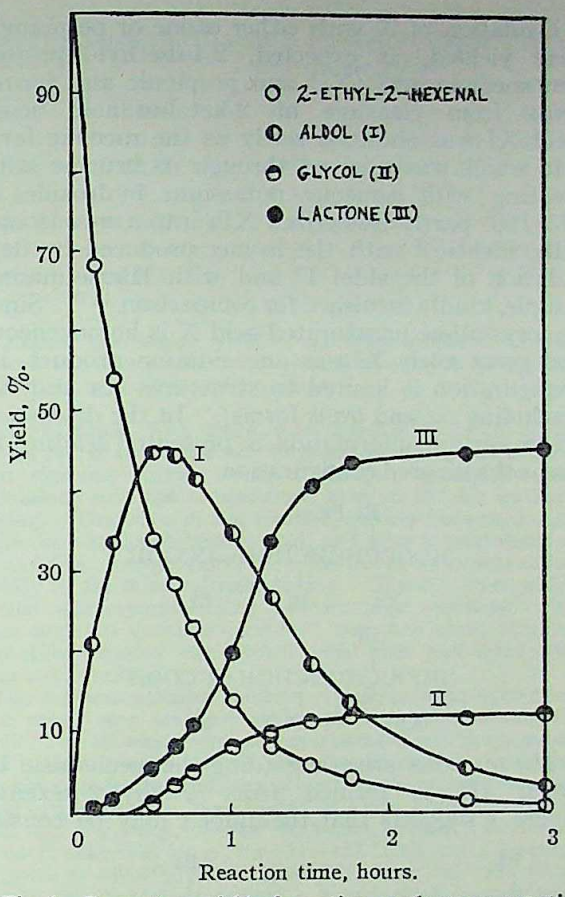


Fig. 1—Percentage yield of reaction products *vs.* reaction time for self-condensation of 2-ethyl-2-hexenal at 25°; for reaction conditions see Experimental part.

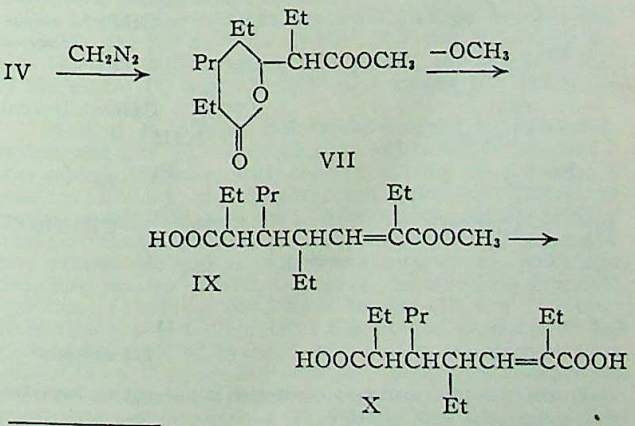
treated with one mole-equivalent of sodium methoxide to open the lactone ring and yield the unsaturated monoester IX.[11] Hydrolysis of IX gave the crystalline free acid X (83% yield from VII); α,β-unsaturation was demonstrated in the latter by its ultraviolet[12] (λ_{max} 218 mμ, ϵ 16,300) and infrared[13] (λ_{max} 5.85–5.95, 6.14μ) absorption characteristics.



(11) Examples of this reaction in five-membered ring systems have been reported; J. A. Elvidge, R. P. Linstead and P. Sims, *J. Chem. Soc.*, 1793 (1953), and earlier papers in this series.

(12) α,β-Dialkylacrylic acids exhibit a maximum absorption in the ultraviolet region at *ca.* 217 mμ, α- or β-monoalkyl substituted acrylic acids at *ca.* 208 mμ; J. Cason, N. L. Allinger and D. E. Williams, *J. Org. Chem.*, **18**, 842 (1953); J. Cason and L. L. Rinehart, *ibid.*, **20**, 1951 (1955).

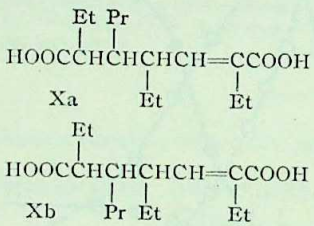
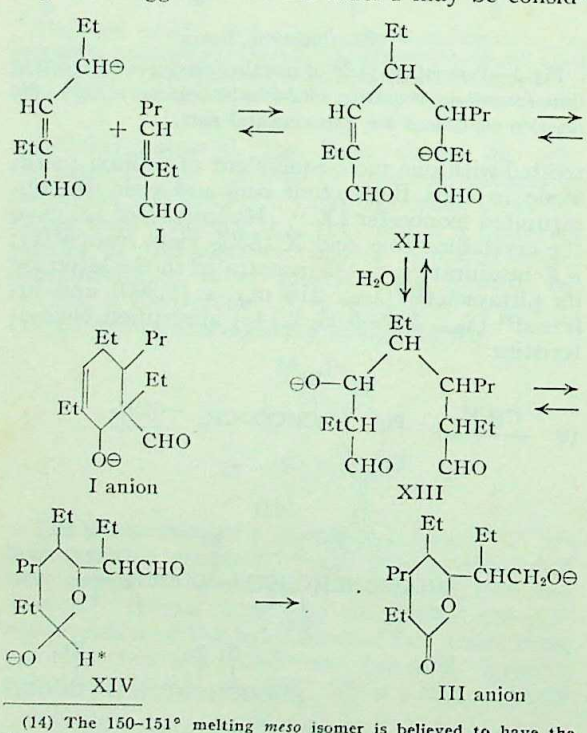
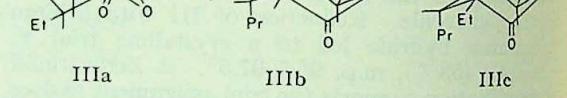
Oxidation of X with either ozone or permanganate yielded, as expected, 2,4-diethyl-3-propylpentanedioic acid (XI) and propionic and formic acids from cleavage of 2-ketobutanoic acid.[3] Acid XI was obtained solely as the racemic form XIa which was resolved through its brucine salts. Heating with aqueous potassium hydroxide at 175–180° partly isomerized XIa into a *meso* isomer XIb, identical with the isomer produced by degradation of the aldol I[3] and with Häusermann's sample, kindly furnished for comparison.[14,15] Since the crystalline unsaturated acid X is homogeneous and gives solely XIa as an oxidation product, its configuration is limited to structures Xa and Xb (excluding *cis* and *trans* forms). In the discussion below certain information is presented leading to Xa as the favored configuration.



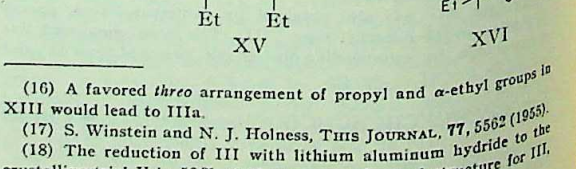
The question arises regarding the mechanism by which III is formed from 2-ethyl-2-hexenal. Figure 1 suggests that the aldol I may be considered as an intermediate, and this is confirmed by experiment, since under the same reaction conditions I is converted exclusively to III in good yield. The mechanism therefore appears to be intramolecular and may reasonably be formulated as shown. In this mechanism the common intermediate precursor of I and III is the anion XII. A hydrated dialdehyde, XIII, is presumed to be the precursor of the cyclic hemiacetal XIV, which undergoes internal disproportionation to III through hydride transfer.



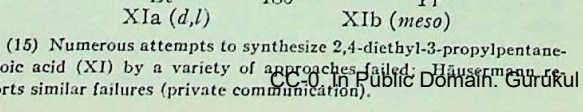
In order for this internal transfer to be sterically possible, both the starred hydrogen and formylpropyl group must be axially rather than equatorially directed; hence the hydroxybutyl group in lactone III must likewise be axial at the time of formation (IIIa). On the assumption that the other three alkyl groups originally occupied the energetically preferred equatorial positions, lactone III should have the conformation IIIa,[16] or more probably the equivalent form IIIb, in which the bulky hydroxybutyl group has become equatorial by a near-strainless ring inversion.[17] However, conformation IIIb would predict the formation of *meso*-XI on degradation of III, whereas the isomer actually isolated was *d,l*-XI. This discrepancy can be accounted for by assuming that the axial ethyl group alpha to the carbonyl of IIIb becomes inverted, in the presence of strong alkali, to the more stable equatorial position (IIIc). Whether all of this inversion occurred before the isolation of III or in the subsequent ring-opening reaction of the ester VII is uncertain.[18]



In conclusion it may be mentioned that under our conditions, very little, if any, 2,4-diethyl-3-propyl-1,5-pentanolactone (XVI) formed, although under more vigorous conditions (50% aqueous sodium hydroxide at 200° for 24 hr.) Häusermann[6] obtained it from 2-ethyl-2-hexenal in 36% yield. This product presumably arises through dealdolization of XIII, followed by disproportionation of the resulting 2,4-diethyl-3-propylpentanedial (XV).[19]



(14) The 150–151° melting *meso* isomer is believed to have the *threo* configuration XIb; *cf.* ref. 3.



(15) Numerous attempts to synthesize 2,4-diethyl-3-propylpentanedioic acid (XI) by a variety of approaches failed; Häusermann reports similar failures (private communication).

(16) A favored *threo* arrangement of propyl and α-ethyl groups in XIII would lead to IIIa.

(17) S. Winstein and N. J. Holness, THIS JOURNAL, 77, 5562 (1955).

(18) The reduction of III with lithium aluminum hydride to the crystalline triol V in 58% yield suggests a favored structure for III, to at least the extent of this yield.

(19) An alternate mechanism involving Michael addition of butanal to 2-ethyl-2-hexenal appears unlikely since this reaction fails in practice (unpublished work, this Laboratory; *cf.* ref. 6).

Experimental[20]

6-Hydroxymethyl-5-propyl-2,4,6-triethyl-2-cyclohexen-1-ol (II).—To purified 2-ethyl-2-hexenal[3] (113 g., 0.90 mole) was added dropwise, with stirring, during 1.5 hr., a solution of 50 g. (0.76 mole) of potassium hydroxide (86% assay) in 65 ml. of methanol and 16 ml. of water. A nitrogen atmosphere was maintained during the reaction but no external cooling was provided. The temperature gradually rose to 80° during 30 minutes, while one-sixth (17 ml.) of the potassium hydroxide solution was being added gradually. Within the next 60 minutes the addition of the alkali was complete and the temperature had dropped to 40°. Stirring was continued for 1.5 hr., water then added and the mixture separated into acid and neutral parts as described previously.[3]

Distillation of the neutral part gave the following main fractions: (1) 2 g., recovered 2-ethyl-2-hexenal; (2) 37 g. (32%) of the glycol II, b.p. 124–129° (0.25 mm.), $n^{25}D$ 1.4926; (3) 7.3 g. of residue. A redistilled sample of the glycol was obtained as a pale yellow, extremely viscous liquid, b.p. 135–138° (0.45 mm.), $n^{25}D$ 1.4935, d^{23}_4 0.921; infrared bands at 3.0, 3.45, 3.53, 5.85w, 6.1w, 6.87, 7.28 and 9.7 μ (chloroform).

Anal. Calcd. for $C_{16}H_{30}O_2$: C, 75.54; H, 11.89; mol. wt., 254.4. Found: C, 75.76; H, 11.48; mol. wt., 252, 256.[21]

Quantitative hydrogenation of a 5.56-millimole sample of the glycol (689 mm., 23°, acetic acid solvent, a few drops of concentrated hydrochloric acid promotor, 5% palladium–charcoal catalyst) resulted in absorption of 1.06 mole-equivalents of hydrogen in 270 minutes, after which time hydrogenation essentially ceased. On quantitative bromination of the glycol with a 5% solution of bromine in carbon tetrachloride, 0.91 mole-equivalent of bromine was absorbed. A Zerewitinoff determination showed 1.90 active hydrogens and no additional methylmagnesium iodide reacted.

The **bis-*p*-nitrophenylurethan** derivative was obtained as yellow microcrystals from high boiling ligroin, m.p. 74–78°. When mixed with a sample of the bis-*p*-nitrophenylurethan derivative of II obtained previously,[3] m.p. 76.5–78.5°, the melting point was not depressed.

Distillation of the acid part from the above reaction gave (1) *ca.* 3 g., b.p. 50–83° (0.4 mm.), mainly butyric acid; (2) 6.6 g., b.p. 83–138° (0.3 mm.), mainly 2-ethyl-2-hexenoic acid; (3) 37 g. (31%), b.p. 150–157° (0.35 mm.), lactone III, $n^{25}D$ 1.4740; (4) 13.0 g. of residue.

The **butyric acid** fraction was redistilled to yield a sample, b.p. 159–162° (760 mm.), $n^{20}D$ 1.3990, neut. equiv. 90; *p*-phenylphenacyl ester, m.p. 81.5–82.5°, alone and when mixed with an authentic sample.

The **2-ethyl-2-hexenoic acid** fraction was dissolved in ether and extracted with sodium hydroxide solution. Acidification of the alkaline extracts gave a sample, b.p. 98–99.5° (2.7 mm.), $n^{20}D$ 1.455,[22] neut. equiv. 145 (calcd. for $C_8H_{14}O_2$, 142.2). The amide derivative, prepared through the acid chloride, melted at 69–69.5°, alone, and when mixed with an authentic sample.[23] *Anal.* Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.71. Found: C, 68.1; H, 10.7.

The total yield of acids and glycol produced in various runs was calculated by determining the number of moles of each product produced per 100 moles of 2-ethyl-2-hexenal employed (mole-per cent. yield); for purposes of calculation the acid residue was assigned an equivalent weight of 270. In these runs the potassium hydroxide concentration, rate of addition of the catalyst, reaction time and temperature were varied. The glycol yields were proportional to the total mole-per cent. yield of acids produced, as shown in Table I.

Preparation of 5,7-Dihydroxy-3-propyl-2,4,6-triethyl-1,5-heptanolactone (III). Method A. From 2-Ethyl-2-hexenal.—2-Ethyl-2-hexenal, purified as described previously,[3] was freshly distilled under nitrogen, directly into the reaction flask (128.4 g., 1.02 moles). A solution of 38 g. of potas-

Table I

Yields of Acids and Glycol II Formed in Various Runs

Run	II	Mole-per cent. yields[a] A	B	C
11	16.0	3.8	5.1	5.4
9	13.5	4.0	4.9	2.5
8	11.5	3.2	3.9	1.9
4	9.5	4.1	3.2	1.6
10	8.3	2.4	3.6	1.7
27	5.5	1.2	1.4	1.6
16	5.0	1.3	1.4	0.8
18	2.5	0.6	0.8	0.3

[a] Actual percentage yield of II from 2-ethyl-2-hexenal is twice the above value: A = butyric acid, B = 2-ethyl-2-hexenoic acid, C = acid residue.

sium hydroxide (85% assay, 0.58 mole) in 18 ml. of water and 64 ml. of methanol was then added during one minute with vigorous stirring while a nitrogen atmosphere was maintained and the temperature held at 25° by ice-bath cooling. The color of the solution quickly became orange while the alkali was being added, and after a total reaction time of 7 hr. (temperature, 25°), 500 ml. of water was added rapidly to the mixture with stirring. The oily layer which formed was separated, the aqueous layer extracted with ether and the extracts combined with the main portion. The ether solution was washed with water and dried over magnesium sulfate.

The aqueous alkaline solution remaining after extraction with ether was acidified with concentrated hydrochloric acid. The oil which formed was separated and the aqueous part extracted with ether. The oil and ether extracts were combined and after distilling the ether, the residue was distilled to give (1) 1 g., b.p. 35–55° (0.7 mm.), mainly butyric acid; (2) 3 g., b.p. 93–114° (0.4 mm.), mainly 2-ethyl-2-hexenoic acid; (3) 1.4 g., b.p. 114–151° (0.3 mm.), forerun; (4) 68.4 g. (49.6%)[4] of lactone III, b.p. 152–157° (0.25 mm.); (5) 10.5 g. of residue. A redistilled sample used for analysis was a colorless, slightly viscous liquid, b.p. 153–155° (0.3 mm.), $n^{25}D$ 1.4757; infrared bands at 2.98m, 3.46, 3.53, 5.80–5.85, 6.86m, 7.25m, 8.32, 9.05–9.10m and 9.6–9.65m μ.

Anal. Calcd. for $C_{16}H_{30}O_3$: C, 71.07; H, 11.18; mol. wt., 270.4. Found: C, 70.93; H, 11.22; mol. wt., 274, 275[21]; sapn. equiv., 264.

The lactone was found not to decolorize bromine in carbon tetrachloride or dilute potassium permanganate in acetone. No hydrogen was absorbed by the compound in acetic acid in the presence of 5% palladium–charcoal catalyst (695 mm., 27°). A Zerewitinoff determination indicated 1.3 active hydrogens and 1.7 additional mole-equivalents of methylmagnesium iodide reacted.

The above ether solution of neutral material was distilled to yield: (1) 2.3 g., b.p. 40–100° (2.7 mm.); (2) 4.9 g., b.p. 100–135° (0.7 mm.), mainly aldol I; (3) 16.6 g. (14%) of the glycol II, b.p. 135–137° (0.5 mm.); (4) 15.4 g. of neutral residue.

Method B. From 6-Formyl-5-propyl-2,4,6-triethyl-2-cyclohexen-1-ol (I).—To 36.9 g. (0.146 mole) of the aldol I was added dropwise, with stirring, during 30 minutes, a solution of 10.9 g. of 85% potassium hydroxide in 18 ml. of methanol and 6 ml. of water. After stirring for 2.5 hr., the mixture was treated with 160 ml. of water and separated into neutral and acid parts as in the condensation procedure described above. Distillation gave the following principal fractions: (1) 19.1 g. (46.8%) of lactone III, b.p. 154–160° (0.55 mm.), $n^{25}D$ 1.4755; (2) 1.5 g. of acid residue; (3) 6.5 g., b.p. 129–140° (0.56 mm.), $n^{25}D$ 1.4873, mainly recovered aldol; (4) 6.7 g. neutral residue. Hall and Tuerck[5] reported a similar experiment in which they employed sodium hydroxide and reported a 47.5% yield of III, b.p. 162–163° (3 mm.), $n^{20}D$ 1.4781.

Influence of Reaction Conditions on the Self-condensation of 2-Ethyl-2-hexenal.—A study was made of the effect of reaction conditions on the yields of the products I, II and III produced from the self-condensation of 2-ethyl-2-

(20) Melting points are corrected; boiling points are uncorrected.

(21) Procedure of R. B. Kitson, A. N. Oemler and J. Mitchell, *Anal. Chem.*, **21**, 404 (1949).

(22) Reported b.p. 107–108° (3 mm.), $n^{20.5}D$ 1.4590; J. Lichtenberger and M. Naftali, *Bull. soc. chim. France*, [5] **4**, 325 (1937).

(23) C. Mannich and E. Kniss, *Ber.*, **74**, 1637 (1941), report m.p. 67–68°.

(24) In another run in which 344.2 g. of 2-ethyl-2-hexenal was used (reaction time 16 hr.), the yield of III was 208.2 g., 56.4%, b. p. 172–176° (1 mm.).

hexenal. Factors studied were reaction time, temperature, catalyst concentration and rate of addition of the catalyst. From these experiments optimum procedures were developed for the preparation of the products. Use of freshly purified and distilled 2-ethyl-2-hexenal, in a nitrogen atmosphere, gave the best yields.

The reaction time determined the yields of product obtained, as shown in Fig. 1 (temperature 25°; potassium hydroxide to aldehyde molar ratio, 0.57; catalyst addition time, *ca.* two minutes). Reaction times longer than 3 hr. gave only slightly increased yields of II and III under these conditions.[24]

A reaction temperature of *ca.* 25° was found to give less undistillable residue than did higher temperatures. Product yields also were higher, except in the case of glycol II, where maximum yield was obtained by permitting the reaction mixture to warm spontaneously to 80°. Using a reaction time of 1 hr., a potassium hydroxide–aldehyde molar ratio of 0.85 and a catalyst addition time of 12 minutes, the percentage yields of recovered 2-ethyl-2-hexenal, I, II and III, respectively, at three different temperatures were as follows: (13°) 37% 2-ethyl-2-hexenal, 42% I, 0% II, 3% III; (25°) 5% 2-ethyl-2-hexenal, 21% I, 13% II, 41% III; (40°) 1% 2-ethyl-2-hexenal, 3% I, 12% II, 46% III.

Employing a reaction time of 1 hr., temperature 25°, catalyst addition time 12 minutes, the yields of recovered 2-ethyl-2-hexenal, I, II and III, respectively, were found to vary with potassium hydroxide–aldehyde molar ratios as follows: ratio 0.85, 5% 2-ethyl-2-hexenal, 21% I, 13% II, 41% III; ratio 0.57, 13% 2-ethyl-2-hexenal, 33% I, 3% II, 22% III; ratio 0.29, 65% 2-ethyl-2-hexenal, 21% I, 0% II, 0.5% III.

The addition time of the catalyst when short (*ca.* 1–2 minutes) gave the maximum yields of I and III (see Fig. 1). A longer addition time was required for the best yields of II; in the optimum procedure described above the time was 1.5 hr. (total reaction time, 3 hr.).

5-Propyl-2,4,6-triethyl-1,3,7-heptanetriol (V).—A solution of 28.7 g. (0.106 mole) of the lactone III in 130 ml. of dry ether was added dropwise, with stirring, during 140 minutes to a solution of 4.9 g. (0.129 mole) of lithium aluminum hydride in 200 ml. of ether.[25] The rate of addition of the lactone was adjusted so as to produce gentle refluxing. After addition of the lactone was complete, refluxing by heating was continued for an additional 20 minutes; first 10 ml. of water and then 160 ml. of 10% sulfuric acid were added cautiously with stirring. The ether layer was separated and the aqueous part extracted twice with ether. The combined ether fractions were washed with water and dried. The ether was removed and the residue crystallized from 400 ml. of petroleum ether to yield 16.9 g. (58%) of V as white prisms, m.p. 96–97°; recrystallization did not raise the melting point; infrared bands at 2.77w, 2.97, 3.43, 6.85, 7.01m, 7.26m, 9.31, 9.87, 10.38m, 10.72w, 11.37w and 12.20w μ (chloroform). Repetition of the above experiment, using a 3-fold excess of lithium aluminum hydride and a reflux time of 22 hr., also gave a 58% yield of V.

Anal. Calcd. for $C_{16}H_{34}O_3$: C, 70.02; H, 12.49. Found: 70.22; H, 12.59.

The filtrate obtained above was distilled to yield 2.1 g., b.p. 123–166° (0.5 mm.); 5.7 g., b.p. 166–177° (0.4 mm.), (very viscous); and 1.1 g. of residue; these fractions were not further investigated.

The triol in a Zerewitinoff determination was found to have 3.1 active hydrogens and react with 0.1 mole-equivalent additional methylmagnesium iodide. It did not absorb hydrogen in acetic acid solvent at one atmosphere pressure in the presence of 5% palladium–charcoal catalyst.

3-Propyl-2,4,6-triethyl-5-hydroxy-1,7-heptanedioic Acid-1,5-lactone (IV).—To 37.9 g. (0.14 mole) of lactone III, suspended in a solution of 200 ml. of 10% sulfuric acid and 30 ml. of acetic acid, was added, with stirring during 30 minutes, 31.6 g. of powdered potassium permanganate, keeping the temperature at 25° by external cooling; stirring was then continued for 1.5 hr. Sufficient sodium bisulfite was added to dissolve the manganese dioxide and the mixture extracted with ether. The ether extracts were washed with water and 10% sodium hydroxide solution. The alkaline extracts were extracted several times with ether and then acidified with hydrochloric acid. The oil which separated was extracted with ether, the extract dried and the solution concentrated. All traces of volatile matter were finally removed by heating for 6 hr. at 100° (0.16 mm.) leaving 29.9 g. (75%) of very pure IV, an extremely viscous yellow liquid, $n^{25}D$ 1.4762; molecularly distilled at bath temperature, 135–139° (2–4 μ), $n^{25}D$ 1.4760. The acid could not be crystallized; infrared bands at 3.45, 5.77, 5.84, 6.85, 7.25, 7.9–9.1 and 9.83mμ (chloroform).

Anal. Calcd. for $C_{16}H_{28}O_4$: C, 67.57; H, 9.93; mol. wt., 284.4. Found: C, 67.26; H, 10.20; neut. equiv., 282 (by direct titration); sapn. equiv., 144.

The *p*-**bromophenacyl ester** derivative was obtained as white platelets from ethanol, m.p. 114.5–115.5°.

Anal. Calcd. for $C_{24}H_{33}O_6$: C, 59.88; H, 6.91. Found: C, 59.78; H, 7.07.

Disilver 3-Propyl-2,4,6-triethyl-5-hydroxy-1,7-heptanedioate.—The lactone acid IV (31.4 g., 0.1104 mole) was dissolved in 400 ml. of 1.075 *N* sodium hydroxide, the solution heated on the steam-bath for 1 hr. and then allowed to stand overnight at room temperature. After extracting with ether, the aqueous solution was diluted with one l. of ethanol, then neutralized by slowly adding, with vigorous stirring, 176 ml. of 1.109 *N* nitric acid (faint pink color to phenolphthalein). A solution of 40 g. of silver nitrate in 550 ml. of water was then added dropwise with stirring. The precipitate was rapidly filtered, washed thoroughly with water and dried in a vacuum desiccator over calcium chloride, keeping light absent; the yield of white powder was 56 g. (98%), m.p. 134–136° dec. Slowly, on standing in the dark, or rapidly, on exposure to light, the salt darkened and became brown.

Anal. Calcd. for $C_{16}H_{28}O_6Ag_2$: Ag, 41.80. Found: Ag, 41.80.

Dimethyl 3-Propyl-2,4,6-triethyl-5-hydroxy-1,7-heptanedioate (VIII).—To the above disilver salt (28.2 g., 0.0545 mole), suspended in 200 ml. of dry ether and 100 ml. of dry benzene, was added, dropwise, 68 g. of methyl iodide during 30 minutes (temperature 23–25°). Stirring was continued for 40 hr., the mixture filtered and the silver iodide precipitate washed thoroughly with ether. The filtrate was dried over magnesium sulfate and the ether removed to leave a yellow oil (pumped at 1 mm., 24 hr., 25°). The crude diester (14.8 g., 82%, $n^{25}D$ 1.4572), could not be distilled without decomposition (see below); infrared bands at 2.93 m, 3.48, 5.83, 6.90, 7.0, 7.30m, 7.95, 8.45, 8.62, 10.5m, 10.65w and 12.6 m μ.

Anal. Calcd. for $C_{18}H_{34}O_5$: C, 65.42; H, 10.37; mol. wt., 330.45. Found: C, 65.31; H, 10.31; sapn. equiv., 164.

3-Propyl-2,4,6-triethyl-5-hydroxy-1,7-heptanedioic Acid-1,5-lactone Methyl Ester (VII). Method A. Demethanolation of Dimethyl 3-Propyl-2,4,6-triethyl-5-hydroxy-1,7-heptanedioate (VIII).—A 4.95-g. (0.015 mole) sample of the dimethyl ester VIII was heated in a small distilling flask at a bath temperature of 155–160° for 30 minutes. During this time 0.25 g. of methanol was collected, b.p. 65–67°; 3,5-dinitrobenzoate, m.p. 109–110°, alone and when mixed with an authentic sample. Distillation of the residue at 0.5 mm. gave fractions: (1) 0.3 g., b.p. 123–136°; (2) 3.2 g. (71% crude VII), b.p. 136–144°, $n^{25}D$ 1.462–1.465 (65% b.p. 138–142°); (3) 1.0 g. residue and holdup. Redistillation of fraction 2 gave 2.1 g., b.p. 136–144° (0.30 mm.), $n^{25}D$ 1.4640, used for analysis; infrared spectrum was identical with sample prepared by method B.

Anal. Calcd. for $C_{17}H_{30}O_4$: C, 68.42; H, 10.13; mol. wt., 297.4. Found: C, 68.22; H, 9.98; sapn. equiv., 149.

Method B. From 5-Hydroxy-2,4,6-triethyl-1,7-heptanedioic Acid-1,5-lactone (IV) and Diazomethane.—A 13.4-g. (0.047 mole) sample of the lactone acid IV dissolved in 50 ml. of ether was treated with excess diazomethane for 1 hr. The volatile material was evaporated and the residue distilled at 1.5 mm. to yield (1) 1.0 g., b.p. 141–155° (1.5 mm.); (2) 9.8 g. (70%) of VII, b.p. 155–157° (1.5 mm.); and (3) 2.7 g. residue. Redistillation of fraction 2 gave an analytical sample, $n^{25}D$ 1.4643; infrared bands at 3.42, 3.50, 5.75, 6.85, 6.92, 7.25, 7.87, 8.12, 8.35, 9.80, 10.1, 10.45m and 12.55m μ.

Anal. Calcd. for $C_{17}H_{30}O_4$: C, 68.42; H, 10.13. Found: C, 68.31; H, 9.

Method C. From Monosilver Salt of 3-Propyl-2,4,6-triethyl-5-hydroxy-1,7-heptanedioic Acid-1,5-lactone and Methyl Iodide.—The acid lactone IV, 11.7 g. (0.0412 mole), in 50 ml. of ethanol was exactly neutralized with 0.1 *N* sodium hydroxide and diluted to 200 ml. with water. A solution of 8.0 g. of silver nitrate in 100 ml. of water was added slowly with vigorous stirring. The white precipitate was filtered, washed with water and dried *in vacuo* in the dark; yield 12.9 g. (80%) of white powder, m.p. 100–110° dec., with sintering at 90°.

Anal. Calcd. for $C_{16}H_{29}O_4Ag$: Ag, 27.6. Found: Ag, 28.2.

To the above silver salt, 12.3 g. (0.315 mole), dissolved in 100 ml. of dry ether was added slowly, with stirring, 22 g. of methyl iodide (temperature 20–25°); stirring was continued for 24 hr. The silver iodide was filtered and washed with ether (7.3 g., 99%). Evaporation of the ether left 8.2 g. of an oil which was distilled to yield the following fractions at 0.4 mm.: (1) 1.9 g., b.p. 83–136°; (2) 4.0 g. (43%) of VII, b.p. 136–146° (80% b.p. 136–144°), $n^{25}D$ 1.4628; (3) 1.7 g. residue; fraction 2 infrared spectrum identical with sample prepared by method B.

5-Propyl-2,4,6-triethyl-2-heptenedioic Acid (X).—A solution of 14.0 g. (0.0468 mole) of ester VII and 1.2 g. (0.052 mole) of sodium metal in 50 ml. of dry methanol was allowed to stand at room temperature for 45 minutes and then refluxed 17 hr. Sodium hydroxide, 15 g., and 20 ml. of water were then added, and refluxing continued for 23 hr. The solution was diluted with 1500 ml. of water and chilled to 4°. A solution of 30 ml. of acetic acid in 200 ml. of water was then added dropwise, slowly, with vigorous stirring during 30 minutes; after seeding with pure X, stirring was continued at 2° for 4.5 hr. and the mixture then placed in the refrigerator overnight. The precipitate which formed was filtered and washed thoroughly with water; 11.1 g. (83.3%), m.p. 87–95°, white, crystalline powder. In another, similar, run a 78% yield of product, m.p. 90–100°, was obtained. A sample recrystallized from dilute ethanol melted at 99.5–100.5°, small prisms; λ_{max} 218 mμ, ε 16,300 (95% ethanol solvent, 10^{-4} *M*); infrared bands at 3.50, 5.85–5.95, 6.14, 6.87, 7.10, 7.28m, 7.80, 8.65w, 9.35w, 10.75 (broad) and 7.8–8.35 μ (broad) (chloroform).

Anal. Calcd. for $C_{16}H_{28}O_4$: C, 67.57; H, 9.93; mol. wt., 284.4. Found: C, 67.17; H, 9.92; neut. equiv., 141.5 (by direct titration).

The bis *p*-phenylphenacyl ester was prepared in the usual manner, recrystallized from ethanol, m.p. 114–115°.

Anal. Calcd. for $C_{44}H_{48}O_6$: C, 78.54; H, 7.19. Found: C, 78.3; H, 7.3.

The unsaturated acid X failed to react with bromine in carbon tetrachloride or with potassium permanganate in acetone. On quantitative hydrogenation of a small sample of the acid, however, 1.0 mole-equivalent of hydrogen was absorbed in 2 hr. (palladium–charcoal catalyst, one atmosphere, 25°, acetic acid solvent), after which time hydrogen uptake ceased. Removal of solvent and catalyst gave a gum which failed to crystallize. The dimethyl ester of X, prepared on a small scale from X and diazomethane, also absorbed one mole-equivalent of hydrogen under the above reaction conditions to yield a saturated dimethyl ester (carbonyl band at 5.81 μ; band at 6.1 μ absent); these esters, prepared on a micro scale, were not distilled. Treatment of the hydrogenated acid with aqueous potassium hydroxide at 160–175° or its dimethyl ester with sodium methoxide in refluxing methanol failed to lead to a crystalline product.

Ozonolysis of 5-Propyl-2,4,6-triethyl-2-heptenedioic Acid (X).—A 500-mg. (1.76 mmole) sample of the acid X in 15 ml. of carbon tetrachloride and 15 ml. of chloroform was ozonized at 0° using a 3-fold molar excess of ozone. The solution was then refluxed 24 hr. with a solution of 10 ml. of *N* sodium hydroxide and 10 ml. of 30% hydrogen peroxide. The solvent layer was separated; the aqueous layer was washed with chloroform and then distilled to remove neutral volatile material. The aqueous residue was acidified with *N* sulfuric acid and extracted with ether. The ether extracts were washed with water (washings added to aqueous part) and saturated sodium bicarbonate solution. The bicarbonate washings were washed with ether, acidified with sulfuric acid and the aqueous part extracted with ether. The ether extracts were washed with water (washings added to aqueous part) and dried. Evaporation of the ether gave 234.6 mg. of a viscous oil (neut. equiv. 130) which crystallized slowly from dilute alcohol to yield 73.5 mg. of crystals, m.p. 97–98°. Recrystallization gave short rectangular prisms, m.p. 98–99°, of racemic 2,4-diethyl-3-propylpentanedioic acid (XIa); when mixed with starting compound X, the melting point was 80–85°; infrared bands: 3.25–3.35 (shoulder), 3.46, 3.50, 3.80m, 5.85, 6.85, 7.10m, 7.25w, 7.85, 8.76w, 8.95w, 9.20w, 9.65, 10.75m (shoulder) and 11.10m μ; broad bands, 3–4, 7.5–8.5 and 10–12 μ (chloroform); this spectrum was practically identical with the uncrystallized oil, above.

Anal. Calcd. for $C_{12}H_{22}O_4$: C, 62.58; H, 9.63; mol. wt., 230.32. Found: C, 62.5; H, 9.5; neut. equiv., 114 (by direct titration).

The combined aqueous portions from the above ozonolysis were made alkaline with sodium hydroxide and distilled to remove volatile neutral material. The aqueous residue was acidified with sulfuric acid and steam distilled to yield 2.15 meq. (1.22 mole-equivalents) of steam volatile water-soluble acidic material. This solution was refluxed with 3 g. of mercuric oxide for 2.5 hr. and distilled to yield 1.50 meq. of acid (0.65 meq. (37%) destroyed formic acid by difference).[3] The remaining distilled water-soluble acid was identified as propionic (85%) by conversion to its *p*-phenylphenacyl ester, m.p. 102–102.5° (melting point not depressed by admixture with authentic sample, m.p. 102–103°).

A 55-mg. sample of the low melting acid, XIa, was dissolved in a solution of 6 g. of potassium hydroxide (85% assay) in 6 ml. of water and heated, with shaking, in a steel bomb at 175–180° for 16 hr. Recovery of the acid in the usual manner gave 45 mg. of an oil which was crystallized from water to yield the crude high melting *meso* isomer, XIb, m.p. 140–145°; one recrystallization raised the melting point to 150–150.5° (rectangular prisms). When mixed with an authentic sample of *meso*-2,4-diethyl-3-propylpentanedioic acid,[26] the melting point was not depressed.

Permanganate Oxidation of 5-Propyl-2,4,6-triethyl-2-heptenedioic Acid. Preparation of Racemic 2,4-Diethyl-3-Propylpentanedioic Acid (XIa).—Permanganate oxidation of X was found to be a more efficient method of securing the racemic dibasic acid, XIa. To a solution of 1.205 g. (4.23 mmoles) of acid X in 40 ml. of saturated sodium bicarbonate solution was added, dropwise, with stirring, during 4.5 hr., a solution of 2.2 g. of potassium permanganate in 100 ml. of water (temperature, 0–5°). Stirring was continued at 0–25° for 17.5 hr. and the mixture warmed on the steam-bath for 30 minutes to remove the pink color. The manganese dioxide was then filtered and washed and the filtrate acidified with dilute hydrochloric acid. The aqueous suspension of the crude acid which separated as an oil was heated to 90° and treated with sufficient ethanol to give a clear solution. The solution on standing several days deposited 521 mg. (51%) of product, m.p. 92–95°, and on further standing 265 mg. of additional crystalline material, m.p. 75–90°; total crude yield, 81%. The crude product could be purified easily by slow crystallization from water or dilute ethanol (seeding); long, needle-like prisms, m.p. 94–96°.

Resolution of Racemic 2,4-Diethyl-3-propylpentanedioic Acid.—A solution of 1.527 g. (6.63 mmoles) of the racemic acid XIa was dissolved in a solution of 40 ml. of ethanol and 150 ml. of water and heated on the steam-bath. A solution of 2.62 g. (6.63 mmoles) of anhydrous brucine in 50 ml. of ethanol was then added slowly to the hot solution. The cooled solution was allowed to evaporate slowly at room temperature and during several days seven successive crops of crystals were removed by alternate filtration and evaporation of the filtrate; 1.70 g. of the crude *l*-acid brucine salt, m.p. 135–144°, and 2.1 g. of the crude *d*-acid brucine salt, m.p. 110–120°, were recovered by this procedure.

Recrystallization of the first crop of crystals, 1.18 g., m.p. 142–144°, from dilute ethanol gave 800 mg. of purified *l*-2,4-diethyl-3-propylpentanedioic acid monobrucine salt, m.p. 142–143°. *Anal.* Calcd. for $C_{35}H_{48}N_2O_8 \cdot 2H_2O$: C, 63.61; H, 7.93; N, 4.24. Found: C, 63.80; H, 7.77; N, 3.94. To the salt, 800 mg., in 50 ml. of hot 10% ethanol, was added dilute ammonium hydroxide dropwise until a slight excess was present. The solution was chilled and the brucine filtered (450 mg.). The filtrate was acidified

(26) Authentic sample kindly supplied by Dr. Häusermann (ref. 6).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

with dilute hydrochloric acid and the oily acid crystallized on standing to yield 216 mg. of partly active *l*-2,4-diethyl-3-propylpentanedioic acid, m.p. 93–94°, $[\alpha]^{20}D$ −2.4° (*c* 10); 95% ethanol used as solvent for all rotations measured.

Fractional crystallization of the crude *d*-acid monobrucine salt gave 929 mg. of the purified salt as rectangular prisms, m.p. 114–121°. Regeneration of the *d*-acid from this sample in the manner used above for the *l*-acid gave 180 mg. of partly active *d*-2,4-diethyl-3-propylpentanedioic acid, m.p. 85–93°, $[\alpha]^{20}D$ 5.4° (*c* 11), and a second crop, 71 mg., m.p. 86–91°, somewhat more active, $[\alpha]^{20}D$ 11.0° (*c* 5).

Dehydration of 5,7-Dihydroxy-3-propyl-2,4,6-triethyl-1,5-heptanolactone.—A 41.9-g. (0.155 mole) sample of the lactone III was slowly distilled with a few crystals of iodine in a nitrogen atmosphere to yield 2.14 g. (0.119 mole) of water. The remaining residue was diluted with ether and washed with potassium hydroxide solution and water. After drying and distilling the ether, the following main fractions were obtained: (1) 3.5 g. of forerun, b.p. 60–134° (4.0 mm.); (2) 10.5 g. (27%) of crude C_{16}-unsaturated lactone mixture, b.p. 134–142° (4.0 mm.); (3) 1.0 g. of recovered III, b.p. 150–158° (1.3 mm.); and (4) 21 g. of residue. The crude lactone mixture was purified by extraction with *N* sodium hydroxide; b.p. 125–127° (0.5 mm.), $n^{25}D$ 1.4728; infrared bands at 3.37, 3.47, 5.64, 5.76, 6.84, 7.25m, 8.38, 8.85m, 9.25m, 10.40m and 11.1w μ.

Anal. Calcd. for $C_{16}H_{28}O_2$: C, 76.14; H, 11.18. Found: C, 76.03; H, 11.31.

On quantitative hydrogenation the unsaturated lactone mixture absorbed 1.0 mole-equivalent of hydrogen (platinum catalyst, one atm., 25°). On quantitative bromination (bromine in acetic acid), 0.68 mole-equivalent of bromine was absorbed. A Zerewitinoff determination showed 0.19 active hydrogen and 1.92 additional moles of methylmagnesium iodide reacted. Other acidic catalysts (sulfuric and phosphoric acids, aluminum oxide at 400°) were used to dehydrate III, but iodine distillation gave the best results.

A 4.83 g. (0.0192 mole) sample of the lactones in chloroform was ozonized using a slight excess of ozone. After removing the chloroform, the ozonide solution was decomposed with water, first at room temperature, then at reflux temperature while air was aspirated through the mixture. The exit vapors were passed through 2,4-dinitrophenylhydrazine reagent to yield 1.26 g. of precipitate, m.p. 85–150°. Fractional crystallization of this material gave (1) 0.74 g., m.p. 112–125°, and (2) 0.28 g., m.p. 135–140°. Recrystallization of the first fraction gave orange needles, m.p. 116–117°; melting point not depressed when mixed with an authentic sample of 2-butanone 2,4-dinitrophenylhydrazone, m.p. 117°. Several recrystallizations of the smaller second fraction gave orange platelets, m.p. 155–157°, identified as acetaldehyde 2,4-dinitrophenylhydrazone (mixture melting point with authentic sample, m.p. 157°, undepressed). Water-soluble, steam-volatile acidic material was isolated; 0.0108 equivalent total. By refluxing with mercuric oxide, 0.0036 equivalent of this acid was destroyed (formic acid, 19%).[3] The remainder of the acid, 0.072 equivalent (37.5%), gave Duclaux numbers, 8.5, 7.5 and 6.8 and a *p*-phenylphenacyl ester derivative, m.p. 106–114°, which could not be recrystallized to constant melting point. Acetic acid is believed to be the main constituent of this portion, with a small amount of higher molecular weight acid(s). Of the 1.26 g. of 2,4-dinitrophenylhydrazone derivative which precipitated, it is estimated from the above fractionation data that 0.0034 equivalent (18%) of 2-butanone and 0.015 equivalent of acetaldehyde (7.5%) were formed. Other ozonolysis products isolated were water insoluble and included 1.1 g. of a steam-volatile neutral oil, 0.37 g. of a neutral non-steam-volatile gum and 0.41 g. of an oily non-steam-volatile acid; none of these fractions could be crystallized, and they were not investigated further.[27]

7-Acetoxy-5-hydroxy-3-propyl-2,4,6-triethyl-1,5-heptanolactone.—A solution of 70.7 g. (0.0262 mole) of the lactone III in 150 ml. of acetic anhydride was treated with one drop of concentrated sulfuric acid and allowed to stand 15 hr. at room temperature, then heated on the steam-bath for 8 hr. After standing overnight and then treating with 2 g. of barium hydroxide, the material was distilled *in vacuo* to remove acetic acid and acetic anhydride. The residue was then filtered and the filtrate distilled twice to yield 63 g. (77%) of the colorless acetate, b.p. 158–162° (0.5 mm.), $n^{25}D$ 1.4662. By slowly distilling the acetate through a glass tube packed with glass wool (450°), low yields (10–20%) of unsaturated lactone were obtained.

Anal. Calcd. for $C_{18}H_{32}O_4$: C, 69.19; H, 10.33. Found: C, 69.57; H, 10.65.

(27) The above data suggest the unsaturated lactone mixture to consist mainly of the isomers

Steric Effects in Hydrolysis of Hindered Amides and Nitriles[1]

BY LIN TSAI,[2] T. MIWA[3] AND MELVIN S. NEWMAN[4]

RECEIVED JANUARY 29, 1957

The relative extent of alkaline hydrolysis in ethylene glycol at 190–192° of seven hindered aliphatic amides has been determined. The results are reasonably well correlated by the Rule of Six. Alkaline hydrolysis of hindered aromatic amides leads to the formation of nitriles. The acidic hydrolysis of hindered aliphatic nitriles to amides and the conversion of these amides to acids by sulfuric acid–sodium nitrite treatment is described.

Perhaps the most inclusive study of steric hindrance to carbonyl addition reactions in the aliphatic series is that involving the acid-catalyzed esterification. In this work the effect of structure on the rate of esterification with methanol of 26 saturated aliphatic acids was reported and discussed in terms of the Rule of Six and other variables.[5] However, the rates of esterification of highly sterically hindered acids could not be measured because the side reaction between the catalyst, hydrogen chloride and methanol became too important a factor when longer times and higher temperatures were needed for esterification. For example, diisopropylacetic acid esterified too slowly to measure under the general conditions used for the other acids. Accord-

ingly, we became interested in other reactions which might be studied quantitatively to yield information on highly hindered acid derivatives. We here report our observations on hydrolysis of highly hindered amides, both aliphatic and aromatic, and of hindered nitriles.

Because of experimental difficulties we were unable to devise a simple accurate procedure to measure the rate constants of alkaline hydrolysis of hindered amides. Experiments in which reactants were sealed in small stainless steel bombs equipped with closures using lead or gold gaskets failed because of leaks which developed erratically at the 190–210° temperatures needed for hydrolysis.[6] Accordingly, we turned to hydrolysis in ethylene glycol–alkali mixtures at atmospheric pressure. The extent of hydrolysis was estimated by titration of the ammonia evolved. The results are listed in Table I.

TABLE I

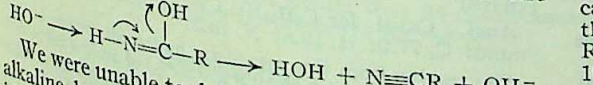
ALKALINE HYDROLYSIS OF HINDERED AMIDES IN ETHYLENE GLYCOL AT 190–192°

Amide	% NH_3 in 48 hr.	Six no.
1 $(C_2H_5)_4CCONH_2$	50.4	9
2 $(CH_3)_3CC(CH_2)_2CONH_2$	34.5	9
3 $[(CH_3)_2CH]_2CHCONH_2$	16.7	12
4 $[(CH_3)_3C](C_2H_5)CHCONH_2$	12.5	12
5 $[(CH_3)_3C][(CH_3)_2CH]CHCONH_2$	3.0	15
6 $[(CH_3)_2CH]_2(CH_3)CCONH_2$	2.4	12
7 $[(CH_3)_2CH]_2(C_2H_5)CCONH_2$	2.2	15

The over-all results are roughly what one would expect by application of the Rule of Six. In amides 6 and 7 we seem to be approaching a limit in steric hindrance, as the change from a methyl to an ethyl group in the α-position makes little difference, whereas in the acid series a similar change often makes a considerable difference (acids 12 and 24 in Table I).[5] We attach no significance to the small differences in ammonia obtained for amides 5, 6 and 7.

Turning to aromatic amides, we found that attempts to follow the alkaline hydrolysis in the ethylene glycol–alkali system used for the aliphatic mixtures revealed the presence of nitriles corresponding to the starting amides. Blank experiments in ethylene glycol alone (190–195°) showed that no nitrile was formed. Alkali is necessary for nitrile formation. We believe that this finding represents the first case of alkaline dehydration of an amide to a nitrile in solution.[7]

The transformation is pictured as a base-catalyzed elimination reaction of the enol form of the amide.



We were unable to detect a similar reaction in the alkaline hydrolyses of the hindered aliphatic amides mentioned above. Our results in the aromatic series are summarized in Table II.

TABLE II

ALKALINE TREATMENT OF HINDERED AROMATIC AMIDES IN ETHYLENE GLYCOL AT 195–197°

Amides	Moles of amide	NaOH–ethylene glycol (0.27 molal), g.	% nitrile (in 12 hr.)	% NH_3
Mesitamide	3.1×10^{-3}	100	56	0.6
2,3,5,6-Tetramethylbenzamide	2.9×10^{-3}	100	62	Trace
2,4,6-Triisopropylbenzamide	2.0×10^{-2}	650	58	0.7

In addition to the studies on alkaline hydrolysis of hindered amides, which was shown to be impractical on a kinetic basis, we have also studied the acid-catalyzed conversion of hindered amides to acids by nitrous acid.

In our study of acid hydrolysis of hindered aliphatic nitriles,[8] the nitrile was dissolved in an excess of strong sulfuric acid and held at specified temperatures for various times. The amide formed and nitrile unreacted were determined. The results of these experiments are summarized in Table III. Here again the increase in steric hindrance parallels the increase in six number. Since nitriles are in general somewhat less subject to steric hindrance than are amides, it is not surprising to find that nitriles of six number of 12 (nitriles 2 and 3, Table III) are hydrolyzed fairly well under rather drastic conditions. However, when the six number rises to 15 and 18 (nitriles 4 and 5, Table III), hydrolysis is extremely difficult and, from a practical point of view, unattainable under the prevailing conditions. Other attempts at higher and lower temperatures were even more unpromising.

In our study of the conversion of hindered amides to acids, we turned to treatment with nitrous acid in strong sulfuric acid solution, as previous work in the literature indicated that this procedure worked fairly well for moderately hindered amides.[9] Our results are summarized in Table IV. Although we did not include very highly hindered amides in this work (because we were unable to get sufficient quantities by hydrolysis of the required nitriles), we include the studies on the moderately hindered amides because this work shows that treatment with nitrous acid in strong sulfuric affords an excellent procedure for conversion to acids.

Experimental[10]

Mesitamide.—Mesitylene was brominated[11] to bromomesitylene which was converted to the Grignard reagent and carbonated to form the acid.[12] Treatment of the acid with thionyl chloride followed by ammonia furnished the amide. Recrystallization from benzene gave pure mesitamide, m.p. 192.0–193.5° (reported[13] m.p. 187–188°).

(6) Many of these experiments were performed by Dr. H. S. Eleuterio, post-doctoral fellow, 1953–1954.

(7) The conversion of benzamide to benzonitrile has previously been accomplished by fusion with lime. See (a) F. Wohler, *Ann.*, **192**, 362 (1878); (b) R. Anschütz and G. Schultz, *ibid.*, **196**, 48 (1879). We have checked this by converting mesitamide to mesitonitrile.

(8) The preparation of the hindered nitriles will be described in a forthcoming publication.

Found: C, 69.7; H, 11.7. [f] In this experiment, 9.5 g. of the nitrile was heated at 150° in 20.1 g. of 75% sulfuric acid and 8.5 g. of acetic acid for 1.5 hr. After the reaction mixture was cooled, 10 g. of sodium nitrite was added. [g] A. Byers and W. S. Hickinbottom, *J. Chem. Soc.*, 1334 (1948). [h] A. A. Sacks and J. G. Aston, THIS JOURNAL, **73**, 3902 (1951), reported the following physical constants for this acid: b.p. 122.5–123.8° (22 mm.), $n^{20}D$ 1.4343.

2,3,5,6-Tetramethylbenzamide (m.p. 187–188°, reported[14] m.p. 178°) was obtained in a similar manner from durene.

Anal. Calcd. for $C_{11}H_{15}ON$: N, 7.9. Found: N, 7.9.

2,4,6-Triisopropylbenzamide (m.p. 216.5–219.5°, reported[15] m.p. 218.7–219.3°) was similarly prepared from 1,3,5-triisopropylbenzene.

***t*-Butylethylacetamide.**—A mixture of 50.4 g. of *t*-butylethylacetic acid[16] (m.p. 76–78°) and 50 g. of thionyl chloride was allowed to stand overnight at room temperature and then heated at 90° for 4 hr. The reaction mixture was distilled twice through a fractionation column to give 51.8 g. (91%) of pure *t*-butylethylacetyl chloride, b.p. 67–69° at 25 mm. The acid chloride was poured into an ethereal solution of ammonia to give the crude amide which was recrystallized from a mixture of benzene–Skellysolve B (petroleum ether, b.p. 65–69°) to furnish 44.8 g. (98%) of *t*-butylethylacetamide, m.p. 136.6–137.2°.[17]

Anal. Calcd. for $C_8H_{17}ON$: C, 67.1; H, 11.9; N, 9.8. Found: C, 67.2; H, 12.2; N, 9.8.

***t*-Butylisopropylacetonitrile and *t*-Butylisopropylacetamide.**—To a solution of sodium ethoxide (prepared from 23 g. of sodium in about 400 ml. of absolute ethanol) was introduced 169 g. of ethyl *t*-butylcyanoacetate[18] and 190 g. of isopropyl iodide. The mixture was heated under reflux for 15 hr. The solvent was removed by distillation under reduced pressure. The residue was taken up in 200 ml. of water and extracted several times with benzene–ether mixture. The combined extracts were successively washed with sodium hydrosulfite, sodium hydroxide and saturated sodium chloride solutions and dried over magnesium sulfate. After removal of the solvent under reduced pressure, the residual liquid was fractionated at 18 mm. pressure to afford 64.5 g. (38%) of unchanged ethyl *t*-butylcyanoacetate, b.p. 110–113°, and 89.0 g. (42%) of ethyl *t*-butylisopropylcyanoacetate, b.p. 128–132°.

A mixture of ethyl *t*-butylisopropylcyanoacetate (75 g.) and 150 g. of potassium hydroxide was fused and distilled. The distillate was again fused with 100 g. of potassium hydroxide and distilled. Fractionation of the distillate afforded 22.2 g. (45%) of *t*-butylisopropylacetonitrile, b.p. 178–181°.

Anal. Calcd. for $C_9H_{17}N$: C, 77.6; H, 12.3; N, 10.1. Found: C, 77.0; H, 12.8; N, 10.2.

The residue from the potassium hydroxide fusion on taking up in water furnished 12.9 g. (23%) of an insoluble solid which was recrystallized from benzene–Skellysolve B to give pure *t*-butylisopropylacetamide, m.p. 124.8–125.6°.

Anal. Calcd. for $C_9H_{19}ON$: C, 68.7; H, 12.2; N, 8.9. Found: C, 68.8; H, 12.0; N, 8.9.

Alkaline Hydrolysis of Hindered Aliphatic Amides.—The solvent used in these experiments was ethylene glycol (b.p. 196–198°) which was purified by refluxing with 2 g. of sodium (per liter of solvent) for several hours and distilling.

A solution of sodium hydroxide in ethylene glycol was prepared by mixing an appropriate amount of carbonate-free 40% sodium hydroxide solution with ethylene glycol. The concentration of sodium hydroxide in the solution was determined by titration of weighed aliquots, after diluting 10-fold with distilled water, against standard sulfuric acid using phenolphthalein as indicator.

The hydrolysis of the amide was carried out in a 3-necked flask equipped with a reflux condenser, a thermometer and an inlet for nitrogen gas which was bubbled slowly through the reaction mixture. The outlet of the reflux condenser was led into a known volume of standard sulfuric acid solution which served as an absorption system for ammonia. The reaction flask was heated by a heating mantle and the temperature was controlled by a Thermocap relay.[19]

A weighed amount of a 0.5 molal solution of sodium hydroxide in ethylene glycol was placed in the reaction flask. The temperature of the system was brought rapidly to 190–192°, and a weighed amount of amide ($^1/_{20}$ of the molar concentration of sodium hydroxide in the solution) was introduced.

The condenser and the absorption system was immediately connected to the reaction flask. Ammonia evolved during the course of the reaction was entrained by the stream of nitrogen and absorbed in the standard sulfuric acid solution. After 48 hr. the reaction was stopped and the amount of ammonia from the hydrolysis was estimated by titration of the excess acid against standard sodium hydroxide solution using as indicator screened methylene blue–methyl red. The results are shown in Table I.

Reaction of Hindered Aromatic Amides with Sodium Hydroxide in Ethylene Glycol.—A procedure similar to that described for the hydrolysis of aliphatic amides was employed. After the formation of nitrile was observed in preliminary experiments, the apparatus was modified by replacing the reflux condenser by a distilling condenser. The nitrile formed during the course of the reaction was removed from the reaction mixture by co-distillation with ethylene glycol. The reaction was carried out for 12 hr. during which about 10% of the reaction mixture was distilled. The amount of ammonia evolved was determined by titration. The nitrile was isolated from the distillate.

Mesitonitrile (m.p. 50°, reported[20] m.p. 53°) was purified by sublimation at 40° and 0.1 mm. pressure. The infrared spectrum (chloroform solution) showed an intense band at 4.6 μ (2170 cm.$^{-1}$) due to the nitrile function.[21] In one experiment, an intimate mixture of 0.30 g. of mesitamide and 2.8 g. of powdered sodium hydroxide was heated at 290–310° under 20 mm. pressure for 0.5 hr. Mesitonitrile (m.p. 49°) was obtained in 86% yield.

2,3,5,6-Tetramethylbenzonitrile (m.p. 73–74°, reported[22] m.p. 76–77°) was purified by sublimation at 50° and 0.08 mm. pressure. The infrared spectrum (chloroform solution) showed an intense band at 4.6 μ (2170 cm.$^{-1}$).

2,4,6-Triisopropylbenzonitrile was purified by chromatography of the crude substance in redistilled Skellysolve F (petroleum ether, b.p. 35–55°) over activated alumina. The solvent was removed under reduced pressure at room temperature. The residue was distilled to afford a pure sample of the nitrile, b.p. 264–268° at 740 mm., n^{20}D 1.5089 (lit.[15] n^{20}D 1.5093). Physical properties and the infrared spectrum of this nitrile were identical with those of a sample of the nitrile obtained by the dehydration of 2,4,6-triisopropylbenzamide by means of thionyl chloride in benzene solution. The results are summarized in Table II.

Acidic Hydrolysis of Hindered Aliphatic Nitriles.—A mixture of the nitrile[8] and sulfuric acid of known concentrations was heated at a specific temperature. After a certain period of heating, the reaction mixture was poured into a large excess of ice-water, and the mixture was worked up by the usual method of extraction. The extent of hydrolysis of the nitrile was indicated by the yield of the amide and the amount of recovered nitrile. The conditions and results of these experiments are summarized in Table III.

Conversion of Aliphatic Amides to Acids.—The amides were treated with a mixture of sodium nitrite and sulfuric acid according to procedures described in the literature.[9] The conditions and results are shown in Table IV.

(19) Niagara Electronic Laboratories, Andover, N. Y. This instrument controlled the supply of electrical power to the heating system. The change of electric capacity necessary for the operation of this type of relay was effected by the movement of the mercury thread in the thermometer to which the relay lead was connected.

The Synthesis and Solvolysis of the 2-Halo-1,4-endoxocyclohexanes[1]

BY JAMES C. MARTIN[2] AND PAUL D. BARTLETT

RECEIVED DECEMBER 17, 1956

A kinetic study of the hydrolysis of *exo*-2-chloro-1,4-endoxocyclohexane has shown it to be less reactive than *exo*-norbornyl chloride by a factor of approximately 2000. Its relative inertness is considered to result from the inductive effect of the oxygen bridge, enhanced by its geometric situation. Solvolysis of *endo*-2-chloro-1,4-endoxocyclohexane was slower than that of its *exo* isomer by a factor of 160 (at 140°). This factor is of the same order of magnitude as the corresponding factor in the solvolysis of norbornyl derivatives suggesting that the anchimeric acceleration of ionization of the *exo*-2 substituent is not greatly affected by substitution of an oxygen bridge for the methylene bridge of the norbornyl derivatives. In every case the solvolysis product was that expected to result from rearrangement, 3-formylcyclopentanol. The structures of these chloro ethers, which were obtained from the photochlorination of 1,4-endoxocyclohexane, were confirmed by dipole moment studies. *exo*-2-Bromo-1,4-endoxocyclohexane, isolated from the N-bromosuccinimide bromination of the parent ether, showed a reactivity 30-fold greater than its chloro analog. An interesting side product (16%) isolated from this bromination reaction was β-bromopropionyl isocyanate.

Introduction

A large amount of work of a quantitative nature has been performed on the solvolytic reactions of the various norbornyl derivatives.[3] In the frame of understanding created by this work we have examined the chemical consequences of the replace-

ment of the 1,4-endomethylene bridge of the norbornyl system by the oxygen bridge of the 1,4-endoxocyclohexane system.

Results and Discussion

The photochlorination of 1,4-endoxocyclohexane at −40° led to the isolation of a series of chloro ethers including *exo*-2-chloro-1,4-endoxocyclohexane and *endo*-2-chloro-1,4-endoxocyclohexane. Infrared analysis showed the *exo* isomer to be formed in amount 2.2 times that of the *endo* isomer. None of the α-chloro ether, 1-chloro-1,4-endoxocyclohexane, which would result from bridgehead chlorination, was isolated. This is in accord with previously reported[4] unsuccessful attempts to obtain bridgehead chlorination in other systems.

The bromination of the parent ether, 1,4-endoxocyclohexane, with N-bromosuccinimide yielded *exo*-2-bromo-1,4-endoxocyclohexane.

These monohalo ethers were separated and purified by fractional distillation. The more highly chlorinated ethers resulting from further treatment with chlorine were separated by means of chromatography on alumina. A summary of the pure compounds isolated is presented in Table I.

TABLE I

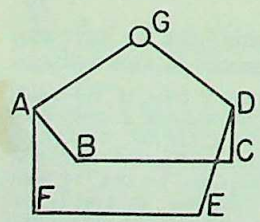
PRODUCTS OF THE HALOGENATION OF 1,4-ENDOXOCYCLOHEXANE

Ether	M.p. or b.p. °C.
endo-2-Chloro-1,4-endoxocyclohexane	68.0 (27)[a]
exo-2-Chloro-1,4-endoxocyclohexane	48.0 (4)[a]
exo-2-Bromo-1,4-endoxocyclohexane	68.2 (2)[a]
Dichloro ether	143.2–144.0
Trichloro ether	154.5–145.8
Tetrachloro ether	77.8–78.8
Hexachloro ether	108.6–109.0
Octachloro ether	158.8–159.4

[a] The value in parentheses refers to pressure (mm.).

The constraint afforded by the bicyclic structure of this series of halo ethers maintains quite constant the angles between the various bonds and, therefore, the angles between the bond moments. This greatly facilitates the interpretation of dipole moment data. If one considers the composite electric moment of the unsubstituted 1,4-endoxocyclohexane to be a vector directed toward the oxygen atom and perpendicular to the plane of carbon atoms 2, 3, 5 and 6, the effect of superposing moments arising from replacement of the various hydrogen atoms by halogen may be computed.

A geometric model for the bicyclic nucleus of this system was derived using vector analytical procedures.[5] The model chosen for these calculations used a value for the C–C bond length of 1.55 Å. and for the C–O bond length, 1.44 Å. The values of the angles in this model were: ∠ FAB = 101°, ∠ ABC = 103°, ∠ AGD = 102° 54′ and ∠ BAG = 101° 14′.



The theoretical dipole moments were calculated as the resultant of the ether dipole moment (the experimental moment of 1,4-endoxocyclohexane, 1.74 *D*) and the C–Cl bond moment (the experimental moment of cyclopentyl chloride, 2.08 *D*)[6].

TABLE II

RESULTS OF DIPOLE MOMENT STUDIES ON THE MONOHALO-1,4-ENDOXOCYCLOHEXANES

Compound	Solvent	Moment, *D* Calcd.	Found
1,4-Endoxocyclohexane	Benzene	..	1.70
	CCl_4	..	1.78
1-Chloro-1,4-endoxocyclohexane	.....	3.20	..
exo-2-Chloro-1,4-endoxocyclohexane	Benzene	3.17	3.07
	CCl_4	3.17	2.99
endo-2-Chloro-1,4-endoxocyclohexane	Benzene	0.82	1.08
exo-2-Bromo-1,4-endoxocyclohexane	CCl_4	3.17	3.03

These data make it clear that the assignment of structure for *endo*-2-chloro-1,4-endoxocyclohexane is the correct one. The data for the other chloro ether are compatible with either *exo*-2-chloro-1,4-endoxocyclohexane or 1-chloro-1,4-endoxocyclohexane. The isolation of 3-formylcyclopentanol (V) as the solvolysis product from both of the chloro ethers confirmed the assignment of the structure *exo*-2-chloro-1,4-endoxocyclohexane. The structure of the bromo ether was similarly shown to be *exo*-2-bromo-1,4-endoxocyclohexane. The hydroxyaldehyde was formed nearly quantitatively in the solvolyses of all three of these halo ethers. The structure 3-formylcyclopentanol was established by Wolff–Kishner reduction to the known[7] *trans*-3-methylcyclopentanol.

The assigned structures for these halo ethers were found to be compatible with the observed infrared spectra and proton nuclear magnetic resonance (NMR) spectra. The NMR spectra, obtained using a Varian Associates model V-4300B high resolution spectrograph, are schematically summarized in Fig. 1.

The parent ether, 1,4-endoxocyclohexane, shows two resonance peaks, of approximate relative intensities 4 and 1, at positions corresponding to Gutowsky δ-values[8] of approximately −0.43 and −0.10 (the methylene and the bridgehead hydrogens, respectively). No evidence of splitting, from spin-spin interaction, was observed for either of these peaks.

The spectra of the *exo*-2-halo-1,4-endoxocyclohexanes show a total of four main resonance peaks corresponding, presumably (in order of increasingly negative δ-values), to the bridgehead hydrogens (intensity 2), the halomethylene hydrogen (1), the methylene adjacent to halomethylene (2) and the other two methylene groups (4). The positions of these peaks are expressed as δ-values: *exo*-chloride, (−0.10, −0.15, −0.37, −0.43); *exo*-bromide (−0.10, −0.15, −0.35, −0.43). The peak at 0.10 is a poorly resolved doublet, as might be expected from the non-equivalence of the bridgehead hydro-

15	*endo*-Cl	.03610[d]	140.0	44.2	HCl	.02	Autocatalytic
16	*endo*-Cl	.03312[d]	140.0	19.6	KCl	.02	Autocatalytic

[a] These first-order rate constants were determined by a least squares treatment of the data. The uncertainties which are indicated are standard deviations. [b] In 80% ethanol (vol.). [c] In 80% ethanol (wt.). [d] In 50% dioxane (wt.).

gens because of the halogen at position 2. The halomethylene hydrogen resonance at −0.15 is strongly split into a triplet, presumably from spin–spin interaction with the protons of the neighboring methylene. The resonance of this neighboring methylene, at −0.37 or −0.35, appears as a doublet, as expected from such an interaction.

The *endo*-chloride shows a similar spectrum with an additional poorly resolved peak, of intensity approximately 1, at −0.32, possibly to be attributed to a transannular interaction of an *endo*-hydrogen at position 6 with the *endo*-chlorine. In addition, there is some evidence of splitting in the methylene peak at −0.43. The positions of the resonance peaks for this compound are (−0.05, −0.12, −0.32, −0.37, −0.43).

Results of kinetic studies on the solvolytic reactions of these ethers are outlined in Tables III and IV. The reactions were followed by acidimetric titration of aliquots.

A direct comparison of the rate constants for the *exo*- and *endo*-2-chloro-1,4-endoxocyclohexanes at 140° in 50% dioxane–water gives a reactivity ratio of 163 for these isomers, the *exo* isomer being the more reactive. Table V gives calculated values for this ratio from the present work, the work of Roberts and the work of Winstein. It can be seen that this ratio is not changed greatly in the 1,4-endoxocyclohexane system from its value in the norbornyl system.

The calculated value (from ΔH^* and ΔS^*) of the rate constant for the solvolysis of *exo*-2-chloro-1,4-endoxocyclohexane in 50% aqueous dioxane at 85.0° is 1.88 × 10^{-7} sec.$^{-1}$. The value of the rate constant for the solvolysis of the corresponding bromo ether is decreased by a factor of 9.6 when the solvent is changed from 50% dioxane–water to 80% (by weight) dioxane–water. Assuming a parallel

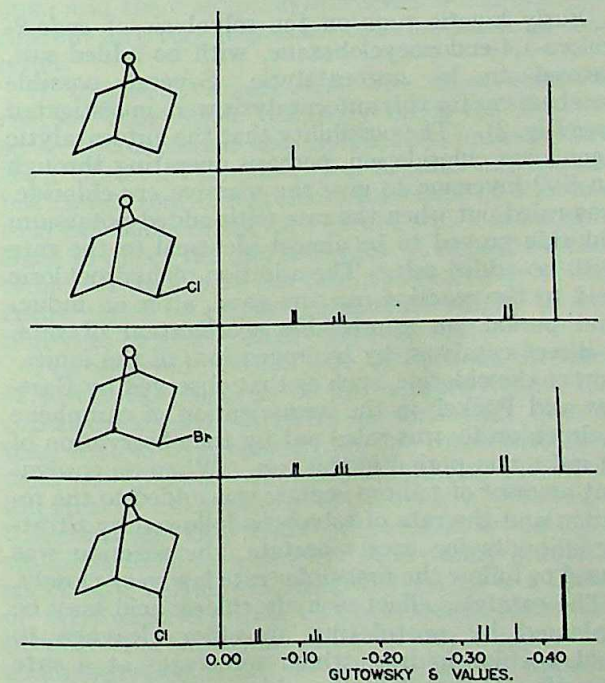

Fig. 1.—Proton nuclear magnetic resonance spectra of 1,4-endoxocyclohexane derivatives.

Digitized by Arya Samaj Foundation Chennai and eGangotri

change in the rate constant for the chloro ether in these two solvents, one calculates a rate constant for the *exo*-chloride at 85.0° in 80% (by vol.) ethanol of 1.96×10^{-8} sec.$^{-1}$. Under these same conditions Roberts[3b] found a rate constant of 3.89×10^{-5} sec.$^{-1}$ for *exo*-norbornyl chloride.

Comparison of these values for the two bicyclic systems shows the norbornyl chloride to be more reactive than its oxygen-bridged analog by a factor of 2.0×10^{3}. A similar calculation for the *endo* isomers gives a factor of 6.0×10^{3}.

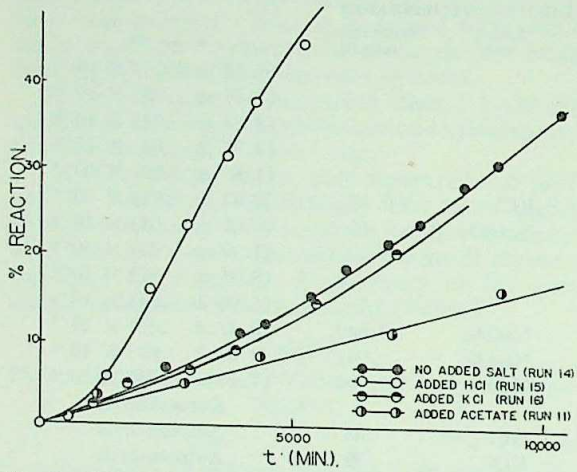

Fig. 2.—Solvolysis of *endo*-2-chloro-1,4-endoxocyclohexane in 50% dioxane–water (by weight) at 140°.

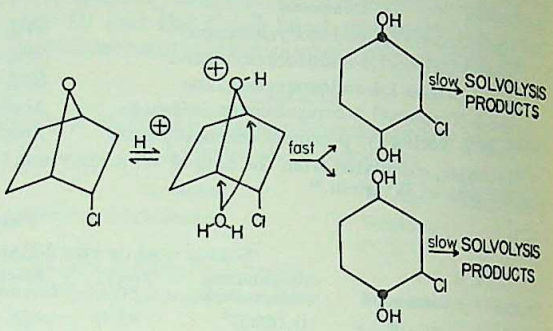
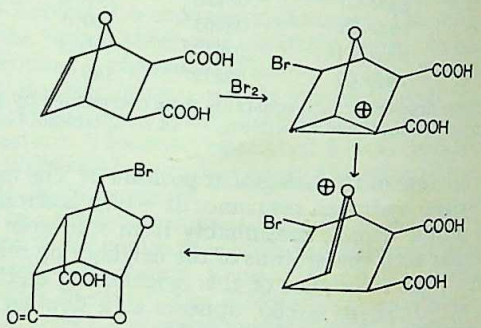
Early kinetic runs on the solvolysis of *endo*-2-chloro-1,4-endoxocyclohexane, with no added salt, proved to be autocatalytic. Several possible mechanisms for this autocatalysis were investigated (see Fig. 2). The possibility that the autocatalytic agent was chloride ion, perhaps operating through an SN2 inversion to give the reactive *exo*-chloride, was ruled out when the rate with added potassium chloride proved to be almost identical to the rate with no added salt. The addition of hydrochloric acid to the reaction mixture gave, after an induction period, an appreciable acceleration of rate. A direct catalysis, by hydrogen ion, of the ionization of the chloride, such as that observed by Bartlett and Pöckel[9] in the isomerization of camphene hydrochloride, was ruled out by the observation of an induction period in this run. When an equivalent amount of sodium acetate was added to the reaction and the rate of solvolysis followed by titrating aliquots for excess acetate, the reaction was found to follow the first-order rate law very closely.

The catalytic effect of hydrochloric acid may be explained by postulating an ether cleavage to yield a chlorohydrin, which solvolyzes at a rate somewhat faster than the chloro ether. In a related case[3a] the solvolysis of 2-chloro-2-methylpropanol-1 is slower than that of *t*-butyl chloride by a factor of 6.5×10^{-3}. Since *endo*-2-chloro-1,4-endoxocyclohexane is approximately 10^{-4} as reactive as cyclohexyl chloride in solvolytic reactions, we might expect the chlorohydrin from the ether cleavage to be about 60–70 times as reactive as the chloro ether itself. Such a ratio of reactivities could account for the observed behavior.

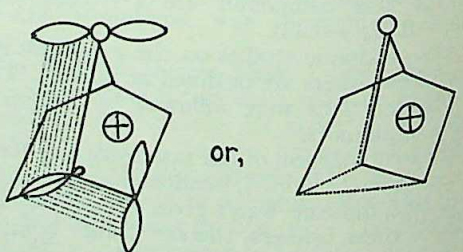


Two different interactions of the unshared electron pairs of the oxygen bridge might be expected to affect the *exo*/*endo* reactivity ratio in these solvolytic reactions.

With regard to the first of these effects, Woodward and Baer[10] postulated an important contribution from the oxonium form of the positively charged intermediate ion as a driving force in the rearrangement which accompanies the addition of bromine to *exo-cis*-3,6-endoxo-Δ^4-tetrahydrophthalic acid.



In the present work we must consider the possible stabilization, by such an oxonium form, of the transition state leading to the positive ion. Any such stabilization involves an interaction between a lone pair orbital of oxygen, the bonding orbital between C_1 and C_6 and the developing p-orbital at C_2, where the leaving group is *exo*.



Since the observed *exo*/*endo* ratio is of the same order of magnitude for the endoxo- and endomethylene series, it is unnecessary to postulate an important contribution of this oxonium form in the transition state. Once the ion is formed, however, slight changes in geometry, perhaps over a very small potential energy barrier, might be expected

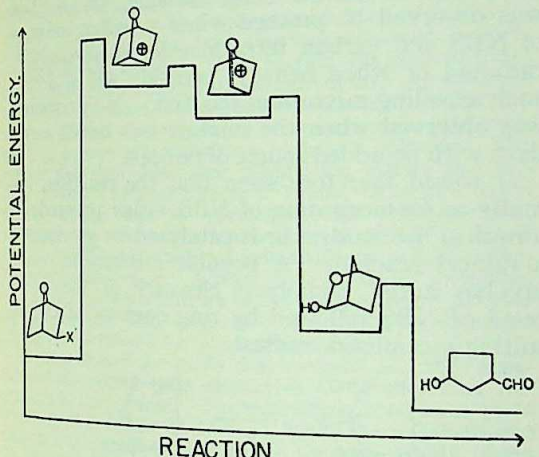
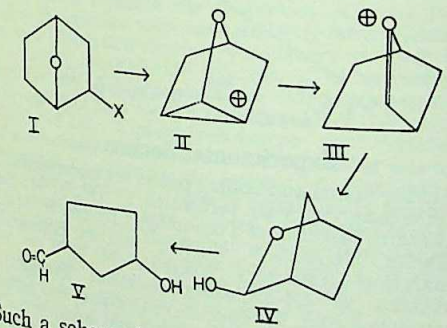
	25	318	1.2×10^{-13}

to twist the molecule into a form much more favorable to overlap between oxygen lone pair orbitals and a p-orbital on C_1. The large stabilization so attained would be similar to that in the transition states for the ionizations of α-halo ethers.

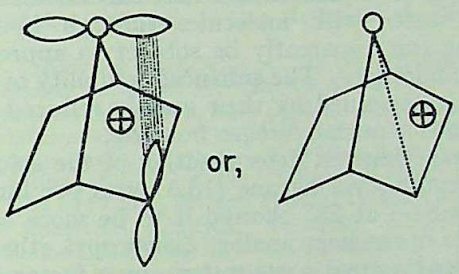


A POSSIBLE POTENTIAL ENERGY SCHEME.



Such a scheme is compatible, but of course not uniquely so, with the observed isolation of rearranged product (as aldehyde) in nearly quantitative yield. It is also compatible with results of experiments designed to intercept the cationic intermediate with azide ion. According to Swain[11] the azide ion is a more active nucleophile than water by a factor of 10^4 to 10^5. In his kinetic treatment of interception experiments using azide ion, Swain considered the alkyl azide to be formed irreversibly where the alkyl group was, for example, triphenylmethyl. In the present work solvolyses with 0.6 *N* added azide (sufficient, using Swain's competition factor, to capture more than 99% of the carbonium ions in competition with water), the product obtained was 3-formylcyclopentanol with less than 3% of an alkyl azide. A possible explanation for this unexpected behavior would involve an attack of azide ion either on II or on III, which is formed very rapidly from II, to give the α-azido ether which is then subject to hydrolysis to 3-formylcyclopentanol.

A second effect to be ascribed to the lone pair electrons might be classified as a homoallylic interaction—a direct interaction between the developing p-orbital at the ionizing center and a lone pair orbital. The situation is superficially similar to that which gave rise to a rate acceleration of 10^{11} in the solvolysis of *anti*-7-dehydronobornyl tosylate.[3k,1] In that system the interaction is between a developing p-orbital at C_7 and the π-electron system of C_2 and C_3. In the present system we might postulate a lesser, but perhaps still substantial, interaction between the developing p-orbital at C_2 and a lone pair orbital on oxygen. The result of such an interaction would be an acceleration of the rate of ionization of an *endo* substituent.



Again, the failure to observe any major difference in the *exo/endo* reactivity ratios for the endoxo and the endomethylene series would seem to rule out any very important contribution from this effect.

It might be argued that the observation of roughly comparable reactivity ratios for the two series of compounds does not, in fact, indicate that these effects are inoperative or of small importance but rather that it represents the result of a fortuitous cancelling of the two effects, which are postulated to affect the *exo/endo* ratio in opposite directions. If such were the case, the reactivity of the entire series of endoxo compounds might be expected to be greater than that observed.

The observed factor of 6×10^3 between the rates of solvolytic reactions of the norbornyl and 1,4-endoxocyclohexyl chlorides is somewhat greater than that to be expected from the consideration of model compounds[12] or that predicted by the dipole interaction calculations of Winstein.[13,14] Winstein concludes that the rate depression in acetolysis reactions to be expected from the purely inductive effect of a neighboring methoxy group is a factor of approximately 100. The observed difference between the solvolysis rates of the endoxo and endomethylene series of compounds is approximately 60 times greater than this.

In the 1,4-endoxo compounds the ether bridge corresponds not only to a β-alkoxy group but also to a γ-alkoxy group relative to substituents at the 2-position. This statement is equivalent to a

recognition that the orientation of the over-all ether dipole is fixed in such a manner as to increase the effectiveness of its interaction with dipoles at the 2-position.

A somewhat similar situation is discernible in data on the acid dissociation constants of conjugate acids of amines.[15]

Amine	pK_{AH} (25°)
Ethylamine	10.81
β-Methoxyethylamine	9.45
Morpholine	8.70
Piperidine	11.28

The pK_{AH} for ethylamine exceeds that for β-methoxyethylamine by 1.36 units, whereas the difference in the corresponding constants for the two cyclic amines is 2.58.

Another possible explanation for the enhanced inductive effect of the oxygen bridge lies in a consideration of the solubilities of ethers in water. Ferguson[16] has pointed out that the association of liquid water with molecules through hydrogen bonding can apparently be subject to appreciable steric hindrance. The enhanced solubility of cyclic ethers is explained by their greatly reduced steric hindrance to such hydrogen bonding.

An experimental determination of the solubility of 1,4-endoxocyclohexane (10.5 parts per hundred parts water) at 25° showed it to be more soluble than its open-chain analog, diisopropyl ether (0.2 parts per hundred parts water), by a factor of approximately 50.

If this increased solubility may be attributed to increased effectiveness of hydrogen bonding of the ether with water, an individual molecule of the bicyclic ether, in aqueous solution, would be much more likely to be involved in a hydrogen bonded association than an acylic ether. In the rate studies of this work one might expect such hydrogen bonding to deactivate the molecule toward an ionization which would place a positive charge on the bicyclic nucleus.

The most straightforward interpretation of the present results, therefore, would postulate the principal effect of the oxygen bridge on solvolysis rates to be a simple inductive effect. Any resonance effects of this oxygen would seem to be relatively unimportant in the transition states of such reactions.

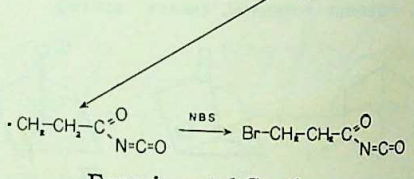
As a side-product in the photochemical bromination of 1,4-endoxocyclohexane with N-bromosuccinimide (NBS), an appreciable yield (*ca.* 15%) of β-bromopropionyl isocyanate was isolated. The material, isolated by distillation at reduced pressure (b.p. 53–56° (2 mm.)), showed an infrared absorption peak at 4.45 μ, an absorption characteristic of organic isocyanates. It reacted vigorously with water to evolve one mole of carbon dioxide and yield crystalline β-bromopropionamide. The identity of the material was further established by comparison of its infrared spectrum and reactivity toward water with that of a sample of β-bromopropionyl isocyanate prepared by the reaction of β-bromopropionyl chloride and silver cyanate.

$$AgCNO + RCOCl \longrightarrow RC(=O)-N=C=O + AgCl$$

The formation of isocyanate was also observed in the absence of 1,4-endoxocyclohexane when a boiling suspension of NBS in carbon tetrachloride was strongly irradiated. The yield, followed by observation of the infrared absorption at 4.45 μ, was small but definite, reaching a maximum after about 24 hr., then disappearing as heating and irradiation were continued. This is compatible with the observed instability of β-bromopropionyl isocyanate.

The reaction of N-bromosuccinimide to give the isocyanate was found to proceed only under those conditions generally conceded to be favorable to radical mechanisms. For example, the reaction was observed to proceed when a boiling mixture of NBS and carbon tetrachloride was strongly irradiated or when benzoyl peroxide was added to such a boiling mixture in the dark. No isocyanate was observed when the mixture was boiled in the dark with no added source of radicals.

It would therefore seem that the reaction, formally an isomerization of NBS, either proceeds by a radical mechanism or is catalyzed by products of a radical reaction. A possible mechanism would involve initial homolytic cleavage of the N-Br bond of NBS followed by ring opening of the resulting succinimide radical.



Experimental Section

All melting points and boiling points are uncorrected.

The microanalyses were performed by Dr. S. M. Nagy, Massachusetts Institute of Technology; by Dr. H. Manser, Eidg. Techn. Hochschule, Zurich; and by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y.

Chlorination of 1,4-Endoxocyclohexane: Procedure.—The starting material, 1,4-endoxocyclohexane, was prepared after the manner of Fehnel, Goodyear and Berkowitz.[17] It was purified by distillation through a 100-cm., vacuum jacketed column packed with glass helices. The product showed b.p. 119–119.5° (766 mm.), $n^{20}D$ 1.4480; infrared spectrum (letters refer to intensity—strong, medium or weak; wave length in μ): 3.39s, 3.45m, 3.50m, 6.81m, 6.90m, 7.59m, 7.69m, 7.94s, 8.39s, 8.77w, 9.11w, 9.31m, 10.01s, 10.27m, 10.72s, 11.05m, 11.40s, 12.18s, 12.71m, 13.12w.

The chlorinations were carried out in a reaction vessel fitted with a fritted-glass gas dispersion tube. The reaction vessel was immersed in a cooling bath of Dry Ice in acetone in an unsilvered Dewar flask. This permitted the irradiation of the reaction mixture with a sunlamp at a distance of about 4 in. The chlorine was measured by condensing it into a calibrated Pyrex trap and measuring its volume at the boiling point (where its density is 1.56 g./ml.). As the chlorine evaporated it was carried from this trap in a stream of dry nitrogen (Airco Prepurified Nitrogen), through a phosphorus pentoxide drying tower and into the reaction vessel through a gas dispersion tube. Any unreacted chlorine

which was carried through the reaction vessel was condensed in a trap at −78°. This chlorine was distilled back into the first trap in the system and recirculated until all of it was used. A loss of chlorine through the final trap became obvious in some of the longer experiments. Each section of this apparatus was suitably protected from suck-back of liquids by interposition of a reversed trap. All of the traps were of approximately 250-ml. capacity. All of the connections in this apparatus were either of Pyrex glass or Tygon tubing. The lamp was a General Electric sunlamp.

The Monochloro Isomers.—In a typical experiment, 1,4-endoxocyclohexane (190 g., 1.94 moles) was placed in a 250-ml. reaction tube in the chlorination system described above and cooled to −22° in a Dry Ice–carbon tetrachloride-bath. To this solution 137 g. (1.94 moles) of chlorine was added slowly, in a stream of nitrogen, through the gas dispersion tube. The mixture was irradiated during this addition by a sunlamp. The chlorine was added in about 1 hr., and the small amount of chlorine from the exit trap was passed again into the reaction vessel. A moderate flow of nitrogen was maintained throughout the reaction to promote stirring and to remove hydrogen chloride formed in the reaction. After 3 hr. all the chlorine was consumed, as indicated by the loss of color. The reaction was allowed to return to room temperature as the stream of nitrogen was continued for 2 hr. more. The crude reaction mixture (260 g.) was then allowed to stand over moist sodium carbonate overnight to destroy any remaining hydrogen chloride. The mixture was then dried over magnesium sulfate and distilled through a 19-plate column at 1 mm. A large fraction distilled at less than 30° (principally the starting ether, 108.0 g.). A second fraction boiling at 30–37° weighed 15.9 g. (6.2%) and consisted principally of *endo*-2-chloro-1,4-endoxocyclohexane. A fraction, b.p. 37–40°, weighing 9.29 g. (3.7%) was a mixture of the two isomers. Another fraction, b.p. 40–43°, weighing 73.0 g. (28.4%) was principally *exo*-2-chloro-1,4-endoxocyclohexane.

The two isomers are easily differentiated and their separation followed by their distinctive C–Cl stretching frequencies in the infrared. The *endo* isomer absorbs at 14.25 μ and the *exo* isomer at 14.5 μ. Since the unsubstituted ether is transparent to radiation in the wave length region 14–16 μ and each of the two monochloro isomers has a well-defined absorption peak in a different part of this region, it was possible to estimate the proportion of these isomers formed in the reaction more accurately by infrared analysis.

The two absorption maxima were shown to obey Beer's law in carbon tetrachloride solution. The extinction coefficient for the 14.25 μ peak of the *endo* isomer was found to be larger than that for the 14.50 μ peak of the *exo* isomer by a factor of 2.1. The analysis was run on the crude product of a chlorination reaction in which the ether was used in sixfold excess to minimize the amount of polychlorination. By comparison of the two (nearly equal) peaks representing the two monochloro ethers, the *exo* isomer was found to be present in quantity 2.2 times as great as the *endo* isomer.

The two monochloro isomers were purified by redistillation. The *endo* isomer boiled at 68° (27 mm.), $n^{25}D$ 1.4780, d_{25} 1.1833; Infrared spectrum (wave length in μ): 3.39s, 3.46w, 3.54w, 6.84m, 6.93m, 7.56w, 7.62m, 7.69m, 7.91m, 8.03s, 8.33w, 8.45s, 8.71m, 9.04m, 9.33w, 9.65m, 10.05s, 10.57s, 10.93w, 11.55m, 12.06m, 12.39s, 12.75s, 13.11s, 14.25s.

Anal. Calcd. for C_6H_9OCl: C, 54.32; H, 6.84; Cl, 26.74. Found: C, 54.51; H, 6.81; Cl, 27.4 (Stepanov determination).

The *exo* isomer boiled at 48.0° (4 mm.), $n^{25}D$ 1.4847, d_{25} 1.1927; infrared spectrum (wave length in μ): 3.39s, 3.52m, 6.84m, 6.95m, 7.61w, 7.75m, 7.81m, 7.91m, 7.97m, 8.04m, 8.24m, 8.33m, 8.40s, 8.70w, 8.86m, 9.30m, 9.55s, 9.76m, 10.00s, 10.18m, 10.63s, 10.95m, 11.03m, 11.29s, 11.84m, 12.25s, 12.53m, 13.03m, 14.50m.

Anal. Calcd. for C_6H_9OCl: C, 54.32; H, 6.84; Cl, 26.74. Found: C, 54.08; H, 6.62; Cl, 27.0 (Stepanov determination).

Dichloro-1,4-endoxocyclohexane.—*exo*-2-Chloro-1,4-endoxocyclohexane (10 g., 0.075 mole) in a small reaction tube equipped with a gas dispersion tube was placed in a chlorination train similar to the one described above except that smaller traps were used in order to reduce the volume of the system. The ether was treated with one equivalent of chlorine (5.4 g., 3.4 ml.) at −22°, with irradiation. After reaction was complete (1 hr.), the reaction was warmed to 30° with nitrogen scrubbing for 2 hr. The 11.32 g. of material yielded 2.4 g. (19%) of crystalline material on cooling in a refrigerator, which, after several recrystallizations from benzene and carbon tetrachloride gave small white needles m.p. 143.2–144.0°; infrared spectrum (wave length in μ): 3.32m, 3.38m, 6.90m, 6.95m, 7.59m, 7.80w, 7.90m, 8.05m, 8.16m, 8.27m, 8.40m, 8.55w, 9.80s, 9.95s, 10.20w, 10.55m, 10.85m, 11.03s, 11.40s, 12.42m, 12.51m, 14.02w, 14.81w.

Anal. Calcd. for $C_6H_8OCl_2$: C, 43.10; H, 4.85; Cl, 42.46. Found: C, 43.07, 42.79; H, 4.65, 4.98; Cl, 43.02, 42.28.

More Highly Chlorinated Ethers.—These ethers were formed from the treatment of pure 1,4-endoxocyclohexane with chlorine as described above. Adding more equivalents of chlorine over longer periods of time, it was necessary to raise the temperature of the reaction slowly to prevent formation of solid material. The various crude reaction mixtures were separated by chromatography into crystalline components which were further purified by recrystallization.

A trichloro ether crystallized from benzene as small white needles, m.p. 154.5–154.8°; infrared spectrum (wave length in μ): 3.35w, 6.95w, 7.02m, 7.58m, 7.80w, 7.91m. 8.06m, 8.13m, 8.25m. 8.38m, 8.63m, 9.50w, 9.95s, 10.18m, 10.30w, 10.60m, 10.82m, 11.11s, 11.42s, 12.45s, 14.22m, 14.90m.

Anal. Calcd. for $C_6H_9OCl_3$: C, 35.74; H, 3.50; Cl, 52.75. Found: C, 35.54; H, 3.28; Cl, 52.02.

A tetrachloro ether gave, from pentane solution, chunky rhomboidal crystals, m.p. 77.8–78.8° (softens 77.0°); infrared spectrum (wave length in μ): 3.42w, 6.99m, 7.63w, 7.98m, 8.10m, 8.50m, 8.57m, 8.98m, 9.36m, 9.90m, 10.00m, 10.21s, 10.31m, 10.46m, 10.99m, 12.47s, 13.48m.

Anal. Calcd. for $C_6H_6OCl_4$: C, 30.55; H, 2.57; Cl, 60.12. Found: C, 30.58; H, 2.69; Cl, 60.28.

A hexachloro ether was obtained as white prisms, m.p. 106.8–107.3°, from pentane; infrared spectrum (wave length in μ): 3.30w, 7.73m, 8.08m, 8.23m, 9.67m, 9.74m, 10.25s, 10.55m, 10.69s, 10.90s, 11.62s, 11.73s, 12.76m, 12.90s, 13.43w.

Anal. Calcd. for $C_6H_4OCl_6$: C, 23.65; H, 1.32; Cl, 69.80. Found: C, 23.83; H, 1.49; Cl, 68.78.

An octachloro-1,4-endoxocyclohexane was recrystallized from ligroin to yield long stave-like crystals, m.p. 158.4–159°; infrared spectrum (wave length in μ): 3.28w, 8.25m, 9.57w, 9.90m, 10.28s, 10.66s, 10.74m, 11.06w, 11.58s, 11.96m.

Anal. Calcd. for $C_6H_2OCl_8$: C, 19.28; H, 0.54; Cl, 75.90. Found: C, 19.30; H, 0.61; Cl, 75.83.

Bromination of 1,4-Endoxocyclohexane.—N-Bromosuccinimide (greater than 99% purity) from Arapahoe Chemicals, Inc., was freshly recrystallized from water before use in these experiments. The substitution of NBS from another source (Fisher Scientific Co.) made no apparent difference in the course of the reaction. Merck Reagent carbon tetrachloride was used as solvent.

In a typical experiment 1,4-endoxocyclohexane (196.0 g., 2.0 mole) was dissolved in 500 ml. of carbon tetrachloride in a 1-l. flask fitted with a reflux condenser and a calcium chloride drying tube. NBS (178 g., 1.0 mole) was added to this solution and the suspension heated to boiling while irradiating with a sunlamp. After about 2 hr. the mixture became homogeneous. The heating and irradiation were continued for 5 hr. altogether, and the resulting deep-red solution was cooled overnight in a refrigerator at 0°. The crystals of succinimide (42.0 g., 42.5%) which were deposited during this time were removed by filtration. The solvent and excess 1,4-endoxocyclohexane were removed by distillation at water-pump pressure. The liquid residue was then fractionally distilled through a 50-cm., vacuum-jacketed column packed with glass helices. The following fractions were taken:

Fraction	B.p., °C. (2 mm.)	Weight, g.
I	53.0–56.0	21.40
II	56.0–62.0	7.63
III	62.0–68.0	7.77
IV	68.0–68.5	20.85
V	68.5–75.0	22.30

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The various fractions were examined by infrared spectroscopy. The fore-run contained carbon tetrachloride and recovered 1,4-endoxocyclohexane. No part of the fore-run showed an absorption near 4.5 μ which could be attributed to an isocyanate.

Fraction I was essentially pure β-bromopropionyl isocyanate. Fraction II contained a small amount of higher boiling material but was mostly the isocyanate. These first two fractions constitute a yield of 16.3% of β-bromopropionyl isocyanate. Redistillation gave a colorless liquid, b.p. 54.0–55.0° (2 mm.), which had a sharp, characteristic odor and was mildly lachrymatory. A small sample of this material was distilled into a tube and sealed off under high vacuum. It began to acquire a yellow color after one day at room temperature and after two weeks was an extremely viscous, semi-solid material of deep orange color.

Fraction IV was essentially pure *exo*-2-bromo-1,4-endoxocyclohexane (11.8%). The distillation was discontinued during the collection of fraction V when a rapid decomposition occurred in the pot leaving a black tar and evolving much hydrogen bromide.

Reaction of the Isocyanate with Water.—To β-bromopropionyl isocyanate (0.50 g., 0.0028 mole) from the reaction described above, tetrahydrofuran containing 10% water was added dropwise until no further gas evolution was observed on adding another drop of the water solution. The evolved gas was carried in a stream of nitrogen through a trap containing aqueous barium hydroxide. The precipitated barium carbonate was filtered, washed with 100 ml. of water and dried at 100° (0.56 g., 1.13 moles per mole of isocyanate). The tetrahydrofuran and excess water were removed from the reaction mixture by distillation at reduced pressure leaving 0.40 g. of a white crystalline material, m.p. 109.5–111.7°. After two recrystallizations from benzene, the material melted 115.6–116.3°. This was mixed with authentic β-bromopropionamide (m.p. 115.3–116.3°) prepared from β-bromopropionyl chloride and ammonia[18] to give a mixed m.p. 115.3–116.3°.

β-Bromopropionyl Isocyanate from Silver Cyanate.—The method used is a rather general one for the preparation of acyl isocyanates.[19] In a 300-ml. round-bottomed flask fitted with a reflux condenser, addition funnel and calcium chloride drying tube, silver cyanate (Eastman Kodak Co., white label grade, 45.0 g., 0.30 mole) was suspended with magnetic stirring in 100 ml. of dry ether. To this suspension was added, over a 2-hr. period, 34.4 g. (0.20 mole) of β-bromopropionyl chloride in 50 ml. of dry ether. The suspension was then heated to boiling with continued stirring for 6 hr. The silver salts were then filtered from the solution, washed with ether and the washings combined with the reaction mixture. Solvent was removed at reduced pressure and the remaining liquid distilled through a 30-cm. Vigreux column at *ca.* 2 mm. The fraction boiling in the range 52–56° (4.4 g., 12%) exhibited an infrared spectrum identical with that of a sample of the isocyanate from the NBS reaction described above. Infrared spectrum (wave length in μ): 3.43w, 4.45s, 5.77s, 7.19m, 7.50w, 7.95w, 8.25w, 8.50m, 8.72m, 9.87m, 9.77m, 9.95m, 15.20m.

Anal. Calcd. for $C_4H_4O_2NBr$: C, 26.00; H, 2.27. Found: C, 26.35; H, 2.70.

This material also reacted vigorously with water to produce β-bromopropionamide.

N-Bromosuccinimide in Carbon Tetrachloride.—Observation of the very intense absorption of β-bromopropionyl isocyanate at 4.45 μ was used to follow its formation from NBS under a variety of conditions. In these experiments NBS (5.0 g.) was suspended in 50 ml. of carbon tetrachloride in a flask fitted with a reflux condenser and protected from atmospheric moisture by a calcium chloride drying tube. During the reaction 1-ml. aliquots were withdrawn at intervals of 6–8 hr. and examined for absorption at 4.45 μ. In parallel experiments, all conducted at the boiling point of carbon tetrachloride, the mixture was in one case irradiated with a sunlamp, shielded from all light in another case and, in a third case, protected from light after adding 0.10 g. of benzoyl peroxide. After 24 hr. spectra of the crude reaction mixtures taken in sodium chloride cells 0.016 in. in thickness against reference cells containing pure carbon tetrachloride showed 63% absorption at 4.45 μ for the irradiated reaction and 85% for the reaction with added benzoyl peroxide. The mixture which was heated in the dark with no added catalyst showed no absorption in this region even after 36 hr. Further heating of the two reaction mixtures which showed absorption at 4.45 μ brought about diminution and eventual loss of this absorption.

exo-2-Bromo-1,4-endoxocyclohexane.—Material from fraction IV of the distillation of the NBS bromination reaction was redistilled (b.p. 68.0–68.2° (2 mm.), $n^{25}D$ 1.5176, d_{25} 1.5410).

Anal. Calcd. for C_6H_9Br: C, 40.7; H, 5.12. Found: C, 40.88; H, 4.89.

This bromo ether (4.4866 g., 0.02534 mole) was dissolved in 20 ml. of 95% ethanol containing 4.748 g. (0.0279 mole) of silver nitrate. The mixture was then allowed to stand in a dark place at room temperature for 24 hr. The precipitated silver bromide was filtered, washed, dried at 95° and weighed (4.7477 g., 0.02528 mole). This corresponds to 45.03% Br in the sample; calcd. for C_6H_9Br, 45.14% Br.

Method of Determining Dielectric Constants.—The heterodyne beat frequency method[20] was used to determine the dielectric constants, at 25.0°, of dilute solutions of the materials being studied, in carbon tetrachloride or benzene. The apparatus used in these determinations is fully described by Osthoff.[21] It consists, in essence, of a fixed frequency crystal oscillator, at 100 kc., coupled with a vacuum-tube oscillator circuit containing the measurement cell and a calibrated precision variable condenser. The frequency of the latter circuit can be very accurately adjusted, by means of the precision condenser, until the beat frequency between the two circuits is zero.

Measurements of Densities.—Densities were measured to an accuracy estimated at one part in 20,000 by means of a single stem pycnometer of 20-ml. volume.

Treatment of Data.—The calculations of the molar polarization at infinite dilution were made by the method of Hedestrand[22] using the convenient notation of Bender, Flowers and Goering.[23] The dipole moments were then calculated from the Debye equation.[20]

Solvolysis of the 2-Halo-1,4-endoxocyclohexanes: Solvents.—Dioxane was purified by the procedure of Hess and Frahm.[24] After this treatment it was distilled through a 100-cm. column packed with glass helices (b.p. 100.6–100.8°). It was then stored under nitrogen in a dark place and used in not more than two weeks.

Absolute ethanol (2 l.) was added to 20 g. of sodium metal and the resulting solution boiled for two days to destroy aldehydes. The ethanol was then distilled and stored under nitrogen until used.

Distilled water from the laboratory source was redistilled from potassium permanganate and stored under nitrogen.

The solvent mixtures used in this work were made up by weighing the required amounts of the pure solvents. The solvent mixture which was made up to volume percentage specifications was weighed out in proportions calculated from the densities of the pure solvents at 25°.

Procedure for the *exo* Isomers.—The kinetic runs were followed by titrating samples individually sealed in glass tubes. These tubes were made by sealing one end of a 12 in. length of 12 mm. Pyrex tubing. Just before use they were carefully flushed with nitrogen and tightly stoppered with a plug of glass wool.

The solutions for kinetic analysis were made up by weighing the halo ether and the added salt into a 250-ml. volumetric flask and making the solution up to volume with the solvent being studied.

A hypodermic needle was used to introduce 16-ml. portions of the solution through the glass wool plugs into the freshly prepared glass tubes. The tubes were then quickly sealed off about 1.5–2 in. above the surface of the liquid, placed in a woven-wire basket and lowered into the constant temperature bath, maintained constant to within ±0.01°.

At the desired intervals of time samples were withdrawn from the bath, quickly cooled in ice-water and then allowed to come to room temperature. Samples of 15 ml. were then accurately measured out, diluted with 45 ml. of distilled water and titrated with 0.1013 *N* aqueous sodium hydroxide. All titrations were performed using a Beckman Autotitrator with a 5-ml. microburet.

Procedure for Solvolysis of the *endo* Isomer.—The same procedure was used with *endo*-2-chloro-1,4-endoxocyclohexane as with the *exo* isomer with the exception that an amount of sodium acetate approximately equivalent to the halo ether was weighed into the sample. The reaction was then followed by titrating the excess sodium acetate in the aliquots to an end-point at *p*H 3.6 with 0.121 *N* hydrochloric acid.

Treatment of Data.—The first-order rate constants were obtained by a least squares treatment of the data as outlined by Youden.[25] The uncertainties are expressed as standard deviations. The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were calculated from the absolute rate equation with the uncertainties again expressed as standard deviations.

Product Studies.—*exo*-2-Bromo-1,4-endoxocyclohexane (17.7 g., 0.10 mole) was dissolved in 250 ml. of 50% dioxane–water in a 300-ml. flask equipped with openings for an amber-glass electrode, a calomel electrode, a reflux condenser and the addition tip from the Beckman Autotitrator. The mixture was magnetically stirred with a Teflon-covered bar. It was brought to the boiling point by an electric heating mantle and maintained at *p*H 6.5–7.5 by the Autotitrator for 2000 min. This required 14.55 ml. of 4.89 *N* sodium hydroxide solution (71% reaction).

The solvent was removed by distillation at water-pump pressure leaving a paste of organic matter and sodium bromide. To this was added 50 ml. of dioxane to dissolve the organic matter, and the inorganic bromide was removed by filtration. The filtrate was then made up to 200 ml. with 50% dioxane–water. Aliquots of 20 ml. were taken for analytical tests.

Using this procedure outlined by Wilds,[26] aldehyde was estimated by titration of the hydrochloric acid released by oximation with hydroxylamine hydrochloride. Two aliquots gave values for aldehyde equivalent to 81.1% and 80.2% of the solvolyzed material.

Other aliquots were used to prepare the 2,4-dinitrophenylhydrazone and the *bis*-dimedone condensation product by the directions of Shriner and Fuson.[27]

The solution in which the 2,4-dinitrophenylhydrazone was formed was diluted with 200 ml. of water to make the precipitation complete and then filtered through a sintered-glass crucible. The derivative was washed with 20 ml. of 0.1 *N* hydrochloric acid, then 200 ml. of water, dried at 100° and weighed. After repeated recrystallization from benzene–pentane mixtures, this derivative gave m.p. 118.6–119.8°. The same derivative was isolated from the sealed tube solvolysis of the *endo*- and *exo*-chlorides; infrared spectrum (wave length in μ): 3.41s, 3.52m, 6.85m, 6.92m, 6.98m, 7.60w, 7.68w, 7.79m, 7.94m, 8.17m, 8.40s, 8.75m, 8.89m, 9.60m, 9.80m, 9.98s, 10.21m, 10.41w, 10.68s, 11.00w, 11.10w, 11.35s, 11.90m, 15.15w, 15.39w.

Anal. Calcd. for $C_{12}H_{14}O_6N_4$: C, 48.98; H, 4.80; N, 19.04. Found: C, 49.15; H, 4.59; N, 18.74.

The dimedone derivative was recrystallized from benzene–pentane mixtures to a constant melting point of 163.3–164.2°; infrared spectrum (wave length in μ): 2.79m, 2.95m, 3.42s, 3.70m, 5.80s, 6.97m, 7.25m, 7.50m, 8.10m, 8.55m, 9.30m, 9.89s, 10.53m.

Anal. Calcd. for $C_{22}H_{32}O_6$: C, 70.18; H, 8.56. Found: C, 70.47; H, 8.61.

Runs protected from oxygen by the use of the sealed tube technique showed substantially higher yields of aldehyde. In these experiments two tubes from a kinetic run were opened simultaneously. One 15-ml. aliquot was titrated directly. The other was mixed with 15 ml. of 0.5 *N* hydroxylamine hydrochloride solution, allowed to stand overnight, then titrated to the same *p*H as shown by a parallel blank run. The difference in the two titers represents aldehyde present.

In run 1, in 80% (by vol.) ethanol at 85.0°, such duplicate points were taken at 5212, 12470 and 16820 min. The percentage of aldehyde in the solvolysis product at each of these points was determined by the above outlined method. These percentages were found to be 100.8, 98.2 and 103.2%, respectively, at these three times.

In a special run at 120.0°, the *exo*-chloride, in 50% dioxane, was shown to yield 97.3 and 99.6% aldehyde at 653 and 1213 min.

The solvolysis product of the *endo*-chloride was analyzed at 160°, using points of run 12, in 50% dioxane with added sodium acetate. In these analyses the customary 15-ml. aliquot was diluted with 30 ml. of water and titrated with standard acid to *p*H 3.4 to learn the extent of solvolysis. The 15 ml. of 0.5 *N* hydroxylamine hydrochloride was added and the solution allowed to stand at room temperature overnight. It was then titrated back to *p*H 3.4 with standard base. At 2245 min. this method indicated 91.7% of the solvolysis product to be aldehyde and at 5110 min., 85.4%. (In these runs at the higher temperature a considerable darkening of the solution was observed in samples withdrawn after about 3000 min.)

Identification of 3-Formylcyclopentanol.—A sample (1.5 g.) of the crude product from a solvolysis of *exo*-2-bromo-1,4-endoxocyclohexane in boiling 50% dioxane was dissolved in 10 ml. of hydrazine (Eastman Kodak Co., 95%) and heated on a steam-bath for 24 hr. The solution was then concentrated to 4–5 ml. by distilling excess hydrazine at reduced pressure. This solution was added to an ethanolic solution of sodium ethoxide prepared by dissolving 1.0 g. of sodium in 10 ml. of absolute ethanol. The solution was sealed in a Carius tube and heated at 190–200° for 36 hr. The resulting solution was acidified with concd. hydrochloric acid and distilled. After removal of the ethanol two colorless liquid phases co-distilled at 55° (60 mm.). The non-aqueous phase was taken up in ether and dried over magnesium sulfate. Removal of the solvent left a colorless oil (0.3 g.), $n^{28}D$ 1.4446; *trans*-3-methylcyclopentanol,[7] $n^{28}D$ 1.4450. To this was added 0.24 g. of phenyl isocyanate, the mixture heated on a steam-bath for 10 min. and then diluted with 30 ml. of pentane. On chilling the material the phenylurethan (0.26 g.) was deposited from the solution as white needles (after recrystallization from pentane, m.p. 81.4–82.0°; phenylurethan derivative of *trans*-3-methylcyclopentanol,[7] m.p. 82°).

Solvolysis with Added Azide.—*exo*-2-Bromo-1,4-endoxocyclohexane (15.0 g., 0.0847 mole) was dissolved in a solution of 250 ml. of 50% dioxane containing 20 g. of sodium azide (0.308 mole, 1.23 molar). The solution was treated as in the previously described product studies, being boiled for 1600 min. at *p*H 6.0–7.0. Removal of the solvent and inorganic bromide left 8.45 g. of a viscous oil which showed an infrared spectrum nearly identical with that of 3-formylcyclopentanol with an added absorption peak of medium intensity at 4.74 μ. Chromatography on alumina of 1.60 g. of the crude product gave 29 mg. of an oil (eluted with 100% ether) which showed a very intense absorption at 4.74 μ. This was dissolved in 5 ml. of methanol and 10 mg. of platinum oxide added. The suspension was stirred under one atm. of hydrogen for 12 hr. The supernatant liquid was then saturated with hydrogen chloride and the crystalline amine hydrochloride (18 mg.) collected and dried, m.p. *ca.* 240°.

Acknowledgment.—The expenses of this research were met in part by a grant from the Mallinckrodt Chemical Works.

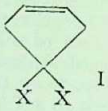
The Reactions of Bivalent Carbon Species. Addition of Dihalocarbenes to 1,3-Butadiene

BY ROBERT C. WOODWORTH AND PHILIP S. SKELL

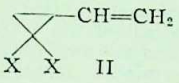
RECEIVED NOVEMBER 21, 1956

The reactions of dibromo- and dichlorocarbenes $:CBr_2$ and $:CCl_2$ to 1,3-butadiene are three center types of addition reactions producing 1,1-dihalo-2-vinylcyclopropanes. The structures of these products were demonstrated by conversion to the 2,2-dihalocyclopropanecarboxylic acids. The similarity of this addition reaction to heterolytic halogenation of 1,3-butadiene is discussed.

The reaction of 1,3-butadiene with dihalocarbenes $:CCl_2$ and $:CBr_2$ would be expected to produce 4,4-dihalocyclopentenes (I) by 1,4-addition or 1,1-dihalo-2-vinylcyclopropanes (II) by 1,2-addition.



I



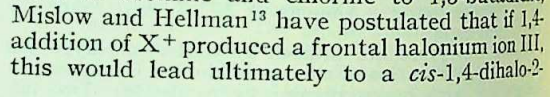
II

Dichloro- or dibromocarbene was generated in the presence of 1,3-butadiene by the action of base on chloroform or bromoform, respectively.[1,2] The major product from the reaction of 1,3-butadiene, bromoform and potassium *t*-butoxide is a heavy, sweet smelling, colorless liquid obtained in 70% yield. It rapidly discolors in air. The major product from the reaction of 1,3-butadiene, chloroform and potassium *t*-butoxide is a volatile, sweet smelling colorless liquid obtained in 50% yield. Since neither I nor II have been described previously, it was desirable that the homogeneity of the reaction products be established. Infrared spectra of fractions distilled from the reaction mixtures indicated that the dibromo product was contaminated only with unreacted bromoform. The dichloro product, however, contained an unknown contaminant boiling a few degrees lower than the main product. Careful fractional distillation of the contaminated material separated a small amount of the pure contaminant which proved to be 1,1-dichloro-2,2-dimethylcyclopropane, on comparison with the boiling point, refractive index and infrared spectrum reported for this compound.[2] This substance is formed in low yield in the reaction of chloroform with potassium *t*-butoxide in the presence of *t*-butyl alcohol,[2] probably by the addition of dichlorocarbene to isobutylene obtained by the dehydrating action of the dihalocarbenes on alcohols.[3] The bands observed in the infrared spectra of the successive fractions from the chloroform–1,3-butadiene reaction mixture can be explained by the major product and a single contaminant, 1,1-dichloro-2,2-dimethylcyclopropane.

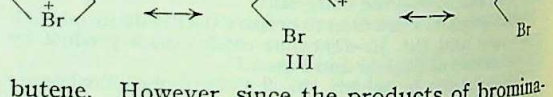
Cleavage of the unsaturated bond with ozone was employed to prove the structures of the addition products. Ozonolysis of I should yield a dicarboxylic acid, and ozonolysis of II should yield a monocarboxylic acid. Ozonolysis of the dibromo- and dichloro-products yielded monocarboxylic acids with the correct analyses and neutral equivalents, respectively, for 2,2-dibromocyclopropanecarboxylic acid and 2,2-dichlorocyclopropanecarboxylic acid. The conclusion from these results is that both dibromo- and dichlorocarbene exhibit 1,2-addition to 1,3-butadiene and the products produced in this reaction have structure II.

Other instances of 1,2-additions to conjugated diolefins have been reported for the reactions of these olefins with diazoacetic esters in the presence of a copper catalyst to produce vinylcyclopropanecarboxylic esters.[4–8] Evidence which strongly suggests the intermediacy of a carbene in copper-catalyzed decompositions of diazo compounds has been presented.[9–12]

In the consideration of the heterolytic 1,4-additions of bromine and chlorine to 1,3-butadiene, Mislow and Hellman[13] have postulated that if 1,4-addition of X^+ produced a frontal halonium ion III, this would lead ultimately to a *cis*-1,4-dihalo-2-butene. However, since the products of bromination and chlorination of 1,3-butadiene were the *trans*-1,4-dihalo-2-butenes, these authors concluded that the intermediate halonium ion probably has structure IV.



III



IV

The affinity of the dihalocarbenes for olefins with electron-releasing substituents[14] and the stereochemical evidence for a singlet state (no unpaired electrons) for carbenes[12] led to the postulate

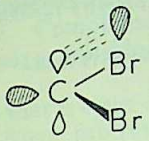
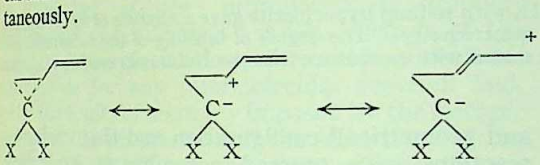
that carbenes may be considered as sp^2-hybridized species, which by virtue of their vacant *p*-orbital exhibit electrophilic behavior predominantly.



IV

From this point of view one might have anticipated that the 2-electron deficient species $:CX_2$ and Br^+ would show similar behavior toward 1,3-butadiene. The intermediate complex in the reactions of dihalocarbenes with 1,3-butadiene may be described by V, in which bonding to both carbons of the double bond is developed simultaneously.



V

The electron-seeking character of the carbenes leads to the suggestion that electron-withdrawing (halogen) substituents on the 1,3-butadiene system will result in cyclopropane formation at the unsubstituted double bond, while electron-donating (alkyl) substituents will direct this addition to the substituted double bond. In partial confirmation of this prediction can be cited the failure to obtain an adduct when dichlorocarbene is generated in the presence of hexachloro-1,3-butadiene. Also it has been reported that carbethoxycarbene adds to the terminal double bond of 1-phenyl-1,3-butadiene[4] and the γ,δ-olefinic linkage of sorbate and α-methylsorbate esters.[7] In contradiction of an earlier report[5] the major product obtained from the reaction of carbethoxycarbene with isoprene is the ethyl ester of 2-methyl-2-vinylcyclopropanecarboxylic acid.[15]

Experimental

Procedure.—Solvent-free potassium *t*-butoxide was prepared by dissolving potassium metal in anhydrous *t*-butyl alcohol (dried by distillation from potassium *t*-butoxide). The excess alcohol was removed by distillation and then by pumping to an ultimate pressure of 2 mm. at a temperature of 95°. The dry cake was pulverized mechanically and the flask fitted with a stirrer, thermocouple and dropping funnel. The flask was cooled in a freezing carbon tetrachloride–Dry Ice-bath. The haloform was added to a slurry of the potassium *t*-butoxide in liquid 1,3-butadiene at such a rate that the reaction temperature never exceeded −10°. The haloform was added at a rate of approximately 0.5 mole per hour to avoid excessive temperature rise as a result of the rapid exothermic reaction. The reactants were stirred for an additional hour after the haloform addition was complete and then diluted with pentane and water. The organic layer was separated, washed with cold water, dried over anhydrous sodium sulfate, the solvent removed by distillation and the residue distilled to obtain the reaction products.

Ozonolyses were carried out in pentane solution, the viscous ozonide separating from the solution as it formed. The ozonides were decomposed in the presence of hydrogen peroxide and sulfuric acid and then refluxed to ensure complete oxidation of the aldehydes.

Reaction of 1,3-Butadiene with Chloroform and Potassium *t*-Butoxide.—The quantities of reactants were 239 g. (4.4 moles) of 1,3-butadiene, 170 g. (1.42 moles) of chloroform and 1.6 moles of potassium *t*-butoxide (from 62 g. of potassium metal). The products were distilled at atmospheric pressure to obtain 103 g. of material boiling at 115–123°, $n^{25}D$ 1.4662–1.4720. These fractions were combined and redistilled through a 50–100 plate column (24 in. × 8 mm. Podbielniak Mini-cal column packed with Hastelloy Heli-grid). The major portion of the product was separated as a fraction boiling constant at 122.5° (730 mm.), $n^{25}D$ 1.4720–1.4722. This product was identified as 1,1-dichloro-2-vinylcyclopropane. The foreruns were recombined and distilled through the same column to separate approximately 3 g. of 1,1-dichloro-2,2-dimethylcyclopropane, a middle fraction boiling at 115.8–116.7° (729 mm.), $n^{25}D$ 1.4450. These physical properties compare favorably with those reported by Doering and Hoffmann[2] (b. 118–120°, $n^{20}D$ 1.4461). The infrared spectrum of this substance appeared to be identical with that reported.[2] All of the fractions obtained between the 1,1-dichloro-2,2-dimethylcyclopropane and the 1,1-dichloro-2-vinylcyclopropane were examined by obtaining their infrared spectra on the neat liquid. All of the bands in the spectra were attributable to these two products, no other bands being evident. The total weight of 1,1-dichloro-2-vinylcyclopropane obtained was 98.5 g. (51%).

Anal. Calcd. for $C_5H_6Cl_2$: C, 43.83; H, 4.42. Found: C, 44.28; H, 4.41.

Ozonolysis of 1,1-Dichloro-2-vinylcyclopropane to 2,2-Dichlorocyclopropanecarboxylic Acid.—From the ozonolysis of 10.0 g. of 1,1-dichloro-2-vinylcyclopropane, there was obtained 8.0 g. of a crude viscous liquid monobasic acid (neutral equivalent 196 and pK_a 3.47) which crystallized from heptane. Recrystallization from hexane raised the melting point to 75–76°. Titrations of the pure acid indicated a monobasic acid, pK_a 3.50, 3.51 (23°, 0.01, 0.005 *M*).

Anal. Calcd. for $C_4H_4Cl_2O_2$: C, 30.86; H, 2.59; neut. equiv., 155. Found: C, 31.16; H, 2.55; neut. equiv., 151, 159, 155.

The *p*-bromophenacyl ester of this acid (recrystallized from ethanol) melted at 122–123°.

Anal. Calcd. for $C_{12}H_9BrCl_2O_3$: C, 40.92; H, 2.58. Found: C, 41.11; H, 2.63.

Reaction of 1,3-Butadiene with Bromoform and Potassium *t*-Butoxide.—The reactants were 152 g. (2.81 moles) of 1,3-butadiene, 125 g. (0.495 mole) of bromoform and 0.51 mole of potassium *t*-butoxide (from 20 g. of potassium metal). The products from this reaction were distilled in vacuum through a Vigreux column to separate a forerun of bromoform (identified through its infrared spectrum) and a fraction boiling 69.5–70.0° (26 mm.), $n^{25}D$ 1.4520, which was identified as 1,1-dibromo-2-vinylcyclopropane. A total of 67 g. of product was obtained (64% of theory, taking into account the recovered bromoform). This product darkens rapidly on contact with air.

Anal. Calcd. for $C_5H_6Br_2$: C, 26.58; H, 2.68. Found: C, 26.61; H, 2.52.

Ozonolysis of 1,1-Dibromo-2-vinylcyclopropane to 2,2-Dibromocyclopropanecarboxylic Acid.—From the ozonolysis of 19.4 g. of 1,1-dibromo-2-vinylcyclopropane, 10.0 g. of crude acid was obtained. Recrystallization of this acid from hexane gave a product whose melting point was 94–95°. Titration curves indicated this acid was a monobasic acid, pK_a 3.48, 3.57 (24°, 0.01, 0.005 *M*).

Anal. Calcd. for $C_4H_4Br_2O_2$: neut. equiv., 244. Found: neut. equiv., 242, 240.

The Reaction of Hexachloro-1,3-butadiene with Chloroform and Potassium *t*-Butoxide.—To a suspension of 0.43 mole of potassium *t*-butoxide in 133 g. of hexachloro-1,3-butadiene and 250 ml. of *n*-pentane, 40 g. of chloroform was added. Unreacted hexachloro-1,3-butadiene was recovered. The same result was obtained when potassium *t*-butoxide was added to a chloroform–hexachlorobutadiene mixture.

Infrared Spectra.—The following infrared spectra were obtained for the neat liquids in a 0.0235-mm. cell using NaCl optics, recording wave length in microns. 1,1-Dichloro-2-vinylcyclopropane: 3.27(m) 3.37(mw) 4.80(vw) 4.92(vw) 5.45(w) 5.56(w) 5.78(mw) 6.11(ms) 6.31(vw) 6.99(m) 7.03(ms) 7.57(mw) 7.73(mw) 8.20(s) 8.36(m) 8.97(vs)

Confirmation of the Intramolecular Nature of the Hofmann "Haloamide" Reaction by Double Labeling

BY THOMAS J. PROSSER AND ERNEST L. ELIEL

RECEIVED JANUARY 2, 1957

Treatment of a mixture of *m*-$DC_6H_4CONH_2$ and $C_6H_5CON^{15}H_2$ with sodium hypochlorite gave a mixture of *m*-$DC_6H_4NH_2$ and $C_6H_5N^{15}H_2$ free of *m*-$DC_6H_4N^{15}H_2$ as established by mass spectrometry. The degree of labeling of the substrates and the sensitivity of the analytical method are such that it can be stated with confidence that the Hofmann reaction is at least 96% intramolecular.

The reaction of an amide with hypohalite to give an amine or derivative thereof, *e.g.*, $RCONH_2 + NaOBr \rightarrow RNH_2 + CO_2 + NaBr$, is known as the Hofmann haloamide reaction.[1,2] This reaction, as well as several other related ones,[3] has long been considered to be intramolecular. Evidence for this is entirely stereochemical and comes from the fact that amides in which the R-group is asymmetric at the point of attachment—such as $C_6H_5CH(CH_3)CONH_2$—yield amines in which configuration is retained and optical activity almost completely preserved,[4] even where activity is due to restricted rotation in a biphenyl system,[5] and that geometric configuration of the R-group is also preserved[6] in the rearrangement of R from carbon to nitrogen which must occur in the Hofmann haloamide reaction. Moreover, the reaction proceeds normally at bridgehead carbon atoms.[7]

While the stereochemical evidence for retention of configuration is thus overwhelming, it is not so convincing that this constitutes proof for the intramolecular nature of the rearrangement, especially in view of the fact that certain intermolecular reactions involving carbanion intermediates have recently been shown to involve retention of optical[8] and geometrical[9] configuration and that carbanion reactions may proceed normally at bridgehead carbon atoms.[10] An independent proof of the intramolecular nature of the Hofmann haloamide reaction thus seemed desirable.

The most convincing evidence for the intramolecular nature of any reaction comes from study of the products obtained in the reaction when carried out on a mixture of two substrates A–B and A′–B′. If only products corresponding to A–B and A′–B′ are obtained in a reaction involving rupture of the A–B bond, then the reaction is intramolecular; but if products corresponding to A–B′ and A′–B are also obtained, then the reaction is at least in part intermolecular. In fact this criterion may well be considered an operational definition of the terms "intramolecular" and "intermolecular." In the case of the Hofmann haloamide reaction, an appropriate experiment would be to rearrange a mixture of $RCONH_2$ and $R'CON^{15}H_2$, cleanly separate the two chemically distinct products RNH_2 and $R'NH_2$ (labeled or unlabeled), and demonstrate by conventional degradation to nitrogen gas and isotope ratio measurements of the latter[11] that RNH_2 contains no excess of the N^{15} isotope. There are, however, two difficulties with such a procedure. One is the need for rigorous purification of RNH_2, to eliminate the possibility of contamination with $R'N^{15}H_2$. This difficulty can be obviated by carrying out the N^{15} analysis by direct mass spectrometry[12] of RNH_2 at reduced ionizing voltage[13]—provided RNH_2 and $R'NH_2$ are not isomeric. The second difficulty is concerned with the need of choosing $RCONH_2$ and $R'CONH_2$ so

that their rates of rearrangement are approximately the same; otherwise one might be completely rearranged before the other begins to react and no crossed products would result *even if* the reaction were intermolecular. Compliance with this condition usually requires considerable preliminary experimentation.

It occurred to us that a clear-cut experiment to distinguish intra- from intermolecular reaction paths would be to rearrange benzamide-*m*-*d* in the presence of benzamide-N^{15}. These compounds must rearrange at approximately the same rate (except for the small isotope effect of the N^{15}) so that, if the reaction is to any extent intermolecular, the product should contain some aniline-*m*-*d*-N^{15}. This species can be easily detected mass spectrometrically, since its mass number is 95 whereas the mass-number of the intramolecular products aniline-*m*-*d* and aniline-N^{15} is 94. Details of the calculations are given below; they show no evidence whatsoever for any intermolecular reaction and, given the limits of accuracy imposed by the isotopic purity of the substrates and the sensitivity of the analytical method, it can be stated with confidence that the Hofmann haloamide reaction is at least 96% intramolecular.[14]

The method used here to demonstrate the intramolecular nature of the Hofmann haloamide reaction commends itself to application in a wide variety of other reactions whose intra- or intermolecular nature is in doubt. The method should frequently be easy to apply, especially in view of the fact that the nature (C^{13}, N^{15} or D, but not O^{18} whose degree of enrichment is insufficient for the purpose at hand) as well as the position of the tracer can be adapted, to a considerable extent, to the experimenter's convenience.[15]

A double-labeling method of the above type has apparently been used only once before[16] in a demonstration of the intermolecular nature of hydride exchange between $(CH_3)_3CD$ and $(CH_3)_2CHC^{13}H_3$. Double-labeling with a somewhat different purpose has been used in biochemical studies.[17]

Experimental[18]

Benzamide-N^{15}.—Labeled ammonia was generated[19] from ammonium-N^{15} nitrate[20] containing 33.4 atom % N^{15} and converted to benzamide-N^{15} by treatment with benzoyl chloride in ether.[21] Recrystallized from water the product was obtained in well-formed crystals (79%) which, however, melted over a range[22] 124–129°.

Toluene-*m*-*d* was prepared from *m*-tolylmagnesium bromide and deuterium oxide (99.5+ %) as previously described.[23] Preliminary experiments indicated that removal of the bulk of the ether prior to addition of the deuterium oxide[24] was necessary to ensure adequate isotopic purity of the product.[25] When DCl and CH_3COOD (used in preference to heavy water alone in view of the difficulties reported in ref. 25) was added to *ethereal* *m*-tolylmagnesium bromide, isotopic purity of the resulting toluene-*m*-*d* was about 10% less than when the method of Weldon and Wilson[25] was used, even though the product was removed from the reaction vessel by vacuum distillation without ever coming in contact with ordinary water or acid. Toluene-*m*-*d* boiled at 106–108°, $n^{20}D$ 1.4960, and was obtained in 69% yield (lit.[26] for toluene, b.p. 110.6° (760 mm.), $n^{20}D$ 1.4968).

Anal.[29] toluene-*d*, 96.0%; unlabeled toluene, 4.0%.

Benzamide-*m*-*d*.—Toluene-*m*-*d* was converted to benzoic-*m*-*d* acid in 73% yield by oxidation with alkaline permanganate essentially as described for the *o*-*d* compound.[27] Treatment of the acid, m.p. 121–125°, with thionyl chloride[27] gave benzoyl-*m*-*d* chloride, b.p. 79–83.5° (16 mm.), in 90% yield. This chloride with concentrated aqueous ammonia yielded benzamide-*m*-*d*, m.p. 125–129°, in 81% yield.

Anal. Calcd. for C_7H_6DNO: D, 14.28 atom %. Found: D, 13.55 atom % corresponding to an isotopic purity of 94.9%.

Anilines.—The Hofmann haloamide reaction of the benzamides was carried out by means of freshly prepared sodium hypochlorite as described before.[21] Benzamide-*m*-*d* gave aniline-*m*-*d*, b.p. 82–82.5° (20 mm.), $n^{20}D$ 1.5858 (lit.[28] b.p. 85.8° (24.1 mm.), $n^{20}D$ 1.5863 for aniline) in 70% yield.

Anal.[29] aniline-*d*, 95.8%; unlabeled aniline, 4.2%.

Benzamide-N^{15} similarly yielded aniline-N^{15}, b.p. 84–85° (24 mm.), $n^{20}D$ 1.5841, in 72% yield. *Anal.*[29] labeled, 31.9%; unlabeled, 68.1%.

A mixture of 2.02 g. of benzamide-*m*-*d* and 1.98 g. of benzamide-N^{15} similarly yielded 2.16 g. (70.1%) of mixed aniline, b.p. 83.5–84.0° (22–23 mm.), $n^{20}D$ 1.5845. The composition of this mixture is discussed below.

Mass Spectra and Calculations.—The mass spectra were recorded on a Consolidated 21-103A instrument at reduced ionizing voltage. Each spectrum was recorded three times. Below are shown the individual and average patterns for aniline, the peak heights and patterns for aniline-*m*-*d* and aniline-N^{15} and the peak heights and treatment of same for the three spectra of the mixture. The spectra of aniline-*m*-*d* and aniline-N^{15} were handled as follows: The 93-peak was assumed to be due entirely to light aniline (since the aniline spectrum showed no 92-peak). The contribution of light aniline to 94 and 95 was then calculated from the aniline pattern and deducted from the 94- and 95-peaks in the spectra of the labeled compounds.[30] The remaining 94- and

(14) If 95+% N^{15} had been used in this investigation, this limit could have been as high as 99%. High-purity nitrogen-15 is now available: *Chem. Eng. News*, **34**, 5324 (1956).

(15) The nature and position of the tracer must be such that it is not subject to exchange in the course of the reaction studied and preparation of the substrates. This is why benzamide-*m*-*d* was chosen in this work in preference to the *o*-*d* or *p*-*d* isomer: Aniline is known to undergo exchange of ring-hydrogen atoms in the *ortho* and *para* positions in acid media: M. Harada and T. Titani, *Bull. Chem. Soc. Japan*, **11**, 554 (1936).

(29) By mass spectrometry at reduced ionizing voltage.

(30) This procedure is not entirely justified theoretically, since in deducting the 94 contribution of aniline, one deducts not only the contribution due to 6 × 1.1% C^{13} but also that due to 0.38% N^{15} and 7 × 0.02% D caused by naturally occurring heavy isotopes. The error is insignificant in the case of aniline-*d* but affects the 95-pattern of aniline-N^{15} to the extent of about 6%. However, even if this error carried entirely into the mixture spectrum, it would affect the 95 residual only to the extent of 0.25 scale division. Actually the effect tends to cancel altogether, since the mixture spectrum is treated in the same way as the aniline-N^{15} spectrum.

[a] Total labeled material (pattern in parentheses). [b] Contribution to 94-peak calculated on the assumption that $^{12}/_{13}$ of this peak is due to aniline-*m*-*d* and $^{1}/_{13}$ to aniline-N^{15}. Contribution to 95-peak calculated from assumed 94-peak and appropriate pattern. [c] Average of first and third values. [d] Average.

95-peaks were used to calculate patterns for aniline-*m*-*d* and aniline-N^{15} and the three patterns for each compound were averaged.

The mixture spectrum was handled as follows: The 93-peak was again taken to be due to aniline and the contribution of aniline to the 94- and 95-peaks was deducted.[30] The residual 94-peaks are due to aniline-*m*-*d* and aniline-N^{15}. Since the patterns at 95 of these two species are very similar, only a rough apportionment between the two species is necessary and this was obtained by assuming that *ca.* $^{3}/_{13}$ of the labeled material bore the N^{15}-label and $^{10}/_{13}$ the D-label.[31] The residual 95 peak was then calculated and found insignificant in all three spectra.

Sensitivity of Method.—In setting an upper limit to the amount of intermolecular reaction giving rise to aniline-N^{15}-*m*-*d* which might escape detection, one has to make an assumption on the minimum height of the 95 residual which can be clearly detected. Since the total height of the 95-peak is only about 17 divisions, the assumption that a residual of at least one scale division can be clearly detected is certainly a most conservative one. Since the sum of the peak heights at the parent peaks due to aniline (at 93) and the labeled anilines (at 94) is about 350 scale divisions, one division at 95 would correspond to about 1 part doubly labeled aniline in 350 or about 0.3% (making the reasonable assumption that the sensitivities for unlabeled, singly labeled and doubly labeled species at the parent peak are roughly equal).

It can be calculated that about 4% intermolecular reaction suffices to produce 0.3% doubly labeled material; thus 4% is the maximum of intermolecular reaction that might have escaped detection. The 4% figure is arrived at as follows: Out of 200 parts of a 50–50 mixture of aniline-N^{15} and aniline-*m*-*d*, according to the above analyses 95.8 parts will be deuterated, 31.9 parts will contain N^{15} (neglecting natural deuterium and N^{15}) and the rest will be unlabeled. If there is 4% of intermolecular reaction, then 8 parts of the above mixture, containing 3.83 parts deuterium and 1.28 parts N^{15} will be subject to random recombination (neglecting any isotope effects), giving rise to 0.61 part in 200 or *ca.* 0.3% of doubly labeled material.

Acknowledgment.—This paper is a contribution from the Radiation Project of the University of Notre Dame supported in part under Atomic Energy Commission Contract AT (11-1)-38 and Navy equipment loan contract Nonr-06900. We are grateful to Mr. Seymour Meyerson of the Whiting Research Laboratory of the Standard Oil Co. (Indiana), for the aniline-*m*-*d* and aniline-N^{15} analyses and for his guidance in the matter of tracer analysis by mass spectrometry at reduced ionizing voltage.

NOTRE DAME, INDIANA

(31) Making the rough assumption that *all* of the 50% deuterated material was labeled but only 30% of the 50% N^{15} material was labeled. The calculations are in no way sensitive to this assumption. For example, in the first mixture spectrum, if all the labeled material was assumed to be aniline-*m*-*d*, the residue would be −0.4 and if all labeled material was assumed to be aniline N^{15}, the residue at 95 would be +0.4.

A Further Study of the Dissociation and Association of Furoic and Thenoic Acids and of the Rates of Saponification of Their Ethyl Esters

BY SHIGERU OAE AND CHARLES C. PRICE

RECEIVED DECEMBER 17, 1956

Additional data on the pK_a's for furoic and thenoic acids and on the rates of saponification of their ethyl esters indicate that the latter are not accurately predicted from the former by the Hammett equation. The difference is not due to differing degrees of association of the acids and, unlike the case of α-naphthoic acid, does not appear to be steric.

We have reported[1] that the saponification of ethyl 2-furoate proceeded at a rate considerably slower than predicted from the pK_a for 2-furoic acid.

In seeking additional evidence for the nature of this alleged effect, we have discovered a regrettable error of a factor of ten in the calculation of the rate constant for ethyl 2-furoate, which largely eliminates the discrepancy. We do, however, wish to report additional data on the pK_a's for furoic and thenoic acids, on the rates of saponification of their ethyl esters over a wider range in temperature and on the degree of their association.

Experimental

2-Furoic, benzoic, 1- and 2-naphthoic acids were commercial products (Eastman Kodak Co.), while the preparation and properties of 2-thenoic acid were described in the previous paper.[2] 3-Thenoic acid was kindly supplied by Dr. E. E. Campaigne of Indiana University. All these acids were recrystallized at least twice. The preparations of ethyl thenoates were also described elsewhere,[2] while the ethyl 2-furoate was obtained from Norwich Pharmacal Co. The esters were redistilled just before use. Dioxane was purified as before.[2] Benzene was purified by repeated crystallization after fractional distillation through an efficient column.

The saponification rate constants were determined as previously.[2] All the volumetric apparatus used was calibrated at each temperature under which kinetic measurements were made, while the thermostat used was maintained within the range of ±0.02°. Typical data are shown in Table I and all of the data are summarized in Table II.

HAMMETT σ-CONSTANTS FOR THE ACID DISSOCIATION CONSTANTS IN 78.1% ETHANOL AND THE RATES OF ALKALINE SAPONIFICATION OF THE ESTERS, IN 70% DIOXANE

Acid	pK_a	$k_2$sapn. × 10^3 at 25°	σ_a[a]	σ_s[b]	$\Delta\sigma$
Benzoic	6.70 (6.37[c])	(3.42[c])	(0.00)	(0.00)	(0.00)
2-Thenoic	5.95 (5.72[c])	3.51 (3.00[c])	0.36 (.31[c])	0.005 (−0.02)[c]	.35
3-Thenoic	(6.23[c])	3.33 (3.17[c])	(.07[c])	− .005 (− .01[c])	.08
2-Furoic	5.43 (5.37)[d]	15.9 (22.7[d])	0.61 (.47[d])	.29 (.36[d])	.32
1-Naphthoic	6.25 (6.13[c])	(1.28[c])	.22 (.12[c])	(− .18[c])	.40
2-Naphthoic	6.30	(3.46[c])	.03	(0.00[c])	.03

[a] $\sigma_a = (pK_a \text{ for benzoic} - pK_a)/2.07$. [b] $\sigma_s = \log (k_{sap.}/3.42)/2.31$. [c] Taken from the data in ref. 2. [d] Taken from the data in ref. 1. [e] C. C. Price and R. H. Michel, THIS JOURNAL, 74, 3652 (1952).

New measurements of the acid strengths of benzoic, 2-thenoic, 2-furoic, 1- and 2-naphthoic acids at 25° in 78.1% ethanol by volume were made as before,[2] using a Beckman glass electrode pH meter model H2. The values obtained are listed in Table III.

Freezing point determinations were made for each acid using 43.60 g. (50.0 ml. at 25°) of pure benzene. Benzoic acid is quite soluble in benzene, but 2-thenoic acid is not very soluble (less than 2.3 g. in 100 ml. of benzene at 5°),

while 2-furoic acid is still much less soluble (less than 0.6 g. in 100 ml. of benzene at 5°). Therefore, the freezing point determination of 2-furoic acid was made only in a rather lower concentration. The determined values are listed in Table IV.

Discussion

The data on rates of saponification, outlined in Tables II and III, show clearly that the rates of saponification of ethyl benzoate, 2-naphthoate and 3-thenoate are in reasonable agreement with values predictable from pK_a (indicated by reasonable agreement between σ_a and σ_s in Table III). The earlier discrepancy[1,2] between σ_a and σ_s for 1-naphthoate, 2-furoate and 2-thenoate persists. However, as judged from energy and entropy of activation, the reasons for these discrepancies are dissimilar. For example, the 1-naphthoate has very much the lowest temperature independent factor (log PZ = 6.9), whereas the 2-furoate and 2-thenoate have the largest (log PZ = 8.29 and 8.31, respectively).

A redetermination of pK_a values for benzoic, 2-furoic, 2-thenoic, 1- and 2-naphthoic acids (Table

III) leads to values of σ_a in reasonable agreement with those from earlier data.[1,2]

Recently there have appeared two papers which are related to our study, the one dealing with the alkaline hydrolysis of ethyl 2-thenoate and 2-furoate[3] and the other of ethyl 1- and 2-naphthoate,[4] both in 85% ethanol. Using these data[3,4] together with the rates of saponification and ρ in the same solvent,[5] we can calculate the Hammett σ-constants for the saponification rates of ethyl benzoate, 2-furoate, 2-thenoate, 1- and 2-naphthoate, as shown in Table VI.

Although the temperature-independent factors in these two separate experiments[3,4] are quite far apart, the over-all picture thus calculated is in fairly reasonable agreement with our data.

To test the hypothesis that the heterocyclic acids might have intra- rather than intermolecular hydrogen bonding, the degree of association of benzoic, 2-thenoic and 2-furoic acids were determined cryoscopically in benzene. These data, summarized in Table IV, indicate that all three acids have almost the same degree of association, and our data do not support the earlier claim that 2-furoic acid is largely monomeric in benzene.[6]

For the solid acids, infrared spectra in potassium bromide disks, as shown in Table V, reveal no significant changes in position or relative intensity of the bands associated with the carboxyl group, in support of the conclusion that all the acids are associated in the crystalline state, as was already pointed out previously by X-ray study,[7] in the case of 2-furoic acid.

Thermal Syntheses of Telomers of Fluorinated Olefins. I. Perfluoropropene[1]

BY MURRAY HAUPTSCHEIN, MILTON BRAID AND FRANCIS E. LAWLOR

RECEIVED NOVEMBER 21, 1956

A novel method of producing addition-type polymers by a process which does not proceed by chain propagation is described. The formation of telomers of perfluoropropene of formula $R[CF_2CF(CF_3)]_nI$ where R = CF_3, C_3F_7, $C_4F_9CF(CF_3)$, $C_4F_9CF(CF_3)CF_2CF(CF_3)$ and $CF_2ClCFCl$ and n = 1 to 15 has been accomplished by purely thermal means. The unique advantages of this simple process as a method of producing telomers of certain types of relatively non-polymerizable olefins are expounded.

This is the first paper in a series dealing with the syntheses of telomers of fluorinated olefins by purely thermal means.

Considerable work from both academic and industrial laboratories has been described on photochemical and peroxide-induced telomerizations of fluoroölefins which are readily polymerized by free radical initiators. Little information has been reported, however, on (1) thermally induced telomerizations and (2) telomerizations of olefins which do not readily homopolymerize in the presence of free radical initiators.[2]

Although perfluoropropene has been copolymerized with fluorinated[3,4] and unfluorinated[3,5] olefins as well as with ethylene oxide,[6] there is no literature reference to the homopolymerization of perfluoropropene to $[-CF_2CF(CF_3)-]_n$, in spite of considerable study.[5] We have now found that polyperfluoropropenes of molecular weights to 2500 may be synthesized by reaction of perfluoropropene with perfluoroalkyl iodides at about 200°. Moreover, the reaction may be controlled to give products of any desired narrow molecular weight range from n = 1 to 15.

Replacement of the iodine atom by fluorine or

chlorine, or its removal by a coupling reaction converts the telomer

$R_f[-CF_2CF(CF_3)-]_nI$ into $R_f[-CF_2CF(CF_3)-]_nF$, $R_f[-CF_2CF(CF_3)-]_nCl$

or $R_f[-CF_2CF(CF_3)-]_n[(CF_3)CFCF_2-]_nR_f$ where R_f is a perfluoroalkyl group.[7] These fluorocarbon materials are useful as heat transfer fluids, hydraulic fluids, oils, greases, waxes, insulators, dielectrics, plasticizers and modifiers of certain fluorocarbon plastics.

The photochemical reaction of perfluoropropene with trifluoroiodomethane was first described by Haszeldine.[8] Under conditions similar to those used in the rapid reaction of tetrafluoroethylene with trifluoroiodomethane[9] (*i.e., vapor phase* irradiation in a silica tube), which gave mainly solid products, $CF_3(CF_2CF_2)_nI$ where $n = 4$ to >20, the slow perfluoropropene–trifluoroiodomethane reaction gave 2-iodoperfluorobutane. A small amount of $CF_3[CF_2CF(CF_3)]_nI$ where $n = 2$ also was formed but no material where the value of n exceeded 2 was reported. It was similarly shown that 2-iodoperfluorobutane reacted very slowly with perfluoropropene to give only $CF_3[CF_2CF(CF_3)]_2I$.

Heretofore, in addition to $CF_3CF=CF_2$, certain unsaturated compounds including C_2H_4, C_2H_2, $CH_2=CHCF_3$, $CH_2=C=CH_2$, $CH_3CH=CH_2$ and $CFCl=CFCl$ have been shown to "telomerize" with great difficulty by ultraviolet or peroxide initiation. The products obtained in these cases were almost entirely the 1:1 adducts. Previous efforts to force olefins such as ethylene, propene, 3,3,3-trifluoropropene or hexafluoropropene to give a polymer $RCFX[olefin]_nY$ with $n > 4$ or 5, by cutting down the proportion of chain-transfer agent RCFXY,[10] merely caused the intermediate radical to undergo reactions other than by addition with a second molecule of olefin, *e.g.*, disproportionation, dimerization or internal expulsion of halogen to give an olefin.[2]

The results of the present investigation (see Tables I and II) demonstrate that perfluoropropene can give telomers such as $C_2F_7[CF_2CF(CF_3)]_nI$ where $n = 10$ and higher.

This simple thermal method of producing telomers of perfluoropropene is applicable to other relatively non-polymerizable or poorly polymerizable olefins (*vide infra*). It is proposed that this method proceeds by "successive addition steps" (probably involving transient radical formation and a single transition state for each addition) with little contribution from a chain mechanism including a propagation step, *i.e.* $RCFX[olefin]\cdot + (n-1)$ olefin $\rightarrow$ $RCFX[olefin]\cdot_n$, etc. For example, in the case of the perfluoropropene reaction with perfluoropropyl iodide, the formation of telomers may be regarded as occurring in discrete steps.[11]

$$C_3F_7I + CF_2{=}CFCF_3 \longrightarrow C_3F_7CF_2CF(CF_3)I$$

$$C_3F_7CF_2CF(CF_3)I + CF_2{=}CFCF_3 \longrightarrow C_3F_7[CF_2CF(CF_3)]_2I, \text{ etc.}$$

$$C_3F_7[CF_2CF(CF_3)]_nI + CF_2{=}CFCF_3 \longrightarrow C_3F_7[CF_2CF(CF_3)]_{n+1}I$$

Thermal syntheses of perfluoropropene with CF_3I, C_3F_7I, $C_4F_9CFICF_3$, $C_4F_9CF(CF_3)CF_2CF(CF_3)I$ and $CF_2ClCFCII$[12] have been successfully carried out. $R[CF_2CF(CF_3)]_nI$ where R = CF_3, C_3F_7, $C_4F_9CF(CF_3)$, $C_4F_9CF(CF_3)CF_2CF(CF_3)$ and $CF_2ClCFCl$ and $n = 1$ to >10 have been obtained. Thus any reactant containing the moieties: $-CF_2I$, $-CF(C_nF_{2n+1})I$ and $-CFXI$ (where X = polyhalogenoalkyl) can be used. In addition, modified reactions of perfluoropropene have been effected simply by heating the olefin in the presence of iodine monochloride.[7] A new reactant, CF_3CFICF_2Cl, is formed *in situ* to begin the formation of telomers. Likewise, iodine has been made to react with perfluoropropene to form modified telomers. At somewhat higher temperatures CF_2Br_2 and fluoroalkyl bromides containing the groups $-CF(C_nF_{2n+1})Br$ and $-CFClBr$ may be used as reactants.[7]

Although the full scope of this method of producing telomers has not been determined, certain conclusions with regard to the types of unreactive (relatively non-polymerizable) olefins to which it is applicable may be drawn. 1. An olefin which on addition of R_fI would form a $-CF_2I$, $-CF(C_nF_{2n+1})I$ or similar linkage, *e.g.*, $R_fI + CF_2{=}CHCF_3 \rightarrow R_fCH(CF_3)CF_2I$,[13] $R_fI + CH_2{=}CFCF_3 \rightarrow R_fCH_2CF(CF_3)I$, would be expected to produce a telomer.

2. Olefins such as ethylene and propene would form on addition of R_fI the linkages $-CH_2CH_2I$ and $-CH_2CHICH_3$. Such C–I bonds do not undergo facile homolytic fission[8] and the temperatures required for telomer formation would probably exceed those necessary for competing size reactions or decomposition. Thus, successful thermal synthesis of telomers of these olefins is improbable.

The maintenance of a sufficiently high energy level to overcome the energies of activation required to promote and sustain the reaction is undoubtedly one of the principal reasons why telomers of unreactive olefins can be produced at appreciable rates by thermal synthesis but not by photochemical or peroxide-induced initiation.

The data in Tables I and II present the important conditions, results and product characterizations of the reactions of perfluoropropene with *n*-C_3F_7I, CF_3I, $C_4F_9CFICF_3$ and $C_4F_9CF(CF_3)CF_2CFICF_3$.

(10) C–Y in RCFXY is weak, yet RCFX is sufficientiy reactive to attack the olefin, *e.g.*, when RCFXY = CF_2I, $CF_2ClCFCII$ or $CF_2ClCFClBr$.

(11) It is proposed that in these addition steps the $C_3F_7\cdot$ and the I· from the same molecule add simultaneously to the double bond, *i.e.*, chain transfer with the solvent (C_3F_7I) is a minor effect. It is likely that the thermally activated molecule [illegible]

dissociation. See A. D. Kirschenbaum, A. G. Streng and M. Hauptschein, THIS JOURNAL, **75**, 3141 (1953).

(12) P. Tarrant and M. R. Lilyquist, *ibid.*, **77**, 3640 (1955), attempted the reaction of perfluoropropene with 1,2-dichloro-2-iodo-1,1,2-trifluoroethane in the presence of benzoyl peroxide as the catalyst at 100°. No addition products or simple telomers were obtained.

(13) The direction of the photochemical addition of CF_2I to $CF_2{=}CHCF_3$ has been established by R. N. Haszeldine and B. R. Steele, *J. Chem. Soc.*, 2685 (1953).

CF_2I chromophore (271 mμ).[8] Thus, in the addition of 1-iodoperfluoropropane to perfluoropropene, the adduct is I and not II. Fluorination of this adduct with cobalt trifluoride gave only perfluoro-*n*-hexane as the product, which confirms the structure I.

$CF_3CF_2CF_2CF_2CFICF_3$ (I) $\qquad$ $CF_3CF_2CF_2CF(CF_3)CF_2I$ (II)

Thermal reactions (telomerizations) in autoclaves of reactive olefins such as chlorotrifluoroethylene and tetrafluoroethylene in contrast to the unreactive perfluoropropene are much more difficult to control to give well defined products of narrow molecular weight ranges. Using reaction times of 1–5 hr. in contrast to several days for the photochemical liquid phase reaction[2] and under otherwise comparable conditions, the $CF_2ClCFClI + CF_2{=}CFCl$ thermal reaction gave products of much wider molecular weight ranges. Under certain thermal conditions $CF_2ClCFClI$ and $CF_2ClCFCl(CF_2CFCl)_nI$ can react with comparable facility with additional olefin. Thus it is difficult even in the presence of an excess of this very efficient chain transfer agent and very short reaction times in autoclaves, to conveniently limit the spread of molecular weights.

The best control of a thermal reaction of chlorotrifluoroethylene was carried out in the liquid phase using a short contact time in a spiral tube reactor at a 5.8:1 mole ratio of $CF_2ClCFClI$ to $CF_2{=}CFCl$. The product composition was *ca.* 22% each of n = 1, 2 and 3 and *ca.* 33% of $n = 4$ to > 10.

In an autoclave reaction, $CF_2ClCFClI + CF_2{=}CF_2$ gave predominantly very high molecular weight telomers of formula $CF_2ClCFCl(CF_2CF_2)_nI$. A liquid-phase reaction in the tube reactor, however, should provide more effective control of the reaction (especially since the C–I bond in a $-CF_2I$ group is stronger than in a $-CFClI$ group) but is potentially extremely hazardous.

In contrast, control of the thermal reaction of perfluoropropene with 1-iodoperfluoropropane is simple. High or even equal ratios of iodide to olefin are not necessary to realize high yields of $n = 1$ and $n = 2$, since a chain transfer step is not necessary. The reaction time is the important variable in controlling the process, and high yields of $n = 1$ may be achieved with iodide-to-olefin ratios varying from 1:1 to <1:5 by terminating the reaction after a suitable time interval and pressure drop. Thus, since perfluoropropene does not telomerize significantly by chain propagation, it is always advantageous to use reasonably high proportions of olefin regardless of the ultimate chain length desired and obtain particular ranges of n by limiting the reaction time. A high initial pressure (olefin concentration) and good agitation enhance olefin–iodide contact and increase the reaction rate.

The rate of reaction of C_3F_7I with perfluoropropene to give $n = 1$ is somewhat more rapid than the reaction of the products $C_3F_7[CF_2CF(CF_3)]_nI$ with the same olefin. This may be attributed to the greater reactivity of the primary $CF_3CF_2CF_2$· radical relative to the secondary $-CF(CF_3)$ radical.

An examination of Table II will reveal that when the mole ratio of $C_3F_6:C_3F_7I$ was 4.3:1 and the initial pressure was 4600 p.s.i. an increase in time of approximately fivefold raised the conversion from 52 to 88%. The product distribution (% yields) for 20 and 98 hr., respectively, were for n = 1, 66, 44; n = 2, 19, 28; n = 3, 16, 16; n = 4, —, 8; n = 5, 0, 4.

When the mole ratio of $C_3F_6:C_3F_7I$ was 10.4 and the time was 336 hr., the total yield of product for n = 3–10 was 83%; n = 3, 41%; n = 4, 30%.

At an initial pressure of 10,700 p.s.i. and at a mole ratio of $C_3F_6:C_3F_7[CF_2CF(CF_3)]_2I = 12.8$ the yield of product after 137 hr. reaction time was *ca.* 60% for n = 3–5 and *ca.* 40% for n = 6–15.

It has been demonstrated that reaction times (for a given conversion) can be shortened greatly by the periodic addition of olefin to maintain a high pressure or concentration.

Experimental

General Procedure.—A 300-ml. Monel autoclave was charged with the fluoroalkyl iodide. The autoclave was cooled in Dry Ice or liquid nitrogen and the olefin was introduced by vacuum transfer. The autoclave was closed and heated to about 200°, usually in a shaker. After the reaction period, the olefin was recovered by condensation in appropriately refrigerated traps. Rectification of the remaining reaction products in a Vigreux unit effected the separation of the individual telomer fractions. Table I lists the physical constants and the analytical data for the new compounds. The conditions and results of the various runs are summarized in Table II. In most cases two-thirds of the autoclave volume was occupied by liquid phase.

In a typical run, 98.0 g. (0.331 mole) of 1-iodoperfluoropropane and 240 g. (1.60 moles) of perfluoropropene (4.83 mole ratio of olefin:iodide) were used. The pressure dropped from 4600 to 2100 p.s.i. in 4 days, most of the drop occurring during the first day. [If after one day the autoclave was repressured with sufficient perfluoropropene (20–40 g.) to raise the pressure to 4500–5500 p.s.i., the rate of reaction as indicated by the pressure drop was increased markedly. Thus, the maintenance of a high olefin concentration by periodic addition of more olefin, would have greatly shortened the times given in Table II.] There were recovered 157 g. of perfluoropropene and 6.7 g. of 1-iodoperfluoropropane. A total of 176 g. of product was collected and characterized as summarized in the tables.

In all of these experiments no more than a few tenths of a gram of free iodine was collected from the autoclave, indicating the absence of significant side reactions at the temperatures used. The perfluoropropene telomers are considerably more stable during distillation than the $CF_2ClCFCl(CF_2CFCl)_nI$ telomers.

During these procedures precautions were taken to exclude oxygen to prevent reactions with the iodides. The $C_3F_7[CF_2CF(CF_3)]_nI$ telomers where n = 1 to 5 are clear fluids varying in viscosity range from a light to a barely flowing liquid. The solids of $n > 5$ are transparent waxes and glasses.

Fluorination of 2-Iodoperfluorohexane.—Cobalt trifluoride (60 g.) supported on copper shot was placed in a vertical copper tube, which was surrounded by a tube furnace. 2-Iodoperfluorohexane (20 g., 0.0448 mole) was added drop by drop on top of the cobalt trifluoride under a dry nitrogen atmosphere at 260–290°. The exit gases were condensed in a Dry Ice-cooled trap, washed with 5% sodium hydroxide (some handling losses occurred), dried with Drierite and distilled to give only *n*-perfluorohexane (75%), b.p. 54°, as shown by its infrared spectrum.[14]

The Thermal Reaction of 1,2-Dichloro-2-iodo-1,1,2-trifluoroethane with Perfluoropropene.—A 300-ml. Monel autoclave filled with Monel balls to reduce the effective volume to 150 ml. was charged with 50 g. of $CF_2ClCFClI$ and 75 g. of perfluoropropene and heated for 112 hr. at 172–197° in a molten salt-bath and then for 15.5 hr. in a shaker at 201°. During this period the pressure dropped from 950 p.s.i. at 172° to 750 p.s.i. at 201°. At this time

an additional 20 g. of perfluoropropene was charged into the autoclave which was heated for 40 hours more at 201°. Seventy grams of olefin and 15 g. of $CF_2ClCFClI$ were recovered. Rectification of the remaining product *in vacuo* gave $CF_2ClCFCl[CF_2CF(CF_3)]_nI$ where n = 1 (25 g.), b.p. mostly 58.5–60.5° at 20 mm., $n^{25}D$ 1.3908, λ_{max} 282 mμ, ε 203. *Anal.* Calcd. for $C_5Cl_2F_9I$: C, 14.0. Found: C, 14.4, 14.5. Where n = 2 (15 g.), b.p. mostly 97.5–104° at 20 mm., $n^{25}D$ 1.3760, λ_{max} 282 mμ, ε 205. *Anal.* Calcd. for $C_7Cl_2F_{13}I$: C, 16.6. Found: C, 16.6, 16.9. Where $n = 3_{av.}$ (7 g.), b.p. mostly 77–87° at *ca.* 0.1 mm., $n^{27}D$ 1.3706, (not analyzed). Where $n = 4_{av.}$ (4 g.), b.p. 87–138° at *ca.* 0.1 mm., $n^{27}D$ 1.3691, λ_{max} 282 mμ. *Anal.* Calcd. for $C_{14}Cl_2F_{27}I$: C, 19.1; mol. wt., 879. Found: C, 19.0; mol. wt. (from absorbancy at 282 mμ of a known concentration in 2,3,3-trichloroheptafluorobutane using an ε value of 205), 850.

The Thermal Reaction of 1,2-Dichloro-2-iodo-1,1,2-trifluoroethane with Chlorotrifluoroethylene. (a) **In Autoclaves.**—A 1-l. stainless steel autoclave was charged with 650 g. (2.33 moles) of 1,2-dichloro-2-iodo-1,1,2-trifluoroethane and 248 g. (2.13 moles) of chlorotrifluoroethylene (1.1:1 mole ratio of iodide to olefin) and heated for 5 hr. at 180° in a molten salt-bath. During this time a pressure drop from 500 to 300 p.s.i. was observed with the major portion of the reaction occurring in the first hour (ΔP = 125 p.s.i.).

Forty-five grams of olefin was recovered from the autoclave by gaseous transfer to a Dry Ice-cooled trap, and the remaining products were distilled through a short Vigreux column. A total of 581 g. of $CF_2ClCFClI$ was recovered, b.p. 99–102°, and telomer fractions, $CF_2ClCFCl(CF_2CFCl)_nI$, were taken as follows: n = 1–2, b.p. 45–93° at 1 mm. (36 g.); n = 3–4, b.p. to 150° at <0.1 mm. (80 g.). When the vapor temperature of 150° was reached, the temperature of the still-pot was sufficiently elevated due to the presence of very high molecular weight telomers to cause extensive liberation of iodine and the distillation had to be stopped. The distilled fractions were identified and the composition of the hard waxy residue (127 g.) was estimated to be n = 4 to >20 (mostly n > 10) by reference to published physical data[3] and ultraviolet molar extinction determinations.

Another experiment was carried out using a molar ratio of $CF_2ClCFClI:CF_2{=}CFCl$ of 15:1 at 160–170° for 5.7 hr. The yield of n = 1 and 2 was <20%, whereas under liquid phase photochemical conditions (5 days) a 75% yield of n = 1 was obtained by Haszeldine.[2]

(b) **In Hot Tubes.**—An attempt to prepare n = 1 by passing $CF_2{=}CFCl$ through a large excess of refluxing $CF_2ClCFClI$ in a vertical column heated to 180° failed to give any significant reaction. Therefore, an alternative reaction system allowing higher pressures and temperatures as well as short contact time was designed.

At an average rate of 9.6 g./min., a mixture of 2230 g. (8.0 moles) of 1,2-dichloro-2-iodo-1,1,2-trifluoroethane and 160 g. (1.37 moles) of chlorotrifluoroethylene was pumped by means of a Lapp Pulsafeeder micropump from a charge cylinder through a stainless steel coil immersed in a molten salt-bath at 200°. Practically all of the coil volume was occupied by liquid phase, and the contact time in this hot zone was calculated as <10 min. During the reaction, the pressure was maintained at 750 p.s.i. by adjusting the rate at which products were vented from the coil to a Dry Ice-cooled receiving gas cylinder. Twelve grams of chlorotrifluoroethylene and 2150 g. of $CF_2ClCFClI$ were recovered. The product distribution of the remaining 211 g. of crude telomer was n = 1 (22%), n = 2 (22%), n = 3 (22%) and n = 4 to >10 (33%).

In the above apparatus at a rate of 17 g./min. at 195–200° and at pressures of 600–650 p.s.i. only slight reaction occurred.

The Thermal Reaction of 1,2-Dichloro-2-iodo-1,1,2-trifluoroethane with Tetrafluoroethylene.—1,2-Dichloro-2-iodo-1,1,2-trifluoroethane (200 g., 0.716 mole) and 30 g. (0.316 mole) of tetrafluoroethylene (2.4 mole ratio of iodide to olefin) were charged into a 300-ml. nickel autoclave and heated in a molten salt-bath for 2.75 hr. at 171°. After the reaction period, during which the pressure fell from 600 to 450 p.s.i., 15 g. of tetrafluoroethylene was recovered. From the remaining products 170 g. of $CF_2ClCFClI$ was recovered (some handling losses), and 16 g. of a white crumbly solid was the only other product. This solid contained only very small amounts of iodine and its ultraviolet spectrum showed a very faint maximum at *ca.* 270 mμ. Its infrared spectrum closely resembled that of polytetrafluoroethylene.

Ultraviolet Spectra.—A Beckman ratio recording spectrophotometer, model DK-2, was used.

Acknowledgment.—We wish to thank Mr. John J. Mullaney for technical assistance, Miss Ruth Kossatz, Miss Eva Raieta and Mr. Harry Rein for spectroscopic measurements, and Mr. John Y. Steel for certain carbon analyses.

Studies in Organic Sulfur Compounds. IX.[1] Preparation and Desulfurization of Optically Active 1,1-Diphenyl-3-mercaptopropan-2-ol[2]

BY CARL DJERASSI AND J. GROSSMAN

RECEIVED DECEMBER 12, 1956

Acid cleavage of spiro-(5-diphenylmethyl-1,3-oxathiolane-2,3′-cholestane) (I) followed by lithium aluminum hydride reduction of the resulting disulfide VII led to optically pure 1,1-diphenyl-3-mercaptopropan-2-ol (IV). Raney nickel desulfurization of this β-mercaptoethanol or of its O,S-dibenzoate (VI) furnished 1,1-diphenylpropan-2-ol or its benzoate, respectively. The rotations of this alcohol (IIIa) and its derivatives were identical with those of the earlier prepared desulfurization product of the hemithioketal I. These results show that no racemization occurs in the formation of alcohols by Raney nickel desulfurization of hemithioketals (*e.g.*, I) or of β-mercaptoethanols (*e.g.*, IV).

The observation[1] that Raney nickel desulfurization of hemithioketals (1,3-oxathiolanes) results in introduction of oxygen has led to an investigation of the scope of this reaction, and the appropriate experiments will be reported at a future time. We have also been concerned with the mechanism of this reaction and certain observations bearing on this aspect form the subject of the present paper.

The desulfurization of spiro-(5-diphenylmethyl-1,3-oxathiolane-2,3′-cholestane) (I) led[1] to over 50% each of cholestan-3-one (II) and 1,1-diphenylpropan-2-ol (III). This alcohol (III) was optically active ($[\alpha]D$ +5.8°, 3,5-dinitrobenzoate $[\alpha]D$ −46.8°), and since an antipode with the same optical properties (but opposite in sign) was isolated by desulfurization of a diastereoisomer of the hemithioketal I, it was assumed that complete re-

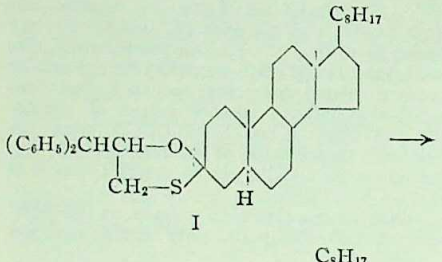
tention of optical activity is observed in this reaction. This leads to the mechanistically important conclusion that the oxygen present in the original hemithioketal I is the one eventually found in 1,1-diphenylpropan-2-ol (III) and that rupture of the C–O bond during the desulfurization occurred only at the position indicated by the dotted line[3] in structure I.

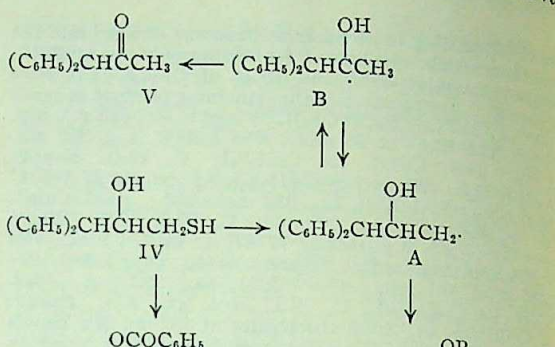


I

II III

The fact that both antipodes of 1,1-diphenylpropan-2-ol (III) were obtained does not exclude rigorously the possibility that partial racemization to *exactly the same extent* may have occurred in the desulfurization of the two diastereoisomeric hemithioketals (I), and independent confirmation was considered necessary since optically pure 1,1-diphenylpropan-2-ol (III) has not been described in the literature.[3a] The approach used in the present investigation also has a bearing on the mechanism of the desulfurization of β-mercaptoethanols, since it has been observed earlier[1] that desulfurization will yield a mixture of alcohol (predominant) and ketone. In the case of 1,1-diphenyl-3-mercaptopropan-2-ol (IV), both 1,1-diphenylpropan-2-ol (IIIa) and 1,1-diphenylacetone (V) were produced, and it could be demonstrated that they were not formed from each other by reduction or oxidation. Mechanistically, two simple paths can be suggested for the formation of the alcohol and these are not mutually exclusive: (a) the initially formed free radical A may pick up hydrogen to lead directly to the alcohol IIIa or (b) there may occur a 1,2-shift to the radical B which could either lose a hydrogen atom to give the ketone V or accept one, thus providing an alternate route to the alcohol IIIa.

Experimentally, these two mechanisms should be differentiable by studying the desulfurization of an optically active β-mercaptoethanol since only intermediate B would involve racemization. It was felt that by preparing optically active 1,1-diphenyl-3-mercaptopropan-2-ol (IV) both questions posed above could be answered in a satisfactory manner.



Since hemithioketals can be cleaved by means of acid,[4] the three diastereoisomeric hemithioketals I[1] constituted an ideal starting material for the preparation of an optically pure β-mercaptoethanol, which had the additional advantage of being crystalline. Treatment of any one of the three diastereoisomeric hemithioketals I[1] with hydrochloric acid in boiling *unpurified* dioxane yielded the same crystalline product, m.p. 140–142°, which was shown to be bis-(1,1-diphenyl-2-hydroxy-3-propyl) disulfide (VII).[5] Diastereoisomers B and C[1] yielded levorotatory material ([α]D − 168°) while diastereoisomer A[1] furnished the dextrorotatory antipode ([α]D +170°). Reduction of the appropriate disulfide VII with lithium aluminum hydride afforded the two optically pure antipodes of crystalline 1,1-diphenyl-3-mercaptopropan-2-ol (IV),[6] further characterized as the O,S-dibenzoate VI. The alcohol IV could be obtained directly from the hemithioketal I when the acid cleavage was conducted in *freshly purified* dioxane, suggesting that peroxides in the unpurified solvent were responsible for disulfide formation.

Raney nickel desulfurization of (+)-1,1-diphenyl-3-mercaptopropan-2-ol (IV) yielded 1,1-diphenylacetone (V) and 1,1-diphenylpropan-2-ol (IIIa) identical in all respects including rotation of the alcohol and its 3,5-dinitrobenzoate (IIIc) with specimens obtained earlier[1] by desulfurization of diastereoisomer A of the hemithioketal I. Furthermore, desulfurization of the O,S-dibenzoate VI[7] led to an optically active benzoate IIIb which had the same rotation as the benzoylation product of 1,1-diphenylpropan-2-ol obtained by desul-

(3) This is based on the assumption that complete retention of configuration rather than complete inversion of configuration is involved in the desulfurization of the hemithioketal.

(3a) NOTE ADDED IN PROOF.—It has been called to our attention that both antipodes of this alcohol and certain of its derivatives have been described already by D. J. Cram and F. A. Abd Elhafez, THIS JOURNAL, **76**, 28 (1954).

(4) J. Romo, G. Rosenkranz and C. Djerassi, *ibid*, **73**, 4961 (1951).

(5) A control experiment with *dl*-1,1-diphenyl-3-mercaptopropan-2-ol (IV) demonstrated that it was converted into the disulfide VII when subjected to the same treatment as the hemithioketal I.

(6) The racemic substance already has been prepared by another procedure by C. Djerassi, M. Gorman, F. X. Markley and E. B. Oldenburg, THIS JOURNAL, **77**, 568 (1955).

(7) It is pertinent to note that no diphenylacetone (V) was encountered in this experiment.

Digitized by Arya Samaj Foundation Chennai and eGangotri

furization of either I or IV. On the basis of these results, we feel confident that the earlier assumed[1] retention of optical activity in the desulfurization of hemithioketals (such as I) is indeed justified and that the desulfurization of β-mercaptoethanols (such as IV) to the corresponding alcohol (such as III) does not involve the carbon atom bearing the alcoholic function.

Experimental[8]

Bis-(1,1-diphenyl-2-hydroxy-3-propyl) Disulfide (VII).—A mixture of 1.5 g. of isomer C (m.p. 153°) of spiro-(5-diphenylmethyl-1,3-oxathiolane-2,3′-cholestane) (I),[1] 100 cc. of *unpurified* dioxane, 8 cc. of concd. hydrochloric acid and 20 cc. of water was heated under reflux for 18 hr., cooled, diluted with water and extracted with ether. The washed and dried ethereal solution was evaporated to dryness and the residue was chromatographed on 50 g. of Fisher alumina deactivated in hexane solution with 5 cc. of 10% acetic acid. Elution with hexane gave 210 mg. of recovered hemithioketal I while 620 mg. of cholestan-3-one (II) (m.p. 127–129°) was eluted with 8:2 hexane–benzene. The desired disulfide (380 mg.) was eluted with 1:1 hexane–benzene and after two recrystallizations from hexane–ether yielded 320 mg. of colorless crystals, m.p. 140–142°, $[\alpha]_D$ −163° (*c* 0.55).

Anal. Calcd. for $C_{30}H_{30}O_2S_2$: C, 74.05; H, 6.22; S, 13.16; mol. wt., 486. Found: C, 74.40; H, 6.20; S, 13.26; Rast mol. wt., 438.

Similar cleavage of 2.0 g. of isomer A (m.p. 194°) yielded 0.42 g. of (+)-bis-(1,1-diphenyl-2-hydroxy-3-propyl) disulfide, m.p. 140–142°, $[\alpha]_D$ +170° (*c* 0.6), while 1.1 g. of isomer B (m.p. 175°) gave 0.2 g. of the (−)-disulfide VII.

The *dl*-disulfide, m.p. 110–112°, was prepared by boiling *dl*-1,1-diphenyl-3-mercaptopropan-2-ol (IV)[6] with unpurified dioxane–hydrochloric acid for 24 hr.

1,1-Diphenyl-3-mercaptopropan-2-ol (IV). (a) By Acid Cleavage in Purified Dioxane of Spiro-(5-diphenylmethyl-1,3-oxathiolane-2,3′-cholestane) (I).—A solution of 4.0 g. of isomer A[1] of the hemithioketal I was heated under reflux for 24 hr. in 200 cc. of freshly purified (distilled from sodium) dioxane with 16 cc. of concd. hydrochloric acid and 40 cc. of water. The mixture was processed as above and after separating much unreacted hemithioketal and some cholestan-3-one, 280 mg. of the desired (+)-1,1-diphenyl-3-mercaptopropan-2-ol (IV) was obtained from the hexane–benzene (1:1) eluates; m.p. 69–72°, raised after recrystallization from hexane–ether to m.p. 74–75°, $[\alpha]_D$ +38° (*c* 1.05). The antipode ($[\alpha]_D$ −36°) was obtained in the same manner from isomer C.

Anal. Calcd. for $C_{15}H_{16}OS$: C, 73.75; H, 6.60. Found: C, 73.29; H, 6.88.

(b) By Lithium Aluminum Hydride Reduction of Bis-(1,1-diphenyl-2-hydroxy-3-propyl) Disulfide (VII).—A solution of 300 mg. of the (−)-disulfide VII in 50 cc. of tetrahydrofuran was heated under reflux for 24 hr. with a large excess of lithium aluminum hydride. Decomposition of the reagent with ethyl acetate followed by addition of 10% hydrochloric acid and isolation with ether yielded 280 mg. of the above described (−)-1,1-diphenyl-3-mercaptopropanol, m.p. 70–74°, which was raised to 74–75° after one recrystallization. Similar treatment of 100 mg. of the (+)-disulfide VII gave 80 mg. of (+)-1,1-diphenyl-3-mercaptopropan-2-ol (IV).

1,1-Diphenyl-3-mercaptopropan-2-ol O,S-Dibenzoate (VI).—A mixture of 200 mg. of (+)-1,1-diphenyl-3-mercaptopropan-2-ol (IV), 1 cc. of benzoyl chloride and 5 cc. of pyridine was allowed to stand at room temperature for 24 hr., diluted with water, and the product was extracted with ether. After appropriate washing and drying, the residue was recrystallized from methanol to furnish 230 mg. of the (+)-dibenzoate, m.p. 129–131°, $[\alpha]_D$ +69° (*c* 0.70); $\lambda_{max}^{CHCl_3}$: 5.76, 5.93, 7.82, 8.43 and 8.95 μ.

Anal. Calcd. for $C_{29}H_{24}O_3S$: C, 76.97; H, 5.35; S, 7.07. Found: C, 76.91; H, 5.45; S, 6.80.

Similar treatment of the *dl*-mercaptopropanol[6] yielded ***dl*-1,1-diphenyl-3-mercaptopropan-2-ol dibenzoate** (VI), m.p. 146–147°, the infrared spectrum (chloroform solution) of which was identical with that of the (+)-isomer.

Anal. Found: C, 77.45; H, 5.44; S, 6.81.

Desulfurization of 1,1-Diphenyl-3-mercaptopropan-2-ol (IV).—A 350-mg. sample of (+)-1,1-diphenyl-3-mercaptopropan-2-ol in 100 cc. of ethyl methyl ketone was heated with stirring under reflux with 6 g. of 3 day old W-2 Raney nickel catalyst (deactivated by heating for 1 hr. in ethyl methyl ketone solution). The reaction mixture was processed in the previously described manner[1] including chromatography. Elution with hexane gave 65 mg. of diphenylacetone (V), m.p. 55–58° (identified by infrared spectrum), while the desired diphenylpropanol (IIIa)[1] (150 mg., m.p. 56–58°, $[\alpha]_D$ +6°) was removed with 1:1 hexane–benzene. The alcohol was converted into (+)-1,1-diphenylpropan-2-ol 3,5-dinitrobenzoate (IIIc)[1] which exhibited m.p. 154–155°, $[\alpha]_D$ −44.4° (*c* 0.95) after recrystallization from methanol, and into (+)-1,1-diphenylpropan-2-ol benzoate, m.p. 78–79°, $[\alpha]_D$ +18° (*c* 2.03).

Desulfurization of 1,1-Diphenyl-3-mercaptopropan-2-ol O,S-Dibenzoate (VI).—The desulfurization of 300 mg. of *dl*-1,1-diphenyl-3-mercaptopropan-2-ol O,S-dibenzoate was carried out in the above described manner with 6 g. of 4 day old W-2 Raney nickel catalyst in 100 cc. of ethyl methyl ketone for 2 days. Recrystallization of the crude reaction product yielded 120 mg. of *dl*-1,1-diphenylpropan-2-ol benzoate (m.p. 90–92°). In order to ensure[7] the absence of 1,1-diphenylacetone in the mother liquors, these were saponified with 10% methanolic potassium hydroxide solution, and the total product was found not to possess any carbonyl band in the infrared. Chromatography yielded 55 mg. of 1,1-diphenylpropan-2-ol, m.p. 59–61°.

When the desulfurization was carried out with (−)-1,1-diphenyl-3-mercaptopropan-2-ol O,S-dibenzoate, there was obtained after recrystallization from methanol (−)-1,1-diphenylpropan-2-ol benzoate (IIIb), m.p. 77–79°, $[\alpha]_D$ −17° (*c* 0.43), the infrared spectrum of which was identical with that of the *dl*-benzoate.

Anal. Calcd. for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37. Found: C, 83.52; H, 6.54.

DETROIT, MICHIGAN

(8) All melting points were determined on the Kofler block. We are indebted to Mrs. Dolores Phillips for the infrared spectral measurements and to Dr. A. Bernhardt (Mülheim, Germany) for the microanalyses. All rotations were measured in chloroform solution in 1-dcm. tubes.

Synthesis of the Thieno[3,2-b]pyrrole System

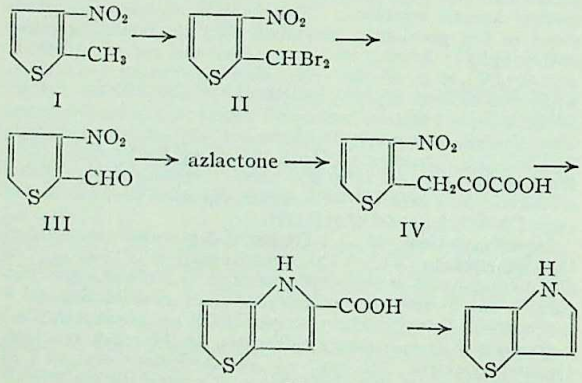
BY H. R. SNYDER, L. A. CARPINO,[1] J. F. ZACK, JR.,[2] AND J. F. MILLS[3]

RECEIVED OCTOBER 11, 1956

The synthesis of thieno[3,2-b]pyrrole (VI) was carried out by conversion of 3-nitro-2-methylthiophene to 3-nitro-2-thenaldehyde followed by application of the azlactone synthesis to give 3-nitro-2-thienylpyruvic acid, which was reduced to the thienopyrrolecarboxylic acid (V). Decarboxylation of V to thieno[3,2-b]pyrrole (VI) was effected by heat in an evacuated sealed tube. A similar reaction scheme proceeding from 2-nitro-3-methylthiophene was examined in order to obtain the isomeric thienopyrrole, but the final step, reduction of the pyruvic acid, was unsuccessful.

A number of thiophene analogs of physiologically active compounds have been found to be active as anti-metabolites. For example, β-3-thienylalanine inhibits the growth of the microorganisms, *S. cervisiae* and *E. coli*.[4] Attention was directed toward the preparation of a thiophene analog of indole with the hope of converting it to the corresponding tryptophan by one of the well-known methods.

The synthesis of thieno[3,2,-b]pyrrole (VI) was carried out by the modified Reissert method[5] as indicated (I → VI).

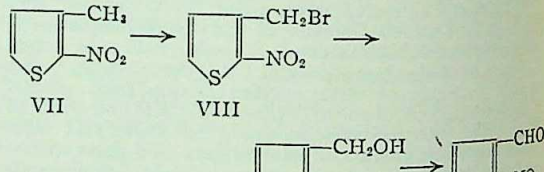


For the preparation of 3-nitro-2-methylthiophene (I) a modification of the method of Rinkes was used.[6] 2-Methylthiophene was converted to 5-methyl-2-acetylthiophene by the method of Hartough and Kosak.[7] The ketone was oxidized to 2-methyl-5-thenoic acid with alkaline hypochlorite.[8] Nitration and subsequent decarboxylation gave I.

One or two moles of N-bromosuccinimide in boiling carbon tetrachloride converted I to the mono- or dibromide II, and the latter was transformed to 3-nitro-2-thenaldehyde (III) *via* the diacetate. The pyruvic acid (IV), which was prepared by hydrolysis of the azlactone of III, was reduced to the thienopyrrolecarboxylic acid (V) by means of aqueous ammonia and ferrous sulfate.[9] This acid (V) is similar in physical appearance and melting point to indole-2-carboxylic acid, and like the latter it imparts a red-brown coloration[10] to a ferric chloride solution. It differs from indole-2-carboxylic acid in that it chars on melting rather than undergoing smooth decarboxylation. Attempted decarboxylation with mercuric acetate also failed. Decarboxylation of V was effected by heating the acid in an evacuated tube.

Thieno[3,2,-b]pyrrole is a white crystalline substance, melting at about 30°, that has an odor very similar to that of indole. When exposed to air at room temperature, it decomposes. It forms a red picrate that decomposes on standing in alcohol. The infrared spectrum (Fig. 1) is similar to that of indole in many respects.

A similar method was examined for the preparation of the isomeric acid. The key steps leading to the aldehyde X are



In contrast to the reactivity of 3-nitro-2-methylthiophene with N-bromosuccinimide, the isomeric compound VII is unaffected by this reagent in boiling carbon tetrachloride.[11] However, it was found that reaction could be made to occur by substituting ethylene dibromide for the lower-boiling solvent.

It was possible to convert the bromide VIII directly to the aldehyde X by oxidation with selenium dioxide, but the results were not consistent.[12] A more reliable method involved oxidation of the alcohol IX by N-bromosuccinimide in a method similar to that of Grob and Schmid.[13]

Conversion of the aldehyde X to the corresponding pyruvic acid was carried out by the method outlined above. Reduction of the pyruvic acid gave a non-crystalline product which underwent decomposition on attempted purification.

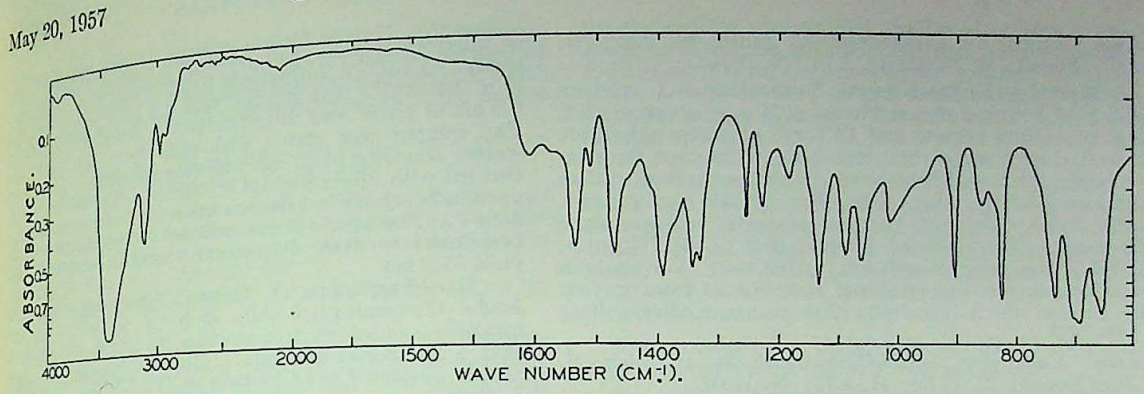

Fig. 1.

Experimental

2-Methyl-5-thenoic Acid.—This acid was prepared by acylation of 2-methylthiophene followed by a haloform reaction according to the procedures described by Hartough, *et al.*[7,8]

2-Methyl-3-nitro-5-thenoic Acid.—The following procedure is a convenient modification of the method of Rinkes.[6] Fuming nitric acid (300 g., sp. gr. 1.5) was added slowly to 700 ml. of acetic anhydride contained in a 2-l. round-bottomed flask fitted with a Hershberg stirrer and cooled by means of a Dry Ice–acetone mixture. The resulting solution was cooled to −12°, and 210 g. of finely powdered 2-methyl-5-thenoic acid was added, with stirring, in portions of 1–2 g., during the course of 45 minutes. A pale pink solid separated; after addition of the acid, the mixture was stirred for ten minutes, during which time the temperature fell to −20°. The crystalline solid was filtered and triturated with 400 ml. of water and 100 g. of ice. When the ice had melted, the pink solid was collected and washed three times with water; the wet product was recrystallized from 95% ethanol. Large orange-pink crystals (126.5 g., 45.7%), m.p., 178–180°, separated on standing. A sample was sublimed at 160° (0.8 mm.) to yield white crystals, m.p. 180–181° (lit.[6] 181°).

A by-product, 2-methyl-3,5-dinitrothiophene, can be isolated by pouring the acetic anhydride filtrate onto 2 kg. of ice and 2 l. of water, filtering the sticky red solid which precipitates and recrystallizing it from ethanol and then from high-boiling petroleum ether to give tan colored crystals (8–15 g.) melting at 97–99° (lit.[6] 99–100°).

3-Nitro-2-methylthiophene.—The following is a necessary modification of Rinkes' procedure.[6] A 1-l. round-bottomed flask containing a mixture of 163 g. of the nitro acid, 290 g. of quinoline and 6 g. of copper powder was fitted with a thermometer suspended into the mixture. A length of rubber tubing leading to an aspirator was loosely inserted into one of the necks of the flask to draw off vapors of water and quinoline. The flask was heated slowly with an electrical heating mantle at such a rate that the internal temperature rose approximately ten degrees every five minutes. The mass became fluid at about 85–95° and, after 55 minutes, the temperature had risen to 210°. At this point the mixture was cooled under tap water, and a solution of 600 ml. of water and 250 ml. of 85% phosphoric acid was added. The mixture was steam distilled; the distillate (5 l.) was acidified with a little dilute hydrochloric acid (1:1), cooled in an ice-bath, and the crude nitro compound (74.5 g., 59.7%) was collected. Recrystallization from low-boiling petroleum ether gave 64 g. of nearly white crystals, m.p. 44–46°. From the filtrate there was obtained an additional 5.5 g. of pure product making the total yield 69.5 g. (55.5%). It was possible to decarboxylate the acid by the mercuric acetate method, but the yield was lower (46%).[14]

3-Nitro-2-thenyl Bromide.—A solution of 14 g. of 3-nitro-2-methylthiophene (m.p. 44–46°) dissolved in 100 ml. of carbon tetrachloride was dried by distillation of a little of the solvent. There was then added, all at once, 17.3 g. of N-bromosuccinimide (recrystallized from water, dried over sulfuric acid) and 0.05 g. of benzoyl peroxide, and the mixture was refluxed for 24 hr. The mixture was cooled in an ice-bath and the crystalline succinimide was separated. The filtrate was evaporated on the steam-bath to an orange, slightly lachrymatory, thick liquid which solidified on cooling in an ice-bath. This was triturated with low-boiling petroleum ether and washed out of the flask with the aid of this solvent to give 20 g. (92%) of sticky orange solid. The crude bromide was recrystallized from about 400 ml. of low-boiling petroleum ether, which deposited 10 g. (m.p. 57–60°) of light yellow needles. An additional 1.1 g. of pure product was obtained from the filtrate so that the total yield was 11.1 g. (51.2%). The analytical sample melted at 60–62°.

Anal. Calcd. for $C_5H_4O_2NSBr$: C, 27.04; H, 1.82; N, 6.31. Found: C, 27.20; H, 2.08; N, 6.39.

3-Nitro-2-thenyl Acetate.—The acetolysis of 3-nitro-2-thenyl bromide was carried out by the method of Shriner, Fuson and Curtin.[15] For analysis the ester was recrystallized once from ethanol and twice from low-boiling petroleum ether, from which it separated in the form of slender white needles melting at 58.5–60.5°.

Anal. Calcd. for $C_7H_7O_4NS$: C, 41.80; H, 3.51; N, 6.96. Found: C, 42.08; H, 3.58; N, 6.92.

3-Nitro-2-thenal Bromide.—A mixture of 1.1 g. of 3-nitro-2-methylthiophene, 2.8 g. of N-bromosuccinimide, 0.01 g. of benzoyl peroxide and 25 ml. of dry carbon tetrachloride was refluxed for 20 hr. The solution was cooled in an ice-bath, the succinimide removed by filtration and the filtrate evaporated on the steam-bath to a thick reddish liquid (1.8 g., 75.8%) which solidified on cooling. For analysis it was recrystallized three times from low-boiling petroleum ether, which deposited the dibromide in the form of faintly yellow triangular plates melting at 72.8–74°.

Anal. Calcd. for $C_5H_3NO_2Br_2S$: C, 19.95; H, 1.01; N, 4.65. Found: C, 19.77; H, 1.20; N, 4.42.

3-Nitro-2-thenaldehyde.—A mixture of 16.5 g. of 3-nitro-2-methylthiophene, 42 g. of N-bromosuccinimide (recrystallized from water, dried over sulfuric acid), 0.15 g. of benzoyl peroxide and 200 ml. of dry carbon tetrachloride was refluxed for 66 hr., cooled in an ice-bath and filtered to remove the succinimide along with some unreacted N-bromosuccinimide.

The filtrate was evaporated on the steam-bath *in vacuo*, and to the remaining oil were added 120 ml. of ethanol, 150 ml. of water and 25 g. of sodium acetate. The resulting mixture was refluxed for 1.5 hr., 50 ml. of hydrochloric acid (sp. gr. 1.18) was added, and the refluxing was continued for 0.75 hr. The solution was then treated with Darco, the filtrate diluted with 1 l. of saturated sodium chloride solution and the resulting mixture extracted with four 50-ml. portions of ether. The ether solution was dried over magnesium sulfate and the solvent removed by distillation. The residue was distilled from a Claisen flask and 6.3 g. (34.8%) of yellow liquid, which partially solidified in the receiver, was collected at 113–127° (2–3 mm.). The aldehyde became reddish brown on standing and therefore was analyzed as the semicarbazone which forms, on recrystallization from dimethylformamide, small yellow crystals melting at 247–248° dec.

Anal. Calcd. for $C_6H_6O_3N_4S$: C, 33.64; H, 2.82; N, 26.16. Found: C, 33.92; H, 2.70; N, 26.40.

2-Methyl-4-(3-nitro-2-thenal)-5-oxazolone.—A mixture of 6.3 g. of 3-nitro-2-thenaldehyde, 4.74 g. of acenturic acid, 0.2 g. of sodium acetate and 13.7 ml. of acetic anhydride was heated for 1 hr. on the steam-bath, whereupon the mixture became red, and bright red crystals separated. After cooling at 5–10° for about 5 hr., the crystals were filtered, washed twice with small portions of acetic acid and once with water. The air-dried product (6.2 g., 64.7%, m.p. 182–185°) was pure enough for further use. For analysis the azlactone was recrystallized three times from methyl ethyl ketone, which deposited yellow-orange needles melting at 185–186°.

Anal. Calcd. for $C_9H_6N_2O_4S$: C, 45.38; H, 2.54; N, 11.76. Found: C, 45.80; H, 2.73; N, 11.67.

When an attempt was made to recrystallize the azlactone (2 g.) from 95% ethanol the solid went into the boiling solution slowly but did not separate on cooling. After evaporation of the alcohol at room temperature, 1.3 g. of reddish brown crystals were deposited, m.p. 147–150°. This compound, in contrast to the azlactone, is easily soluble in hot ethanol and was recrystallized for analysis from this solvent, which deposited a mass of lemon-yellow needles melting at 150.5–152°. Presumably this is ethyl α-acetamino-β-(2-nitro-3-thienyl)-acrylate, which was formed by opening of the azlactone ring by ethanol.

Anal. Calcd. for $C_{11}H_{12}O_5N_2S$: C, 46.48; H, 4.26; N, 9.86. Found: C, 46,81; H, 4.16; N, 10.00.

3-Nitro-2-thienylpyruvic Acid.—A mixture of 6.1 g. of 2-methyl-4-(3-nitro-2-thenal)-5-oxazolone (m.p. 182–185°) and 170 ml. of 1 *N* hydrochloric acid was refluxed for 2 hr. The yellow-orange solution was treated with Darco, filtered and allowed to cool in the ice-chest overnight. The yellow solid which separated (4.5 g., 82.1%) was recrystallized from acetic acid, which deposited 3.5 g. of tiny yellow crystals, m.p. 195–197° dec. From the filtrates, diluted with water, there was obtained an additional 0.3 g. of the pure acid. The total yield was 3.8 g. (69%). The analytical sample, prepared exactly as described above from a different batch of the azlactone, was recrystallized twice from acetic acid, which deposited tiny yellow needles, m.p. 191.5° dec. It is not known why the product obtained above (m.p. 195–197°) melted at a higher temperature than the analytical sample.

Anal. Calcd. for $C_7H_5O_6NS$: C, 39.07; H, 2.34; N, 6.51. Found: C, 39.43; H, 2.14; N, 6.62.

Thieno(3,2-b)pyrrole-2-carboxylic Acid (V).—A solution of 30 g. of ferrous sulfate heptahydrate in 33.5 ml. of warm water was added in one portion to the deep violet-red solution of 3.5 g. of 3-nitro-2-thienylpyruvic acid (m.p. 195–197°) in 33.5 ml. of water and 23.5 ml. of concentrated aqueous ammonia (sp. gr. 0.90). The black mixture was warmed on the steam-bath for 0.5 hr. with occasional shaking. The mixture was filtered and the residue on the filter extracted with 20 ml. of hot dilute aqueous ammonia. The resulting brown solution was treated with Darco and evaporated on the steam-bath *in vacuo* until the ammonium salt began to separate. The mixture was cooled, acidified with hydrochloric acid (sp. gr. 1.18) and the brownish powdery solid collected (1.3 g., m.p. 193–195° dec., yield 48%). Recrystallization from ethanol–water (1:1) gave 0.9 g. (33.3%) of brown needles, m.p. 197–198° dec. After three recrystallizations from ethanol–water (1:1), the acid separated in the form of small white needles, m.p. 193–194° dec., which darkened slightly on standing.

Anal. Calcd. for $C_7H_5O_2NS$: C, 50.31; H, 3.02; N, 8.38. Found: C, 50.58; H, 3.18; N, 8.85, 8.52.

Since thieno(3,2-b)pyrrole-2-carboxylic acid undergoes extensive charring on melting, it could not be decarboxylated by heating above the melting point. On heating at 155–160° (0.5–1.5 mm.), the acid merely sublimes. On shaking with a mixture of 10% ferric chloride solution and ethanol (1:1), the acid develops a reddish brown color. The acid dissolves in concentrated sulfuric acid to give a bright yellow-orange solution which develops a red color on standing.

Chromatography of Thieno(3,2-b)pyrrole-2-carboxylic Acid.—Silicic acid (9.0 g.) was ground with 5 ml. of water in a mortar, slurried with 40 ml. of chloroform and packed in a 50-ml. buret. The column was washed with 200 ml. of chloroform that had been previously saturated with water. Thieno(3,2-b)pyrrole-2-carboxylic acid (32.3 mg., m.p. 193–194°) was ground with 0.5 g. of silicic acid and 0.5 ml. of water, and this material was added to the column. The column was eluted with chloroform saturated with water; fractions of 10 ml. size were collected. These were titrated with dilute sodium hydroxide. The thieno(3,2-b)-pyrrole-2-carboxylic acid was collected in fractions number 3 to 7. The product was isolated by acidification of the basic extracts of the chloroform fractions; m p. 203–204°, yield 31.2 mg.

Decarboxylation of Thieno(3,2-b)pyrrole-2-carboxylic Acid.—Chromatographically pure V (178.2 mg., 1.07 mmoles) was sealed in a reaction tube that was equipped with a break-seal side arm. The reaction tube was completely immersed in an oil-bath at 210–220° for 30 minutes. A clear liquid condensed on the walls of the tube when it cooled. The break-seal side arm was attached to a high vacuum line and the carbon dioxide was distilled to a calibrated manometer from a −90° trap. The amount of carbon dioxide found was 1.07 mmoles (100%). The vapor pressure was measured at −110° and found to be 29 mm. (carbon dioxide has a vapor pressure of 26 mm. at −110°). The reaction tube was washed out with carbon disulfide, and the extracted material was sublimed at 10^{-3} mm. onto a cold finger cooled with a Dry Ice–acetone mixture. A total of 45.0 mg. (36.6%) of a white product was obtained. The material had an odor very similar to that of indole and melted between 30 and 35°. The infrared spectrum (Fig. 1), determined as a smear, was consistent with the proposed structure (VI). The product decomposes at room temperature when exposed to the air for a few minutes. A solution of picric acid in ethanol was added to the material and a red precipitate resulted. The picrate decomposes to an amorphous black powder on standing overnight in ethanol.

A control experiment was carried out with 1 mmole of indole-2-carboxylic acid. A 100% yield of carbon dioxide and a 60% yield of indole were realized.

Attempted Mannich Reaction with Thieno(3,2-b)pyrrole.—Glacial acetic acid (60 mg., 1.0 mmole) was added to 46 mg. (0.5 mmole) of piperidine followed by 50 mg. of formalin. Thieno(3,2-b)pyrrole (45 mg., 0.366 mmole) was added, and the solution was allowed to stand for 5 hr. The solution was washed into a centrifuge tube, and 2 ml. of 2.0 *N* sodium hydroxide was added. A very small amount of oil resulted. No crystalline product could be isolated.

A control reaction was carried out with 1 mmole of indole. A 75% yield of the piperidine Mannich base of indole resulted.

2-Nitro-3-methylthiophene.—To prepare this compound (46% yield) the method of Rinkes[16] was used with certain modifications. In a typical run 100 g. of 3-methylthiophene dissolved in 200 ml. of acetic acid was added during 15–20 minutes to a nitrating mixture of 200 ml. of acetic acid and 100 g. of fuming nitric acid (sp. gr. 1.5) at −15 to −12°. If the addition was not carried out rapidly, much tar was formed.

2-Nitro-3-thenyl Bromide.—A mixture of 132 g. of 2-nitro-3-methylthiophene, 200 ml. of dry ethylene dibromide, 206 g. of N-bromosuccinimide (recrystallized from hot water and dried over sulfuric acid) and 0.8 g. of benzoyl peroxide was refluxed gently for 3 hr. During the first hour the solution had a red-brown color, and vapors of bromine escaped at the top of the condenser. The color abruptly became dark brown and bromine vapors were no longer evolved. The solution was cooled in an ice-bath, 100 ml. of carbon tetrachloride was added and the dark brown succinimide was filtered and washed with three 50-ml. portions of carbon tetrachloride. The filtrate was washed with four 200-ml. portions of water, dried over magnesium sulfate, and the solvent was distilled from a steam-bath with the aid of a water aspirator. The residue was distilled under vacuum from a 1-l. flask (a large flask was required because of excessive frothing during the later stages of the distillation) fitted with a 6-in. Vigreux column. Two fractions were collected: fraction I, 29 g., b.p. 88–110° (1.1–1.3 mm.); fraction II, 123 g., b.p. 110–147° (1.2–3.0 mm.).

Both fractions solidified on standing. The lower-boiling material was mainly unreacted 2-nitro-3-methylthiophene. The higher boiling fraction was mainly 2-nitro-3-thenyl

Digitized by Arya Samaj Foundation Chennai and eGangotri

bromide and corresponded to a yield of 60%. It was pure enough for further use, but if desired it could be purified by recrystallization from low-boiling petroleum ether from which it separated in the form of long white needles which melted at 63–65°.

Anal. Calcd. for $C_5H_4NO_2SBr$: C, 27.04; H, 1.82; N, 6.31. Found: C, 27.48; H, 1.80; N, 6.31.

The bromide was characterized as the pyridinium salt which was prepared by allowing the components to stand in dry ether. The salt separated from ethanol in the form of shiny leaflets, m.p. 232–233° dec.

Anal. Calcd. for $C_{10}H_9N_2O_2BrS$: C, 39.87; H, 3.00. Found: C, 40.07; H, 2.89.

2-Nitro-3-thenyl Alcohol (XXXI).—A mixture containing 161.5 g. of 2-nitro-3-thenyl bromide (crude, as prepared above), 161.5 g. of sodium formate and 1700 ml. of 50% ethanol was refluxed for a period of 2 hr., and then 200 ml. of hydrochloric acid (sp. gr. 1.18) was added and the solution refluxed for 1.5 hr. longer. The hot solution was treated with Darco and diluted with 2 l. of water. The aqueous solution was saturated with sodium chloride, and the oil was extracted with ether. The ether solution was dried over magnesium sulfate, and after removal of the solvent by distillation from a steam-bath, the residue was distilled under vacuum. Two fractions were collected: fraction I, 15 g. (12.8%), b.p. 98–114° (0.2–0.55 mm.); fraction II, 63.7 g. (55%), b.p. 129–146° (0.6–0.8 mm.).

Both fractions solidified during collection. The second fraction was sufficiently pure for conversion directly to the aldehyde in the next step, while the first fraction was purified by crystallization from methanol or 70% ethanol, from which the alcohol separated in the form of yellowish crystals, m.p. 90–92°.

Anal. Calcd. for $C_5H_5O_3NS$: C, 37.73; H, 3.17; N, 8.80. Found: C, 38.32; H, 3.12; N, 8.71.

2-Nitro-3-thenaldehyde.—In a 1-l. round-bottomed flask fitted with a reflux condenser and Hershberg stirrer were mixed 76.7 g. of crude 2-nitro-3-thenyl alcohol (prepared as given above), 48 g. of finely powdered calcium carbonate, 85.2 g. of N-bromosuccinimide (recrystallized from water, dried over sulfuric acid) and 500 ml. of carbon tetrachloride (dried by distillation). The mixture was refluxed gently with stirring. During the first hour of heating, the mixture was watched carefully, because the refluxing became vigorous enough to require removal of the source of heat momentarily. The solution became brown in color, and some bromine vapor escaped from the top of the condenser. After a total of 3.5 hr. of refluxing, the reaction flask was cooled in an ice-bath and the orange solid filtered off. The orange residue was washed on the filter with three small portions of carbon tetrachloride, and the combined yellow filtrates were dried over magnesium sulfate. After removal of the solvent *in vacuo* on the steam-bath, the residue was distilled under vacuum. Two fractions were collected: fraction I, 10.1 g. (13.4%), b.p. 84–87° (0.3 mm.); fraction II, 35.1 g. (46.5%), b.p. 91–112° (0.3–0.9 mm.).

Both fractions partially crystallized on standing. Fraction I was less pure than fraction II, although it could be used in the next step without difficulty. For analysis, a small amount of fraction II was recrystallized twice from a mixture of low-boiling petroleum ether and absolute ether (1:1), which deposited the aldehyde in the form of short yellow needles, m.p. 55.5–56.5°.

Anal. Calcd. for $C_5H_3O_3NS$: C, 38.21; H, 1.92; N, 8.91. Found: C, 38.59; H, 2.09; N, 8.92.

The semicarbazone was prepared in the usual manner. For analysis it was recrystallized from dimethylformamide, from which it separated in the form of small bright yellow needles, m.p. 265–266° dec.

Anal. Calcd. for $C_6H_6O_3N_4S$: C, 33.64; H, 2.82; N, 26.16. Found: C, 34.02; H, 2.98; N, 26.02.

2-Methyl-4-(2-nitro-3-thenal)-5-oxazolone.—This azlactone was prepared in 55.8% yield from X exactly as given for the isomeric compound except that nitromethane was used to recrystallize the product for analysis. The oxazolone separated in the form of orange plates, m.p. 196–198° dec.

Anal. Calcd. for $C_9H_6N_2O_4S$: C, 45.38; H, 2.54; N, 11.76. Found: C, 45.58; H, 2.56; N, 11.87.

2-Nitro-3-thienylpyruvic Acid.—This acid was prepared in 51.3% yield as given for the isomeric compound IV except that the heating was continued for 3 hr., since this isomer proved to be more stable toward hydrolysis. The compound separated from acetic acid in the form of bright yellow needles, m.p. 186° dec.

Anal. Calcd. for $C_7H_5O_5NS$: C, 39.07; H, 2.34; N, 6.51. Found: C, 39.36; H, 2.42; N, 6.45.

Acknowledgment.—The authors are indebted to Miss Emily Davis, Mrs. K. Pih, Mrs. Jean Fortney, Mrs. Esther Fett, Mrs. L. Chang and Mr. Jozsef Nemeth for the elementary analyses reported herein, and to Mr. James Brader for the infrared determinations.

Phosphopeptides Obtained by Partial Acid Hydrolysis of α-Casein[2]

BY N. J. HIPP, M. L. GROVES AND T. L. MCMEEKIN

RECEIVED NOVEMBER 12, 1956

A partial acid hydrolysis of α-casein was resolved into fractions containing phosphopeptides by chromatography on Dowex 50. The impure fractions were further purified by chromatography and the electrophoretically pure subfractions were analyzed for their amino acid composition on Dowex 50. In addition to phosphoserine the following dipeptides were found: phosphoserylglutamic acid, phosphoserylalanine and phosphoserylphosphoserine. The extensive destruction of serine on complete hydrolysis of the peptides is discussed.

The physiological significance of phosphorus in casein and other phosphoproteins has been the subject of a number of recent investigations.[3] The presence of phosphorus is also advantageous in structural studies on casein since partial hydrolysis with enzymes and acid produces phosphopeptides which can be uniquely separated from the non-phosphopeptides. Numerous phosphopeptide fractions have been prepared from casein, particularly by enzymic digestion.[4] Lipmann[5] has shown that at least 50% of the casein phosphorus is present as ser-

ine phosphate after partial acid hydrolysis. de Verdier[6] has isolated small amounts of phosphothreonine from casein. Methods have been described by de Verdier[6] and Ågren and Glomset[7] for the fractionation of phosphopeptides from partial hydrolysates of casein.

The present study describes the separation and composition of some of the phosphopeptides produced by partial acid hydrolysis of α-casein

Experimental

Partial Acid Hydrolysis of Casein.—Exploratory experiments established that heating at 80° for 10 hours in 2.2 *N* hydrochloric acid was to be preferred for preparing phosphopeptides with minimum formation of inorganic phosphorus. These conditions were observed, using a 3-g. sample of finely divided α-casein prepared by the urea method[8] suspended in 360 ml. of hydrochloric acid. At the end of hydrolysis the solution was light brown and contained a small amount of insoluble material. Hydrochloric acid was removed at 25–30° with the Craig rotary evaporator.[9] Evaporation was repeated three times after the addition of water. The residue was then extracted with 0.05 *N* hydrochloric acid and the insoluble material removed by centrifugation. The soluble portion was made to 100-ml. volume. Under these conditions of hydrolysis, 40% of the peptide bonds of α-casein were broken as was shown by Van Slyke amino nitrogen analyses. The insoluble material accounted for 10% of the original nitrogen or phosphorus and was probably essentially unchanged α-casein.

Phosphoserine and phosphotyrosine used for identity purposes, were made by the method of Levene and Schormüller[10] as modified by Plimmer.[11] The analysis and properties of the phosphoserine have previously been reported.[12] The sample of synthetic phosphothreonine was kindly furnished by Dr. Bernard J. Jandorf of the Army Chemical Center, Maryland.

Color values for the phospho-amino acids on a molar basis relative to leucine using the photometric ninhydrin method of Moore and Stein[13] were as follows: phosphoserine 1.03, phosphotyrosine and phosphothreonine 0.94. With a Dowex 50-X8,[14] 120 mesh (see below), 0.9 × 100 cm. resin column using 0.05 *N* hydrochloric acid as influent as used by Schaffer, *et al.*,[15] phosphoserine and phosphothreoine are resolved into sharp peaks at 92 and 163 ml., respectively, and phosphotyrosine is resolved into a broader peak at 460 ml.

Ion-exchange Chromatography.—Dowex 50-X8 resin, 200–400 mesh, was treated with hydrochloric acid and 1 *N* sodium hydroxide as described by Moore and Stein.[16] The resin used for the separation of the phosphopeptides was passed through a 120-mesh screen and that used for the determination of amino acids through a 200-mesh screen. The hydrogen form of the resin that was used for the separation of phosphopeptides was obtained by washing the sodium form in a column with 1 *N* hydrochloric acid until the effluent was free of salt as determined by evaporation of 200-ml. aliquots. It was found that the completeness of the removal of sodium ion from the resin had a pronounced effect on the resolution of the phosphopeptides on elution with dilute hydrochloric acid. All of the resin columns were poured in at least five sections with a slurry of the resin in the first influent solvent and at least five hold-up volumes were run through the column before it was charged. A column 0.9 × 100 cm. was used for the exploratory runs of acid hydrolysates and a column 3.8 × 100 cm. for the 3-g. hydrolysate. Sufficient pressure was applied to the column to give a flow rate of 4 ml. per hour with the smaller columns and 50 ml. per hour for the large columns. Fractions of 1 ml. were collected from the small column and 8.5 ml. from the large column with an automatic fraction collector. The location of the phosphopeptides was determined by the photometric ninhydrin method of Moore and Stein[13] using 0.5-ml. aliquots from the large columns. The location of the inorganic phosphorus was determined by spot tests[17] and estimated by the method of Sumner.[18]

The Dowex 1-X10 resin, 200–400 mesh, was washed on a fritted glass Buchner funnel with 500 ml. of 2 *N* sodium hydroxide using slight suction. After washing with water followed by 1 *N* hydrochloric acid and then water, the resin was suspended in about 5 times its volume of water and after standing 2 hours the supernatant was decanted. The last step was repeated about 5 times until the final wash was almost clear. The resin was then passed through a 120-mesh screen.

Paper Chromatography.—Two-dimensional paper chromatograms for the qualitative determination of amino acids were prepared by the descending method as described by Levy and Chung[19] using butanol–acetic acid–water (4:1:5) and buffered phenol.

For the determination of the homogeneity of phosphopeptide fractions one-dimensional chromatograms using the butanol–acetic acid–water solvent system has been found to be useful. For the slow-moving acidic phosphopeptides the best results are obtained by running the chromatogram for more than 24 hours and allowing the solvent to drip from the serrations at the end of the paper.

Paper Electrophoresis.—The method described by Kunkel and Tiselius[20] with Whatman 3-MM paper between glass plates was used. The best results were obtained by performing the experiments in a cold room at 4°. A potential of 400 volts was applied to the paper between glass plates 15 × 45.5 cm. using 0.1*N* acetic acid as the buffer. For paper electrophoresis of the phosphopeptides the use of acetic or formic acid as buffer gave satisfactory results. No satisfactory resolution of phosphopeptides was obtained when Veronal was used as the buffer at *p*H 8.6.

N-Terminal Group Analysis.—The peptides were treated with the Sanger reagent,[21] 1-fluoro-2,4-dinitrobenzene (DNFB), as described by Davie and Neurath.[22] The DNP peptides were hydrolyzed with constant boiling hydrochloric acid in sealed tubes for 8 hours at 105° since Levy and Li[23] have found that 90% of the DNP terminal serine is destroyed when DNP-ACTH is hydrolyzed for 24 hours at 110° with constant boiling hydrochloric acid. The ether-soluble extracts of the hydrolyzed DNP peptides were then chromatographed on paper with 1.5 *M* phosphate buffer at *p*H 6.0 as described by Levy.[24] The colorless water-soluble fractions were chromatographed on paper with butanol–acetic acid–water.[19] The DNP amino acids used for control substances were prepared and described by Mellon, *et al.*[25]

Amino Acid Content of Phosphopeptides.—The amino acid composition of the phosphopeptides was determined by the Moore and Stein method[16] using Dowex 50-X8 resin. The peptides were hydrolyzed with 6 *N* hydrochloric acid at 120° for 20, 70 and 140 hours. The values for the serine content of the 70- and 140-hour hydrolysates were extrapolated to zero time to determine the initial serine content. A chromatogram of a 20-hour hydrolysate of phosphopeptide 4-C, which are the conditions frequently used for complete hydrolysis of protein, clearly showed incomplete hydrolysis

of the organic phosphorus as well as of the peptide. This was confirmed by the chromatogram of the 70-hour hydrolysate where the peak due to phosphoserine could not be detected and the serine and glutamic acid content increased. Differences in the rate of destruction of serine in the hydrolysis of various proteins are discussed by Smith and Stockell.[25] They predict, on the basis of the reports by Sanger[27] and Leach,[28] that serine, threonine and aspartic acid will be liberated completely from peptides after 20 hours of hydrolysis. It is apparent, however, that complete hydrolysis of phosphoserine and its peptides is not obtained in 20 hours. Rees[29] has shown that the destruction of serine on hydrolysis is accompanied by the formation of ammonia. Smith and Stockell[26] have shown that for the hydrolysis of papain and carboxypeptidase the increase in ammonia parallels the destruction of serine, but that the percentage loss of serine at a given time depends on the initial amino acid content of the protein, as well as on unknown factors. For the determination of the destruction of serine on hydrolysis of phosphoseryl peptides, ammonia was determined with a short column (0.9 × 15 cm.) of Dowex 50-X8 as described by Moore and Stein[16] using only the *p*H 5.0 and *p*H 6.5 citrate buffers, since basic amino acids were not present.

Results

Chromatography of Phosphopeptides on Dowex 50-X8.—The partial acid hydrolysate from 3 g. of α-casein was made to 100 ml. as previously described. Seventy-five milliliters, amounting to 2.25 g. of protein, was chromatographed on a 3.8 × 100 cm. column of Dowex 50-X8. The results for two hydrolysates are shown in Fig. 1. The chromatograms show that the hydrolysis and resolution into phosphopeptide fractions are highly reproducible. The nitrogen and phosphorus content of these fractions are given in Table I. Under the conditions employed the non-phosphorus portion of the hydrolysate is retained by the resin. Of the total phosphorus put on the column 90.7% was eluted and is associated with only 8.9% of the nitrogen. The relatively high amount of nitrogen and phosphorus in the base-line fractions is due in part to the large number of tubes with low optical density that were not satisfactorily resolved, and possibly in part to the low color values of the components. All of the inorganic phosphorus that was formed on hydrolysis, equivalent to only 9.35% of the phosphorus of α-casein subjected to hydrolysis, is eluted in fraction 2, near the front of the chromatogram, together with peptides containing organic phosphorus. It is of interest to note that the phosphopeptides in fraction 1 have less affinity for the resin than does inorganic phosphorus. The total organic phosphorus in the six fractions, equivalent to 56% of the phosphorus put on the column, is associated with 5.1% of the nitrogen put on the column. The atomic ratios of N–P of the fractions reported in the last column of Fig. 1 are higher than they should be since they contain free ammonia; the uptake of ammonia by the acid solution during the concentration and handling of the fractions is difficult to prevent. The low ratios of nitrogen to phosphorus, however, reflect the concentration of phosphorus when compared to α-casein with a ratio of 34.4.

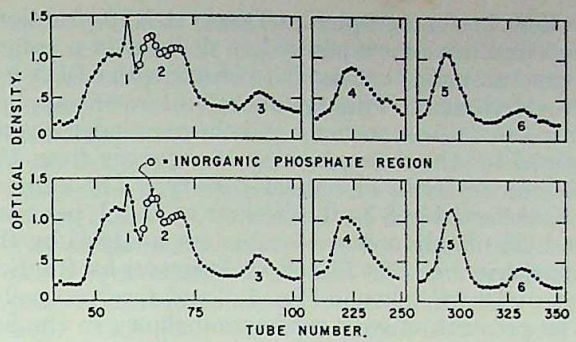

Fig. 1.—Chromatogram of the phosphopeptides in a partial hydrolysate of α-casein. Chromatography was carried out on a 3.8 × 100 cm. column of Dowex 50-X8 at 37.5° using 0.05 *N* hydrochloric acid as influent. The effluent was collected in 8-ml. fractions. Aliquots (0.5 ml.) were removed for analysis by the ninhydrin method. Each chromatogram was run on separate hydrolysates. The graph is corrected to an equivalent basis for variations in volume due to changes in the weight of drops during a run.

Paper electrophoresis showed only one of these fractions to be homogeneous. The other fractions contained up to four or more components. Fraction 5, which appeared to be homogeneous, had the same mobility as phosphoserine, but on complete hydrolysis it was found to contain aspartic acid and glutamic acid in addition to serine.

TABLE I

NITROGEN AND PHOSPHORUS COMPOSITION[a] OF PHOSPHOPEPTIDE FRACTIONS OBTAINED FROM PARTIAL ACID HYDROLYSIS OF α-CASEIN

(Fractions are numbered as in Fig. 1. The Dowex 50 column was charged with 286.0 mg. of nitrogen and 20.63 mg. of phosphorus.)

Fraction	Nitrogen, mg.	Organic phosphorus, mg.	Atomic ratio,[e] N/P
1	4.74	3.96	2.7
2	2.94	2.39[c]	2.7
3	0.96	0.73	2.9
4	2.74	1.70	3.6
5	2.43	2.26	2.4
6	0.85	0.50	3.8
Base line[b]	10.76	5.04	4.7
Total	25.42	16.58	
Recovery, %	8.9	90.7[d]	

[a] Values are corrected for aliquots taken from fractions for ninhydrin analysis based on average weight of fraction. [b] Includes all tubes of the chromatogram not taken for the fractions. [c] In addition this fraction contains 2.14 mg. of inorganic phosphorus which is equivalent to a conversion of 9.35% of the phosphorus of α-casein to inorganic phosphorus. [d] Includes the inorganic phosphorus in fraction 2. [e] The calculated atomic N/P ratio of α-casein is 34.4.

Rechromatography of Fractions.—Exploratory experiments with an anion-exchange column of Dowex 1-X10 in the hydrogen form, using dilute hydrochloric acid as influent, showed that only the last three fractions from the Dowex 50 column could be resolved into several subfractions. Attempts to resolve the first three fractions with various forms of Dowex 50 or Dowex 1 and 2 using a number of volatile influent solvents have not been successful.

For chromatography on Dowex 1-X10, fractions 4, 5 and 6 were evaporated to dryness in a rotary evaporator and then made to 25 ml. with 0.01 *N* hydrochloric acid. Twenty-four milliliters was applied to a 1.9 × 20 cm. column and the remainder was retained for the determination of recovery from the column in terms of optical density. The effluent was collected in 8.5-ml. fractions at 25 ml. per hour and 0.5-ml. aliquots were taken for analysis by the ninhydrin method. The chromatograms for fraction 4, 5 and 6 are shown in Figs. 2, 3 and 4, respectively. The per cent. of each subfraction shown in the figures is in terms of total optical density units eluted from the column. The average recovery from the column for each of the three fractions in these terms exceeded 96%.

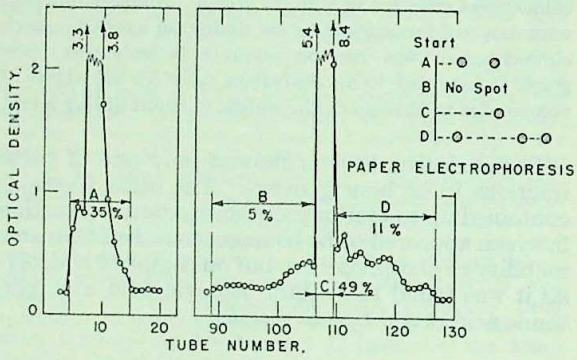

Fig. 2.—Chromatogram of fraction 4 obtained as shown in Fig. 1. Chromatography was carried out on a 1.9 × 20 cm. column of Dowex 1-X10 using 0.01 *N* hydrochloric acid as influent to tube 92 where a gradient with 0.1 *N* hydrochloric acid was used. The normality at subfraction C was 0.015. The effluent was collected in 8.5-ml. fractions and 0.50-ml. aliquots were removed for analysis by the ninhydrin method. Paper electrophoresis was performed as described in the text.

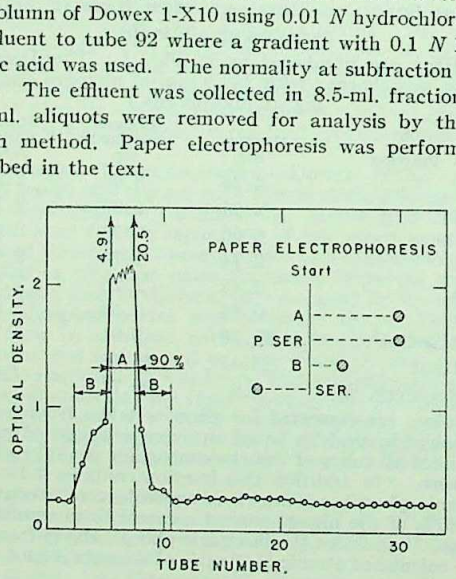

Fig. 3.—Chromatogram of fraction 5 obtained as shown in Fig. 1. Chromatography was carried out on 1.9 × 20 cm. column of Dowex 1-X10 using 0.01 *N* hydrochloric acid as influent. The effluent was collected in 8.5-ml. fractions and 0.50-ml. aliquots were removed for analysis by the ninhydrin method. Paper electrophoresis was performed as described in the text.

For paper electrophoresis, the subfractions were combined and concentrated *in vacuo* and made to the same optical density in order to obtain comparable concentrations. The electrophoretic results are also shown in Figs. 2, 3 and 4. The influent for the chromatography of fraction 4 shown in Fig. 2 was 0.01 *N* hydrochloric acid to tube No. 92 where a 500-ml. ground joint wash bottle was used as a mixing chamber for gradually increasing normality by addition of 0.1 *N* hydrochloric acid. The acidity of the effluent at subfraction C (Fig. 2) was 0.015 *N* as shown by titration. The results obtained by paper electrophoresis showed that only subfraction C was homogeneous; subfractions A and D contained a total of five components, and B was insensitive to the ninhydrin spray.[19]

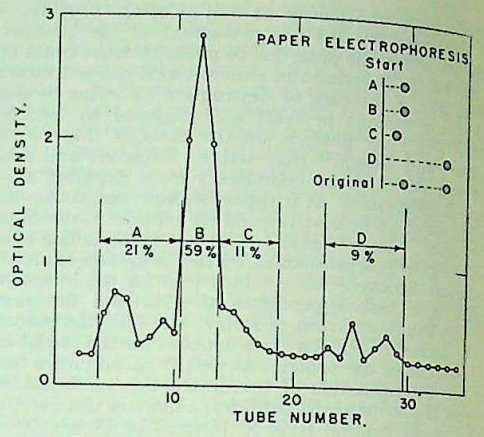

Fig. 4.—Chromatogram of fraction 6 obtained as shown in Fig. 1. Chromatography was carried out on 1.9 × 20 cm. column of Dowex 1-X10 using 0.01 *N* hydrochloric acid as influent. The effluent was collected in 8.5-ml. fractions and 0.50-ml. aliquots were removed for analysis by the ninhydrin method. Paper electrophoresis was performed as described in the text.

Fraction 5, which appeared to be homogeneous by paper electrophoresis, having the same electrophoretic mobility and behavior on Dowex 50-X8 as phosphoserine, was rechromatographed on Dowex 1-X10 with 0.01 *N* hydrochloric acid as influent solvent. The chromatogram of fraction 5 (Fig. 3) shows that 90% of the fraction is now concentrated in two tubes and that the fraction contained two electrophoretic components. The nature of the chromatogram indicates that complete resolution was not obtained. This was later confirmed when subfraction A was resolved on the Dowex 50-X8 column of Moore and Stein[16] for the determination of amino acids. Phosphoserine emerged without holdup at the front as reported by Moore and Stein,[30] followed by another peak separated by one tube having a low optical density. This was considered to be a satisfactory resolution in view of the high proportion of one component. On the basis of optical density and without correction for the color factor, which is unknown for the minor component, subfraction A contains 96.3% phosphoserine.

Chromatography of fraction 6 on Dowex 1-X10 with 0.01 *N* hydrochloric acid as influent solvent is shown in Fig. 4. The four subfractions as shown by paper electrophoresis contained three components. As judged by the nature of the

chromatogram, subfraction D should contain two components one of which may be insensitive to the ninhydrin spray; in subfraction A the chief component has apparently the same electrophoretic mobility as the component in subfraction B which contained 59% of the total material. Fraction 6, therefore, contains at least five components as determined by an analysis of its subfractions compared with only two components that were found by paper electrophoresis of the original material.

The character of the three chromatograms suggests that each of the main subfractions contained some impurity. This could not be established by either paper electrophoresis or paper chromatography, even when large amounts of samples were used for analysis. That the subfractions did contain up to about 10% of impurity was later confirmed when the amino acid compositions were determined.

The main subfraction of each fraction shown to be homogeneous by electrophoresis (4-C, Fig. 2; 5-A, Fig. 3; and 6-B, Fig. 4) was analyzed qualitatively for amino acid composition after complete hydrolysis. Each of the subfractions was found to contain glutamic acid, aspartic acid and serine, and subfraction 6-B also contained alanine. The only N-terminal amino acid that was found by paper chromatography studies on the hydrolyzed DNP subfractions was serine.

The resolution of fractions 1 and 2 (Fig. 1) into several subfractions with paper chromatography using butanol–acetic acid–water (5:4:1) suggested that chromatography on a cellulose column under similar conditions might be successful. Experiments with a 1 × 25 cm. cellulose column resolved each fraction into several ninhydrin-positive peaks. The first influent solvent was a butanol–acetic acid–water (10:1:2) system, which did not interfere with the ninhydrin determination, followed by 50% ethanol–water gradient and then by an aqueous hydrochloric acid gradient. Analysis of the subfractions obtained in large scale experiments with 3.8 × 25 cm. columns showed that only one of them (from fraction 2, designated 2-C) was electrophoretically homogeneous. This was eluted at the change-over to 50% ethanol–water and contained serine and glutamic acid.

Amino Acid Analyses of Subfractions.—The amino acid analyses of the main subfractions which were electrophoretically homogeneous are shown in Table II. The results are expressed in terms of the molar ratios of the constituent amino acids. Except as noted, the values in the table for 4-C were calculated from the data on the 140-hour hydrolysate since the 70-hour hydrolysis was not complete. For 5-A and 6-B the values are the average of the 70- and 140-hour hydrolysate values which agreed within experimental error. The values reported for subfraction 2-C were obtained on an hydrolysate which was complete after only 20 hours.

The amino acid chromatograms of some of the subfractions showed several ninhydrin peaks for which the amino acids could not be found or established by paper chromatography and are not included in Table II. For subfractions 4-C, 5-A and 6-B one of these peaks, less than 0.02 of a residue, appeared at the front of the chromatogram where phosphoserine is eluted. In control experiments, however, with a mixture of the amino acids and phosphoserine subjected to the same hydrolytic conditions, no new peaks appeared and the phosphoserine was hydrolyzed completely. The first peak, therefore, is due to an impurity which on hydrolysis yields an acid compound; the second peak, equivalent to less than 0.03 of a residue, appeared just before the serine peak with good resolution. This peak may well be due to threonine, although it could not be detected by paper chromatography presumably because of its low concentration. It is possible, therefore, that a peptide containing threonine constitutes a minor impurity in the subfractions.

TABLE II

AMINO ACID COMPOSITION OF ELECTROPHORETICALLY HOMOGENEOUS PHOSPHOPEPTIDE SUBFRACTIONS OBTAINED FROM PARTIAL ACID HYDROLYSIS OF α-CASEIN

(Results are expressed in terms of the molar ratios of the constituent amino acids.[a])

	Subfractions			
	4-C	5-A	6-B	2-C
Aspartic acid	**0.11**	0.03	0.06	..
Glutamic acid	**0.92**	0.07	0.12	0.14
Alanine	..	..	**1.08**	..
Serine (extrapolated[b])	0.73	0.86	0.93	0.96[e]
Serine (min.[c])	1.00	1.00	1.00	1.00
Phosphoserine[d]	..	1.02	..	..

[a] Based on the minimum serine content taken as unity. [b] Value obtained by straight-line extrapolation of data from 70- and 140-hour hydrolysis to zero time. [c] Calculated from the phosphorus content and based on the assumption that the phosphorus is present as the mono-ester of serine. [d] Determined on unhydrolyzed subfraction by chromatography on Dowex 50-X8 resin of Moore and Stein.[16] [e] Value is the sum of the serine and the ammonia formed by destruction of serine determined on a single hydrolysis with 6 *N* hydrochloric acid at 120° for 6 hours by chromatography on the Dowex 50-X8 resin.

The chromatogram of the hydrolysate of subfraction 4-C contained additional components eluted as an unresolved double peak in the region where glycine and alanine appear. This double peak, present to the extent of 0.38 of a residue in the 20-hour hydrolysate, was reduced to 0.14 of a residue in the 70-hour hydrolysate; no further reduction was obtained in the 140-hour hydrolysate. This is a sufficient quantity to be detected by paper chromatography, but the presence of glycine or alanine could not be established. The double peak, therefore, contains a peptide which is apparently resistant to 140-hour hydrolysis. That this peptide might contain valine is suggested by the appearance of a peak in the chromatogram of 0.08 of a residue where valine is expected to be eluted and by the known resistance to acid hydrolysis of peptides containing valine.[26,31]

The compositions of the individual subfractions in terms of integral number of amino acid residues per mole are given in boldface type in Table II. The method of analysis, however, is capable of revealing the presence of impurities in the subfractions at levels which are not detectable by paper

electrophoresis or by paper chromatography of the hydrolyzed amino acids.

From an analysis of the data in Table II the composition of the subfraction as given in Table III can be calculated based on the following additional experimental evidence: (1) serine was the only amino acid that was found to be N-terminal in each of the subfractions (not determined for 2-C) by paper chromatography of the hydrolyzed DNP subfractions. Since the DNP phosphopeptides are resistant to hydrolysis, the long periods of heating required for complete hydrolysis cause an excessive destruction of serine, making the quantitative determination of N-terminal serine difficult. (2) The chain length of the main constituent of the subfractions was estimated by a determination of the ratio of the ninhydrin color value of the hydrolyzed as compared to the unhydrolyzed material. The ratio is of significant value when the chain length is small, and the amount of impurity of unknown chain length is low. Furthermore, this ratio can be used only for the estimation of short chain lengths with any degree of certainty, because the relative color value of serine and other dipeptides varies considerably as shown by Harris, *et al.*,[32] and Dowmont and Fruton.[33] These variations may lead to false conclusions, particularly for longer chain peptides. For the first three subfractions in Table III the experimentally determined ninhydrin ratio of the 70-hour hydrolysate to the unhydrolyzed is 2.0, 1.2 and 2.0, respectively. For subfraction 2-C using a 20-hour hydrolysate, the experimentally determined ratio is 1.8; however, due to the uncertainty of the relative color value of the unhydrolyzed peptide, this ratio is taken as 2. The value of 1.2 for subfraction 5-A can be accounted for by the presence of 10% of a tripeptide as an impurity which is consistent with the Van Slyke amino-nitrogen values.

The Van Slyke analysis on subfraction 4-C is of particular interest. This subfraction reacted with nitrous acid to yield all of its nitrogen as α-amino nitrogen under the usual conditions. The liberation of 2 moles of nitrogen with nitrous acid from γ-dipeptides of glutamic acid and other γ-glutamyl dipeptides was shown to occur by Sachs and Brand.[35,36] Since serine, however, was found to be the N-terminal amino acid of the dipeptide, a γ-glutamyl structure for the dipeptide is not possible. A mechanism for the liberation of peptide nitrogen from γ-glutamyl-peptides with nitrous acid was shown to parallel the formation of reaction products with a lactone structure by Sachs and Brand.[35] The same mechanism may be applicable for the phosphoserylglutamic acid dipeptide where the elements of water necessary for lactone formation are present in the phosphate radical.

TABLE III

COMPOSITION OF SUBFRACTIONS[a]

	% of constituents on mole basis			
	4-C	5-A	6-B	2-C
Pser. Glu	90			
Pser. Asp	10			
Pser.		90[c]		
Pser. (Asp, Glu)		10		
Pser. Ala			90	
Pser. (Ala, Glu, Asp)			10	
Pser. Pser.				75[d]
Glu. Pser.[b]				25[e]

[a] The abbreviations for amino acids and conventions for indicating their sequence are those of Sanger and Tuppy[34]; when the sequence of amino acids in a peptide is known, they are separated by periods, and when not known they are enclosed in parentheses and separated by commas. Additional abbreviations: Pser = O-phosphoserine. [b] This structure is assigned because the peptide Pser.Glu is resolved in another fraction from Dowex 50 (4-C). [c] On the basis of ninhydrin optical density, 96% of this subfraction is phosphoserine. [d] This value is 87% if the impurity in this subfraction is a tripeptide, such as (Glu, Pser.Glu) instead of a dipeptide. [e] Equivalent to 12% on molar basis and 10% on weight basis of glutamic acid as impurity in subfraction.

Discussion

The amount of destruction of serine found on hydrolyzing serine phosphopeptides as shown in Table IV is greater than has been reported for the destruction of serine in proteins. The values usually taken for the destruction of the hydroxy amino acids were established in the careful study by Rees[29] averaging 10% for serine and 5% for threonine after 24 hours in boiling 6 *N* hydrochloric acid. In the experiments by Hirs, *et al.*,[37] the loss of serine was 16% and that of threonine was 8% when either ribonuclease or a synthetic mixture of amino acids corresponding to an hydrolysate of serum albumin was heated for 20 hours with 6 *N* hydrochloric acid in sealed tubes at 110°. Good recoveries, however, were obtained by extrapolation of the analytical results to zero time. Gordon and Ziegler[38] found that serine and threonine were completely stable in the hydrolysis of α-lactalbumin at 120° even when the protein was hydrolyzed for 140 hours. The results in Table IV show that the lability of serine is apparently dependent in some degree on the amino acid with which it is associated. The value of 64.6% recovery for the 70-hour hydrolysate of subfraction 5-A, which is essentially phosphoserine, is comparable to the value of 61.0 obtained by Hirs and associates[37] for the recovery of serine from a 70-hour hydrolysate at 110° of a synthetic mixture

TABLE IV

RECOVERY OF SERINE FROM SUBFRACTIONS HEATED WITH 6 *N* HCl AT 120°

Subfraction	% Recovery[a] Time of hydrolysis 70 hr.	140 hr.	By extrapolation to zero time
4-C[b]	55.5	38.3	73
5-A	64.6	42.0	87
6-B	75.2	54.5	93

[a] Calculated from the phosphorus content and based on the assumption that all of the serine is phosphorylated and is present as the monoester. [b] A 20-hour hydrolysate contained phosphoserine.

corresponding in composition to a hydrolysate of bovine serum albumin. This suggests that the phosphate itself has no appreciable effect on the hydrolytic destruction of serine. It is apparent from the last column of Table IV that a correction for losses of serine by extrapolation of the results to zero time, assuming first-order kinetics for the decomposition, would lead to considerable error.

Phosphoserylglutamic acid was first isolated by Levene and Hill[40] from an enzymatic digest of casein. de Verdier[39] has reported the presence of phosphoserylglutamic and phosphoserylalanine and several other peptides of phosphoserine from acid digests of casein but was not able to establish that serine was N-terminal.

Synthesis of Some Model Pyrimidine Nucleosides

BY H. TODD MILES

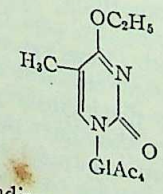
RECEIVED NOVEMBER 23, 1956

Methods of preparing some N-alkyl and O-alkyl pyrimidine nucleosides are described.

In order to study the tautomeric forms of certain nucleosides and nucleotides in solution[1] by their infrared spectra it was desirable to have derivatives of the possible tautomeric forms in which the labile hydrogen is replaced by methyl or ethyl groups. The present article describes the synthetic methods used for the compounds not previously reported.

Direct N-Methylation of Nucleosides.—Levene and Tipson[2] reported the preparation of 3-methyluridine by use of diazomethane on 2′,3′-di-O-acetyl-5′-O-triphenylmethyluridine in ether solution. It was found recently[1] that 3-methyluridine could be prepared much more conveniently by direct treatment of the nucleoside in methanol with diazomethane, thus obviating the introduction and subsequent removal of acetyl or trityl groups. By this method 3-methylthymidine, 1-β-D-glucopyranosyl-3-methyluracil and 1-β-D-glucopyranosyl-3-methylthymine have been prepared for the first time. In each case only the product of N-methylation was isolated.

Preparation of the O-Alkyl Nucleosides.—The 1-(2′,3′,4′,6′-tetra-O-acetyl)-β-D-glucopyranosyl-4-alkoxypyrimidines (I and VII) were prepared by the method of Hilbert and Johnson.[3] Compound I has been reported before[3] and readily can be isolated from the reaction mixture in crystalline form.



VII

The corresponding thymine compound VII, however, has not been isolated by previous workers[4,5] though it obviously has been present in reac-

tion mixtures. Since the O-ether was required as such and not merely as an intermediate, attempts were made to prepare it by varying the pyrimidine and the glucosyl halide reactants, the temperature and the pressure; but from none of the reactions could the desired product be isolated. Finally a chromatographic method was found which permitted isolation of the pure material from the reaction mixture.

Deacetylation of I and VII was accomplished by treatment with a catalytic amount of potassium methoxide, followed by removal of the potassium ion by titration with 60% perchloric acid to a *p*H meter reading of 8.1.[6] In each case the product was a glass, which could be reacetylated to the original O-alkyl material.

Synthesis of 1-Glucosyl-4-dimethylamino-2-pyrimidone (V).—In order to have a model compound for cytidine which would be incapable of tautomerizing, it was desired to prepare a compound of structure V. For this purpose it was found that when the enol ether I or its ethoxy analog was treated with dimethylamine at room temperature V was produced in almost quantitative yield. Acetylation with acetic anhydride in pyridine gave the tetraacetate of V.

Conversion of O-Methyl- to N-Methylnucleoside.—This transformation was carried out by two methods. The first was a thermal lactim–lactam rearrangement in which the enol ether I was heated at 230° to give the N-methyl compound II.

Although the formation of methyl bromide as a by-product of the glycosylation reaction of Hilbert and Johnson[3] results in the formation of N-methylpyrimidines, no formation of N-methylnucleosides has been reported among the reaction products. It was found, however, that heating the enol ether with methyl iodide at 100° resulted in the smooth conversion of I to II. When the analogous O-ethyl compound was heated with methyl iodide, the product has a methyl rather than an ethyl group on the nitrogen, as would be expected from direct N-methylation followed by thermal elimination of ethyl iodide.

Compound II also was prepared by methylating 1-β-D-glucopyranosyluracil with diazomethane, as described above, and acetylating the product III to give II.

Since the water-soluble compounds are to be used as model compounds for spectral study, it is necessary that their structures be proved by other means. The availability of the same compound by independent synthetic routes does much to establish a structure as well as to provide desirable flexibility in choice of starting materials. Such independent evidence was sought originally in the present case because the N-methyl determinations carried out in the usual way gave erratic results, the value found generally being about an eighth of the calculated amount. It has since been found possible to obtain good N-methyl values, though both analysts have reported that the methyl groups are very difficult to split off.[7]

Paper Chromatography.—The R_f values of the water-soluble members of the present series as well as some of the natural nucleosides were determined in two solvents and are presented in Table I. While these values are not precise physical constants they are reasonably reproducible even when no elaborate precautions are taken; they indicate the relative mobilities of the compounds and show which separations can be achieved readily. The compounds were detected by quenching of the fluorescence caused in the paper by a Mineralite ultraviolet lamp. Ascending chromatograms were used.

In all cases the 3-N-methyl compound had a higher R_f than the parent nucleoside, presumably because of its greater relative solubility in the nonaqueous phase. Comparison of IV with X, of IV with uridine, and of uridine with thymidine suggest that with analogous compounds the R_f generally decreases with the number of hydroxyl groups on the sugar and increases with the number of methyl groups on the ring, especially if a labile hydrogen has been replaced by methyl.

A useful application of paper chromatography of these compounds is in following the diazomethane methylation. It is easy to tell whether the reaction has gone to completion or not and even, roughly, the ratio of reactant to product.

A Convenient Micro Method for Distinguishing O-Methyl from N-Methyl.—The greatest usefulness of paper chromatograms in the present study was in demonstrating with a few micrograms of material whether a methyl or ethyl group was attached to oxygen or nitrogen. When little material is available it is often impractical to carry out an acid hydrolysis of the enol ether and isolate the crystalline nucleoside.

A few micrograms of the methyl nucleoside were added to concentrated hydrochloric acid. After the solution had stood overnight the acid was evaporated and the reaction product was chromatographed. The compounds which were derived from acetates of nucleoside enol ethers (the structures of the acetates have been demonstrated by acid hydrolysis of larger quantities to known nucleosides[3,5]) by potassium methoxide deacetylation gave products which had the same R_f values as the corresponding nucleosides.

N-Methyluridine, whose structure was proved by Levene and Tipson,[2] and the other compounds prepared by diazomethane methylation in this study were unaffected by acid treatment. Since both N-methyl and O-methyl compounds move well above the parent nucleoside in all solvents, there is no difficulty distinguishing the two by acid treatment even when they have the same R_f.

The R_f's after acid treatment of the seven compounds tested are given for two solvents in Table I.

Experimental[7,8]

3-Methylthymidine.—To a solution of 800 mg. of thymi-

land. The second N-CH_3 determination of IX(A) was done by Alicino by running the same sample through the procedure four times and using longer heating periods. The first three titrations gave roughly a third each of the theoretical value, and the fourth titration a negligible amount. A repeated N-CH_3 analysis of 3-methylthymidine has not yet been obtained.

[a] Solvent A: triethylamine, *t*-butyl alcohol, water (2:10:3). [b] Solvent B: 88% formic acid, *n*-butyl alcohol, water (10:10:3); let stand 24 hr. and use upper layer. Fresh solvent was not used because of the rapid esterification, which caused a marked change in composition and deposition of an aqueous layer during the running of the chromatogram. A 24-hour period of storage was chosen for convenience, though it does not represent equilibrium. [c] The values are reported for compounds from which the potassium ion has been removed. When this has not been done, the R_f values are lower though still reproducible for a given sample.

dine (Schwarz) in 70 ml. of methanol was added 80 ml. of a solution of diazomethane[9] in ether. The loss of color and evolution of nitrogen were rapid during the early part of the reaction. After the addition the solution was allowed to stand several hours in an ice-bath. The product after evaporation of solvent was a sirup which could not be induced to crystallize.

The reaction mixture was then chromatographed on 100 g. of potato starch in butanol saturated with water. The progress of the chromatogram was followed by the optical density at 260 mμ. The peak of optical density came at about 80 ml. of effluent, and the fractions from 60 to 120 ml. of effluent, representing 540 mg., were combined and crystallized from a mixture of methanol, ethyl acetate and ether.[10]

Further crystallizations were from methanol and ether and gave a material melting at 132.5–134° (unless the material had been thoroughly dried, it melted at about 72°, then resolidified and melted at 130–131°).

Anal. Calcd. for $C_{11}H_{16}N_2O_8$: C, 51.56; H, 6.29; N, 10.93; OCH_3, 0.00; NCH_3, 5.85. Found: C, 51.51; H, 6.34; N, 10.46; OCH_3, 0.00; NCH_3, 0.89.[7]

1-Glucosyl-3-methyluracil (III).—To a suspension of 170 mg. of IV (prepared by the Hilbert and Johnson[3] method) in 15 ml. of methanol was added 8 ml. of ether solution of diazomethane.[9] The reaction was slower than the first one, so 1 ml. of water was added and the suspension refluxed to bring most of the material in solution and then cooled before the slow addition of another 7 ml. of diazomethane solution. The product was treated with charcoal, filtered, and most of the solvent evaporated.

The initial sirup was finally induced to crystallize from a mixture of methanol, ethyl acetate and ether.[10] After four more crystallizations and drying under vacuum, the m.p. was 247–248.5°.

Anal. Calcd. for $C_{11}H_{16}N_2O_7$: C, 45.83; H, 5.60; N, 9.72; NCH_3, 5.20. Found: C, 45.79; H, 5.56; N, 9.93; NCH_3, 5.09.

The same compound was prepared from a sample of II by deacetylation with potassium methoxide. After crystallization from methanol and ether the latter material had an infrared spectrum identical with III prepared by the diazomethane reaction, and a mixture of the two showed no melting point depression.

1-(Tetra-O-acetyl-β-D-glucopyranosyl)-3-methyluracil (II). A. Reaction with Methyl Iodide.—To a mixture of 7 ml. of methyl iodide and 4 ml. of acetone was added 400 mg. of I (in other preparations the ethoxy analog was used with equal success). The reaction tube was sealed and heated at 100° for about 60 hours. The tube was opened, the solvent evaporated, the residue taken up in methanol, treated with charcoal and filtered. The compound crystallized to give 320 mg. of m.p. 99–103°. The material was recrystallized to a constant m.p. of 105–108° after drying. A sample of narrower melting range was not obtained in any of these experiments.

Anal. Calcd. for $C_{19}H_{24}N_2O_{11}$: C, 50.00; H, 5.30; N, 6.14; OCH_3, 0.00; NCH_3, 3.29. Found: C, 49.09; H, 5.02; N, 5.98; OCH_3, 0.00; NCH_3, 2.98.

The low carbon value of the analysis can be attributed to inadequate purity of the compound, although it was recrystallized five times from methanol to a constant melting range. For some reason the compound appears to be unusually difficult to purify.

Since II could be formed by two methods from the known compound I and by simple acetylation from III (which gave a very good analysis) there is no reason to doubt that the compound has the indicated structure. The conversion of II back to III by deacetylation confirms that no unusual change had taken place on acetylation.

B. Pyrolysis of I.—A combustion tube containing 300 mg. of I was flushed out with helium, sealed and heated in a Carius furnace at 230° for 24 hr. A solution of the material in methanol deposited 200 mg. of crystals, m.p. 104–107°. The light tan material was treated with charcoal and recrystallized, the m.p. remaining the same. An infrared spectrum of a chloroform solution of this material was superimposable on that of II prepared by method A.

C. Acetylation of III.—Fifty mg. of III (prepared by diazomethane methylation of IV) was added to 1.5 ml. of pyridine and 1.5 ml. of acetic anhydride and the mixture allowed to stand in the cold for a week. The solution was worked up to give 30 mg. of m.p. 100–105°, which had an infrared spectrum in chloroform solution identical with those of the samples prepared by methods A and B.

Preparation of 1-(Tetra-O-acetyl-β-D-glucopyranosyl)-4-ethoxy-5-methyl-2-pyrimidone (VII).—A mixture of 8.5 g. of 2,4-diethoxy-5-methylpyrimidine and 13.4 g. of freshly recrystallized tetra-O-acetyl-α-D-glucopyranosyl bromide was heated in a 50-ml. flask at 60°. Through a side arm protected by a Dry Ice trap the flask was connected to a house vacuum line of about 100 mm. pressure. The flask was heated for a week, the last day at 75°. From the reaction mixture there was obtained 19 g. of sirup which resisted all attempts at crystallization (small amounts of methylpyrimidines formed in this and similar reactions were filtered off from ether solution).

A successful chromatographic method was found and applied as follows to 14 g. of the sirup. A column of 350 g. of Magnesol[11] (Food Machinery and Chemical Co.; the material was previously washed with acetone and then dried) was prepared from a benzene slurry and a benzene solution of the 14 g. of reaction mixture poured on it.

(9) The diazomethane solutions used in these reactions were prepared by covering solid N-methyl-N-nitroso-N′-nitroguanidine with 10 ml. of ether per g. of solid and adding 40% potassium hydroxide solution slowly to the chilled mixture. At the completion of the reaction the diazomethane solution was decanted.

(10) In recrystallizing this and other water soluble members of the present series the compound was dissolved in a minimum quantity of methanol at the boiling point and either ethyl acetate (in which most of the compounds are only slightly soluble) or ether (in which they are insoluble) or both were added slowly to the point of cloudiness. Chilling at −10 to 0° then generally caused crystal formation.

The eluting solution was ethanol in benzene, the volume used at each concentration being as follows: 500 ml., 100:1 benzene–ethanol (even with concentrated solutions there is very little volume change on mixing benzene and ethanol); 700 ml., 50:1; 700 ml., 20:1; 1000 ml., 10:1; 200 ml., 5:1; 300 ml., 2:1.

The effluent was tested for the desired material by placing a drop on filter paper and looking for quenching of fluorescence. As long as no quenching material came off, large fractions of 500–1000 ml. were collected and evaporated to confirm the absence of material; 100-ml. fractions were evaporated and weighed as the solute came off the column. The fractions from 1970 to 2000 ml. effluent were combined to give 4.2 g. of sirup, which crystallized spontaneously on standing two days. The fractions from 2000 to 2200 ml. effluent gave an additional 1.3 g. of sirup, which crystallized on seeding. The remainder of the effluent provided no crystalline material.

The substance obtained from the column was recrystallized to a m.p. of 132–133°.

Anal. Calcd. for $C_{21}H_{28}N_2O_{11}$: C, 52.07; H, 5.83; N, 5.97. Found: C, 52.00; H, 5.91; N, 5.87.

The enol ether obtained in this manner was deacetylated with potassium methoxide as described above to give a glass, which could be reacetylated to the original tetraacetate.

More careful chromatography of 5 g. of reaction sirup on 90 g. of Magnesol, using an automatic fraction collector and taking 7-ml. cuts, gave a 1.6-g. fraction which provided 1.3 g. of material melting at 131.5–133°. If the same per cent. yield of crystalline product had been obtained in the larger chromatogram, the yield of crystalline material for the reaction would have been about 31% instead of the observed 19%.

Although previous workers[5] failed to isolate the present compound they obtained its acid hydrolysis product, β-D-glucopyranosylthymine, in 43% yield.

1-β-D-Glucopyranosyl-3-methylthymine (XI).—The most convenient preparation of 1-tetra-O-acetyl-β-D-glucopyranosylthymine (VIII) proved to be the method of condensing dithyminylmercury with tetra-O-acetyl-α-D-glucopyranosyl bromide reported recently by Fox, Yung, Davoll and Brown.[12]

Six g. of VIII was dissolved in 40 ml. of chloroform and 10 ml. of methanol. On chilling VIII came out of solution, but as the material reacted with the first 15 ml. of diazomethane solution (a total volume of 40 ml. was eventually used) it all went into solution. The solvent was evaporated, more chloroform added, the solution treated with charcoal and again evaporated. The sirupy product could not be induced to crystallize; after standing several days without solvent, it crystallized spontaneously. The yield of IX was 5 g., m.p. 112–116°. A mixture of ethanol, ether and a little hexane was found to give the best results of the solvents tried. The m.p. of the purified material was 120–122°.

Anal. Calcd. for $C_{20}H_{26}N_2O_{11}$: C, 51.06; H, 5.57; N, 5.96; OCH_3, 0.00; NCH_3, 3.19. Found: C, 51.23; H, 5.46; N, 5.89; OCH_3, 0.00; NCH_3, 3.13 (M); 3.57 (A).[7]

The above tetraacetate IX was converted to XI by treating a solution of 500 mg. of pure tetraacetate in 18 ml. of absolute methanol with several mg. of potassium, warming for 10 min. and leaving overnight. When ether was added to the solution, the product came out as a sirup. The potassium ion was then removed by titration with perchloric acid followed by centrifugation.[6] This time when ether was added to the point of turbidity and the solution cooled, crystals separated. The yield was 250 mg. of m.p. 197–200°. This material was treated with alumina and charcoal in methanol and crystallized 5 times to a constant melting range of 196–202°. (The upper limit is the point at which the last crystals visible under the polarizer disappear.) Despite the broad range, the analysis indicated that the material was pure and had the expected constitution.

Anal. Calcd. for $C_{12}H_{18}N_2O_7$: C, 47.68; H, 6.00; N, 9.27; OCH_3, 0.00; NCH_3, 4.96. Found: C, 47.79; H, 5.90; N, 9.33; OCH_3, 0.00; NCH_3, 3.85.

Alternate Preparation of IX.—In view of the originally poor NCH_3 analyses it was considered desirable to carry out the reverse of the above transformation, that is, the methylation of 1-β-D-glucopyranosylthymine, a known compound,[5] to give IX.

Accordingly, dry hydrogen chloride was passed into a cold solution of VIII in 200 ml. of methanol for 15 minutes and the stoppered solution allowed to stand a day. The solution was evaporated under vacuum and the sirup crystallized from methanol and ether. After one recrystallization the m.p. was 272–274.5°, in agreement with the reported value[5] of 271°.

The glucosylthymine was then treated in aqueous methanol (10% water to increase solubility) with ethereal diazomethane, as described above for IV. The product was a sirup that crystallized on seeding with a crystal of IX obtained by the potassium methoxide deacetylation described above. After recrystallization the present material, when mixed with XI, showed no melting point depression and had an identical infrared spectrum.

1-β-D-Glucopyranosyl-4-dimethylamino-2-pyrimidone (V).—To a mixture of 30 ml. of dimethylamine and 15 ml. of methanol in a pressure bottle was added 1.5 g. of the 4-ethoxy analog of I. The bottle was closed and allowed to stand at room temperature for two days. Most of the solvent was evaporated under air stream on the steam-bath and ethyl acetate and ether[10] then added to cause crystallization. The yield was 0.95 g. (99%). The material even after several crystallizations and drying for analysis exhibited a double melting point, the first at about 170–180°, with subsequent crystallization of the melt, the second at 271–273°.

In an earlier experiment the same reaction was carried out with I at 60° and the same product obtained in 82% yield.

Anal. Calcd. for $C_{12}H_{19}N_3O_6$: C, 47.83; H, 6.36; N, 13.95; NCH_3, 9.96. Found: C, 47.53; H, 6.59; N, 13.96; NCH_3, 6.75.

The tetraacetate of V was prepared by reaction with acetic anhydride in pyridine in the cold. The m.p. of the pure material was 281–282°.

Anal. Calcd. for $C_{20}H_{27}N_3O_{10}$: C, 51.17; H, 5.80; N, 8.95; NCH_3, 6.40. Found: C, 51.21; H, 5.87; N, 9.04; NCH_3, 6.74.

The Structure of Flavothebaone[1]

BY J. MEINWALD AND G. A. WILEY[2]

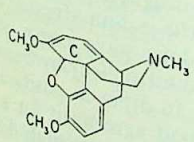
RECEIVED JANUARY 8, 1957

Structure V is deduced for flavothebaone, a rearranged derivative of the alkaloid thebaine, on the basis of a probable mechanism for its formation from thebainehydroquinone (IIIa). This structure differs from part-structure IV originally proposed by Schöpf, in 1938, and from VI and VII put forward, in 1954, by Bentley. New experimental evidence provides strong support for this formulation. Thus, the discovery that dihydrothebainehydroquinone (VIII) undergoes a parallel transformation proves that the C_7–C_8 unsaturation is not essential for the flavothebaone rearrangement. Spectral as well as chemical evidence corroborates the presence of an *isolated* α,β-unsaturated carbonyl system. This new feature is reconciled with the red color developed by flavothebaone in base. The ultraviolet spectrum of flavothebaone, not directly predictable from V, is discussed briefly.

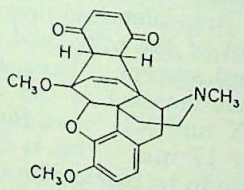
Introduction and Theoretical Discussion

The reaction of *p*-benzoquinone with the alkaloid thebaine (I), described for the first time by Sandermann[3] and by Schöpf,[4] in 1938, gives the expected Diels-Alder adduct thebainequinone (II). This adduct may be regarded as the diketo form of a hydroquinone, and in accord with the generally observed behavior of this type of compound it may be doubly enolized under a variety of conditions to thebainehydroquinone (IIIa). IIIa suffers a deep-seated change on strong acid treatment, losing one methylene group and giving rise to the rearrangement product flavothebaone, $C_{24}H_{23}O_5N$.

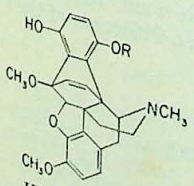
Extensive studies by Schöpf revealed that flavothebaone contained one new phenolic hydroxyl group, an intact tertiary nitrogen, and an α,β-unsaturated ketone system.[4] When flavothebaone is dissolved in base, a striking red coloration develops. This phenomenon led Schöpf to the conclusion that the unsaturated ketonic chromophore *must be conjugated with the hydroquinone ring.* Since methylation of the hydroquinone hydroxyls or saturation of the double bond produced derivatives which were not red in base, this relationship seemed entirely reasonable. On the basis of these early studies, Schöpf tentatively advanced part structure IV for flavothebaone, but was unable to arrive at a complete structure.



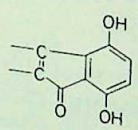
I



II



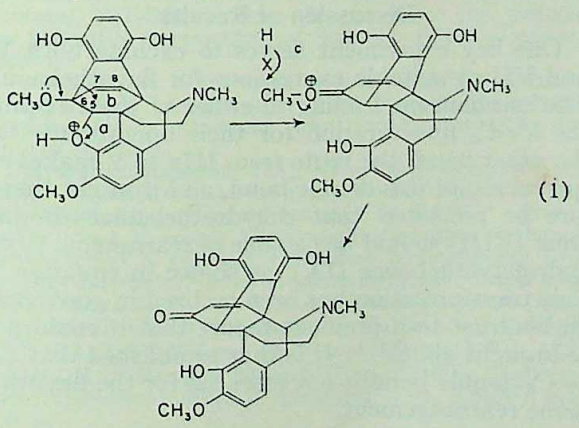
IIIa, R = H
IIIb, R = CH_3



IV

The work of Schöpf incorporated a large number of carefully performed transformations, including a successful Hofmann degradation and Beckmann rearrangement. Oxidative degradations were less fruitful. In view of the complexity of the flavothebaone molecule, it seemed that little progress could be hoped for until a plausible structure could be derived which would serve as a sound working hypothesis. Toward this end, it was of interest to speculate on what acid-catalyzed reactions IIIa might be expected to undergo.

Of the many rearrangement pathways open to the substrate IIIa, one reaction sequence appeared to be so compelling as to eliminate from detailed consideration all other possibilities until the favored scheme could be tested. The postulated sequence, as shown in equation 1, is initiated by protonation of the cyclic ethereal oxygen, and proceeds *via* (a) cleavage of the C_5–O bond, (b) migration of the hydroquinone moiety from C_6 to C_5, and finally (c) attack of the resultant hybrid by any nucleophilic species to give V. This simple mechanism



(1)

V

seemed particularly attractive in view of the high yield and lack of side products obtained in the reaction. It involves only a single 1,2-shift of an electronically excellent migrating group which furthermore is almost exactly *trans* to the vanishing C_5–O bond. Since the easily derived structure V possesses a new phenolic hydroxyl group, an intact tertiary nitrogen and an α,β-unsaturated ketone system, this formula was tentatively assigned to flavothebaone.

That the application of theoretical considerations to the evidence discussed above does not necessarily lead to this conclusion was dramatically demonstrated by the publication of a highly imagi-

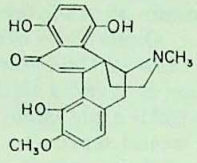
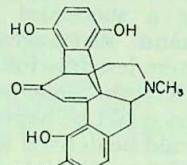
native discussion of the flavothebaone problem by Bentley in 1954.[5] This discussion appeared well after work aimed at testing the validity of structure V had begun in these laboratories, and served to stimulate interest in this research by offering alternate flavothebaone structures. A complete review of this significant discussion is beyond the scope of the present paper, but the key points may be readily summarized. Rather complex mechanistic considerations led to structures VI ($C_{22}H_{21}O_6N$) *or* VII for flavothebaone. Bentley was able to exclude VI by confirming Schöpf's molecular formula and by an analysis of ultraviolet data. With some reservations he was thus led to VII as the correct flavothebaone structure. Brief



VI



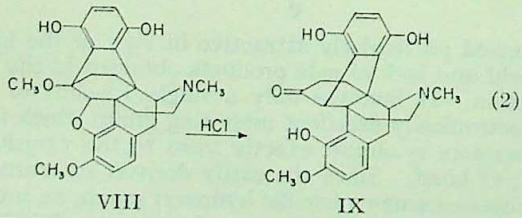
VII

consideration was also given to V, but this possibility was quickly dismissed, largely because of its failure to incorporate extended conjugation.[6]

After a preliminary account of the results of our flavothebaone researches had appeared,[1] Bentley and co-workers published a brief note in which "flavothebaone is allotted structure V."[7] Although they did not present the reason(s) for abandoning their earlier assignment or the evidence supporting V, it is apparent that these workers have deduced structure V independently.

Discussion of Results

One key experiment serves to exclude both VI and VII as suitable expressions for flavothebaone. The mechanisms leading to either of these require the C_7–C_8 unsaturation for their operation.[5] On the other hand, the route from IIIa to V makes no special use of this double bond, and it might therefore be predicted that dihydrothebainehydroquinone (VIII) should be capable of rearranging to dihydroflavothebaone (IX), as shown in equation 2. This transformation has been realized in good yield (in contrast to a previous report that it could not be brought about[5]). It is thus established that the C_7–C_8 double bond is not essential for the flavothebaone rearrangement.



VIII IX (2)

Three types of evidence indicate the presence of an *isolated* α,β-unsaturated ketone system in flavothebaone. The first of these is outlined on Chart 1, and provides information on the point of attachment of the carbonyl group. Lithium aluminum hydride reduction of flavothebaone trimethyl ether (X) gives rise to flavothebaol trimethyl ether (XI). XI is readily reoxidized to X by manganese dioxide, indicating its allyl or benzyl nature.[8] In sharp contrast, dihydroflavothebaol trimethyl ether (XIII), prepared by lithium aluminum hydride reduction of dihydroflavothebaone trimethyl ether (XII) or by catalytic reduction of XI, is resistant to manganese dioxide oxidation even under more drastic conditions. These observations indicate that the carbonyl group of flavothebaone must be insulated from both aromatic rings.

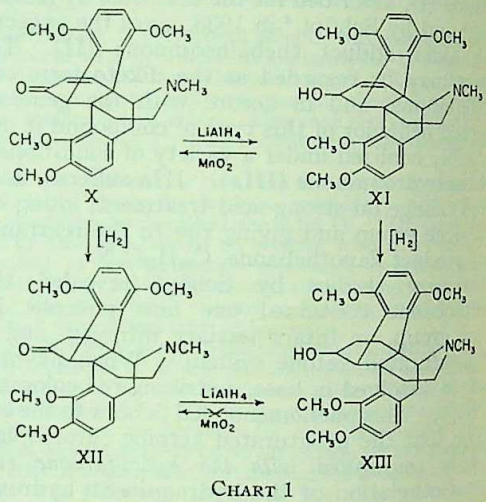


CHART 1

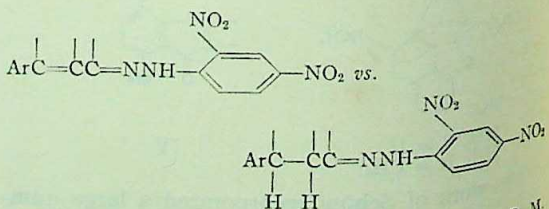
Infrared data support this conclusion. XII shows a single carbonyl absorption band at 5.82 μ (in $CHCl_3$ solution), as would be expected for an isolated carbonyl chromophore. X, on the other hand, shows carbonyl absorption at 5.97 μ (in $CHCl_3$ solution), in accord with expectation.

Ultraviolet data provide insight into the environment of the other end of the α,β-unsaturated carbonyl system. Thus, the long wave length ultraviolet maxima of the 2,4-dinitrophenylhydrazones of X and XII were found to *differ* in position by only 17 mμ. This is in good agreement for a $\Delta\lambda$ value to be expected for a pair of compounds differing by one conjugated double bond,[9] but is much too small to be compatible with a difference of the type shown below.



(5) K. W. Bentley, "The Chemistry of the Morphine Alkaloids," Clarendon Press, Oxford, 1954, pp. 293–301.

(6) It should be pointed out that VII has the conjugation extending to the catechol rather than to the hydroquinone ring. As a result of this, it becomes impossible to use VII to rationalize Schöpf's findings with respect to the color reaction as discussed above.

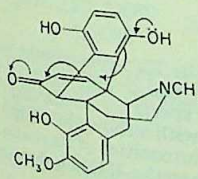
All these observations support V to the exclusion of all other structures so far considered. There are two objections that must be overcome, however, before this formulation can be accepted without reservation. The first of these is the necessity of rationalizing the red color of flavothebaone in base. Re-examination of this phenomenon reveals that the coloration is not due to the development of an intense, long wave length absorption maximum, as had been generally assumed, but rather to the appearance of a long, low-intensity tail in the visible. In fact, the actual spectral change accompanying anion formation is to *shorter* wave lengths (from λ_{max} 280 mμ (3.50), 345 mμ (3.55) to λ_{max} 257 (4.04), 298 mμ (3.84)). Furthermore, the reversibility of this color formation never has been demonstrated. When this point was investigated, it was found that although on a preparative scale flavothebaone can be recovered from basic solutions, *in very dilute solutions* (such as those used for determining ultraviolet spectra) *the reaction is not reversible.* This result takes on increased significance when compared with the behavior of flavothebaone monomethyl ether (XIV). This derivative undergoes a spectral shift to longer wave lengths in base (from λ_{max} 280 mμ (3.49), 344 mμ (3.53) to λ_{max} 293 mμ (3.78) and 404 mμ (3.32)) and the change is reversed by addition of acid, even in very dilute solutions. Finally it should be mentioned that even dihydroflavothebaone (IX), in which no extended conjugated system can exist, develops a brownish color irreversibly in base. From all this it seems clear that the appearance of a color in base is associated with a *reaction* of the unprotected hydroquinone ring which is more complex than simple anion formation.[10] One objection to structure V for flavothebaone is thus overcome.

The remaining difficulty is the unexpected 345 mμ maximum in the flavothebaone spectrum, which could not have been predicted on the basis of structure V. In view of the weight of the evidence presented thus far, it seems best to regard this spectrum as a problem *per se*. It is nevertheless a problem that must be resolved before V can be accepted unconditionally. A number of "abnormal" ultraviolet spectra have come to light recently,[11]



and it is tempting to ascribe this long wave length absorption to "homoconjugation" interaction, perhaps of the sort shown in formula XV. In the absence of any direct analogy for this particular system, however, it is necessary to put this speculation on firm ground by examination of a suitable model system. A synthesis of an appropriate model is now underway. The results of this study as well as of some confirmatory degradations which are now in progress will be presented in a subsequent publication.

Acknowledgments.—This problem was first brought to the attention of one of the authors by Dr. Bernhard Witkop in 1948. We are indebted to Professor Gilbert Stork for valuable discussions and encouragement, and to Dr. Max Tishler, Merck and Co., for a generous supply of thebaine.

Experimental[12]

Dihydrothebainehydroquinone (VIII).—Thebainehydroquinone (IIIa) was hydrogenated in glacial acetic acid over PtO_2 according to the procedure of Schöpf.[4] The H_2 uptake was 1.12 moles and a crude product was obtained in 94% yield. After recrystallization from absolute methanol the m.p. was 281–282° (lit.[4] 273°); infrared spectrum (KBr): 2.98, 3.78 and 3.99 μ (diffuse); ultraviolet spectrum: λ_{max}^{EtOH} 299 mμ (3.79).

Flavothebaone (V).—Compound V was prepared according to the method of Schöpf.[4] Best yields were obtained (in excess of 90%) when thebainehydroquinone (IIIa) was heated at 100° with concentrated HCl for 6 rather than 3 hours. The phenolic base was isolated most conveniently as the bright yellow acid hydrochloride trihydrate ($C_{24}H_{23}O_5N\cdot 2HCl\cdot 3H_2O$). Recrystallization from water gave the hydrochloride trihydrate ($C_{24}H_{23}O_5N\cdot HCl\cdot 3H_2O$). Further drying in a vacuum desiccator gave pale yellow needles of a hydrochloride monohydrate ($C_{24}H_{23}O_5N\cdot HCl\cdot H_2O$)[4]; infrared spectrum (KBr): 2.99, 3.17, 3.72, 5.98, 6.18, 6.32 μ; ultraviolet spectra (taken on $C_{24}H_{23}O_5N\cdot HCl\cdot 3H_2O$): λ_{max}^{EtOH} (0.1 *N* H^+) 279 mμ (3.51) and 346 mμ (3.56); λ_{max}^{EtOH} (0.1 *N* OH^-) 257 mμ (4.04) and 298 mμ (3.84).

Anal. Calcd. for $C_{24}H_{23}O_5N\cdot HCl\cdot H_2O$: C, 62.65; H, 5.65. Found: C, 62.82; H, 5.80.

An additional amount of V, as the free base, could be precipitated from the aqueous recrystallization liquors with saturated $NaHCO_3$ solution. In our hands this material was difficult to recrystallize and further purification was not achieved.

Flavothebaone dissolves in sodium hydroxide solution to give a deep red solution. Acidification of this solution reprecipitates flavothebaone (identified by ultraviolet and infrared spectra).

Dihydroflavothebaone (IX).—The hydrogenation was carried out on flavothebaone hydrochloride trihydrate using 10% Pd:$BaSO_4$ catalyst as described by Schöpf.[4] The H_2 uptake was 1.16 moles. Recrystallization from methanol–water yielded a colorless crystalline hydrochloride (presumably dihydrate); infrared spectrum (KBr): broad 2.98–3.25, 3.74(w), 5.85, 6.20, 6.32 μ; ultraviolet spectra (intensities calculated on the basis of $C_{23}H_{25}O_5N\cdot HCl\cdot 2H_2O$): λ_{max}^{EtOH} (0.1 *N* H^+) 291 mμ (3.73) and 309 mμ (3.70); λ_{max}^{EtOH} (0.1 *N* OH^-) 259 mμ (3.89) and 303 mμ (3.84); 2,4-dinitrophenylhydrazone: infrared spectrum: 2.94, 5.84(w), 6.17, 6.28 μ.

Anal. Calcd. for $C_{30}H_{29}O_8N\cdot HCl\cdot H_2O$: C, 56.10; H, 5.02; N, 10.90. Found: C, 56.33; H, 4.97; N, 10.55.

Rearrangement of Dihydrothebainehydroquinone (VIII) to Dihydroflavothebaone (IX).—Dihydrothebainehydroquinone (4.70 g.) was dissolved in 25 ml. of glacial acetic acid. This solution was added to a concentrated HCl solution held at 95–100° on a water-bath. White crystals soon began to appear. After 9 hours the solution was cooled and the crystals filtered, washed and dried (2.77 g.). Additional material was obtained by diluting the filtrate with water and cooling to 5° (1.84 g.). The total yield was 86% (based on the dihydrate formulation). Recrystallization from water yielded colorless crystalline hydrochloride. The infrared spectrum (KBr) was indistinguishable from that of the authentic sample of IX; ultraviolet spectra (in-

(10) A very careful attempt to make the formation of an anion from flavothebaone reversible in dilute solution by operating under an atmosphere of nitrogen is described in the Experimental section.

(11) Some early cases are cited by J. Meinwald, S. L. Emerman, N. C. Yang and G. Büchi, THIS JOURNAL, **77**, 4401 (1955). Two excellent recent papers dealing with this general problem have been published by R. C. Cookson and N. S. Wariyar, *J. Chem. Soc.*, 2302 (1956), and by R. R. H. Jones, G. H. Mansfield and M. C. Whiting, *ibid.*, 4073 (1956).

(12) All melting points were taken on a calibrated Fisher–Johns hot-stage. Ultraviolet spectra were recorded using a Beckman ultraviolet spectrophotometer, model DK.

tensities calculated on the basis of $C_{23}H_{25}O_5N \cdot HCl \cdot 2H_2O$): λ_{max}^{EtOH} (0.1 *N* H^+) 291.5 mμ (3.70) and 309 mμ (3.71); λ_{max}^{EtOH} (0.1 *N* OH^-) 257 mμ (3.99) and 302 mμ (3.78).

A 2,4-dinitrophenylhydrazone was prepared and found to have an infrared spectrum (KBr) indistinguishable from that of authentic dihydroflavothebaone 2,4-dinitrophenylhydrazone.

Flavothebaone Trimethyl Ether (X).—Methylation of flavothebaone was carried out as prescribed by Schöpf employing sodium ethoxide and phenyltrimethylammonium chloride.[4,13] The free base was obtained in 72% yield and gave a m.p. of 252.5–253.0° with sintering below 240° (lit.[4] 253°) after recrystallization from absolute methanol; infrared spectrum ($CHCl_3$ soln.): 5.97, 6.25, 6.34 μ; ultraviolet spectrum: λ_{max}^{EtOH} 266–290 mμ (3.43) and 337 mμ (3.49); 2,4-dinitrophenylhydrazone: m.p. 298–299° (browns after melting) ultraviolet spectrum: λ_{EtOH}^{max} 3.94 mμ (4.35).

Anal. Calcd. for $C_{33}H_{33}O_8N_5$: C, 63.15; H, 5.30. Found: C, 63.29; H, 5.40.

Flavothebaol Trimethyl Ether (XI).—To an agitated suspension of flavothebaone trimethyl ether (5.0 g.) in 250 ml. of absolute ether which had previously been cooled to 0–5°, was added a 2-fold amount of ethereal $LiAlH_4$ solution over a 2-hour period. After stirring 24 hr. at 0–5°, saturated Na_2SO_4 solution and then solid anhydrous Na_2SO_4 were added. After several hours the mixture was filtered and the solid washed thoroughly with ether. The ether was evaporated to leave a white solid (4.57 g., 91%). Several recrystallizations from absolute ethanol gave white feathery crystals, m.p. 267.5–268°, with browning after melting; infrared spectrum ($CHCl_3$ solution): 2.91, 6.23, 6.36 μ; ultraviolet spectrum: λ_{max}^{EtOH} 291 mμ (3.70), shoulder around 300 mμ.

Anal. Calcd. for $C_{27}H_{31}O_6N$: C, 72.14; H, 6.95; N, 3.12. Found: C, 72.17; H, 7.10; N, 3.39.

MnO_2 Oxidation of Flavothebaol Trimethyl Ether (XI).—Active MnO_2 (500 mg.), prepared after the method of Attenburrow, *et al.*,[8] was ground to a fine powder and suspended in 150 ml. of absolute benzene. Flavothebaol trimethyl ether (50 mg.) was added and the mixture agitated for 4 hours. After filtration and evaporation of the benzene a yellowish residue was left which had an ultraviolet spectrum identical with that of flavothebaone trimethyl ether. After recrystallization from absolute methanol its melting point was 252.5–254° and not depressed when mixed with an authentic specimen.

Dihydroflavothebaone Trimethyl Ether (XII).—Flavothebaone trimethyl ether was hydrogenated over PtO_2 in glacial acetic acid as described by Schöpf.[4] Colorless needles were obtained on recrystallization from absolute methanol, m.p. 242–244° with browning after melting (lit.[4] 219–20°, clear at 238°); infrared spectrum ($CHCl_3$ solution): 5.82, 6.21, 6.31 μ; ultraviolet spectrum: λ_{max}^{EtOH} 291–300 mμ (3.66); 2,4-dinitrophenylhydrazone: m.p. 251–252°. ultraviolet spectrum: λ_{max}^{EtOH} 377 mμ (4.4).

Anal. Calcd. for $C_{33}H_{35}O_8N_5$: C, 62.94; H, 5.60; N, 11.12. Found: C, 62.82; H, 5.64; N, 11.18.

Dihydroflavothebaol Trimethyl Ether (XIII). A. From Flavothebaol Trimethyl Ether (XI).—Flavothebaol trimethyl ether (250 mg.) was hydrogenated over PtO_2 in 40 ml. of glacial acetic acid. After 70 minutes H_2 uptake had stopped at 0.91 mole. After filtration and evaporation of most of the acetic acid, the free base was precipitated with aqueous ammonia. Recrystallization from absolute ethanol gave colorless clusters of needles, m.p. 193–194°.

B. From Dihydroflavothebaone Trimethyl Ether (XII).—Dihydroflavothebaone trimethyl ether (500 mg.) was slurried in 50 ml. of absolute ether and reduced with $LiAlH_4$. The product was worked up in the usual way and after several recrystallizations from absolute ethanol, gave colorless needle clusters, m.p. 193–194°, with no depression on mixing with a specimen prepared by method A; infrared spectrum (KBr): 2.80, 6.25, 6.37 μ; ultraviolet spectrum: λ_{max}^{EtOH} 288.5 mμ (3.74), shoulder *ca.* 300 mμ.

Anal. Calcd. for $C_{27}H_{33}O_5N$: C, 71.81; H, 7.37; N, 3.10. Found: C, 71.62; H, 7.11; N, 3.37.

Treatment of Dihydroflavothebaol Trimethyl Ether (XIII) with MnO_2.—Agitation of dihydroflavothebaol trimethyl ether with active MnO_2 in absolute benzene for 24 hr. gave back only unchanged starting material, identified by m.p., mixture m.p. and ultraviolet spectrum.

Thebainehydroquinone Monomethyl Ether[14] (IIIb).—IIIb was prepared from thebainehydroquinone (IIIa) as described by Schöpf, by heating with methyl *p*-toluenesulfonate in the absence of base.[4] After recrystallization from absolute methanol, off-white rectangular plates were obtained, m.p. 238–240° (lit.[4] 238°); infrared spectrum (KBr): 3.01, 6.13, 6.25 μ; ultraviolet spectra: λ_{max}^{EtOH} (0.1 *N* H^+) 310 mμ (3.83) and shoulder *ca.* 290 mμ; λ_{max}^{EtOH} (0.1 *N* OH^-) 320 mμ (3.63) and shoulder *ca.* 294 mμ.

Flavothebaone Monomethyl Ether (XIV).—XIV was prepared by rearrangement of thebainehydroquinone monomethyl ether (IIIb) as described by Schöpf.[4] Isolated as the hydrochloride and crystallized from water, it formed light yellow cubes (presumably a dihydrate); infrared spectrum (KBr): 2.94, 3.13, 3.27, 3.69(w), 5.85, 5.95, 6.20, 6.30 μ; ultraviolet spectra (intensities calculated on basis of the dihydrate formula): λ_{max}^{EtOH} (0.1 *N* H^+) 280 mμ (3.49), 344 mμ (3.53) and shoulder *ca.* 320 mμ; λ_{max}^{EtOH} (0.1 *N* OH^-) *ca.* 240 mμ shoulder on intense end-absorption, 293 mμ (3.78) and 404 mμ (3.32).

Ultraviolet Spectral Studies.—The spectra presented in Table I were taken as described below.

TABLE I

Compound and medium	λ_{max}^{EtOH} mμ (log ε)	Color of solution
Flavothebaone		
Acidic	279(3.51), 346(3.56)	Yellow
Basic	257(4.04), 298(3.84)	Red-brown
Reverse (acidic)[a]	285(3.54), 315sh.	.....
Reverse after 20 hr.[a]	283(3.62), 315sh.	.....
Double reverse (basic)[a]	257(3.46), 298(3.50)	.....
Dihydroflavothebaone		
Acidic	291(3.73), 309(3.70)	Colorless
Basic	259(3.89), 303(3.84)	Pale pink
Reverse (acidic)[b]	285(3.71), 310(3.33)	.....
Flavothebaone monomethyl ether		
Acidic	280(3.49), 344(3.53), 320sh.	Yellow
Basic	293(3.78), 404(3.32)	Bright yell.
Reverse (acidic)[b]	280(3.52), 344(3.54), 320sh.	Yellow

[a] It appears that the KCl precipitate adsorbs some of the alkaloid. Note that the double reverse has lower intensities than the original spectrum in alkaline solution. [b] These reverses were done with ethanolic H_2SO_4 in place of HCl. It appears from the intensities of flavothebaone monomethyl ether after reverse that the $KHSO_4$ does not adsorb appreciable quantities of alkaloid.

A. Acidic.—Ten-ml. aliquots of ethanolic solution of alkaloid were acidified with 2.5 ml. of 1.0 *N* ethanolic HCl and diluted to 25.0 ml. with ethanol. These solutions were run against a similarly prepared solvent blank.

B. Basic.—Ten-ml. aliquots were prepared and run as A substituting 1.0 *N* ethanolic KOH for the HCl.

C. Reverse.—These experiments were run by taking 10.0-ml. aliquots of alkaloid stock solutions and adding

(13) Poor results were obtained when this reagent was contaminated with the iodide from which it is prepared. A good grade of this reagent is readily prepared by agitating a solution of phenyltrimethylammonium iodide with excess AgCl for 48 hr. After filtering and stripping the water, a crude product is obtained which gives a negative test for I^- (no iodine color in organic layer on shaking a sample with "Clorox" and CCl_4). It is conveniently crystallized from acetone–ether.

(14) The position of the new methyl group in IIIb had originally been assigned as shown by Schöpf. A series of experiments, involving chiefly a spectral study of IIIb and many related compounds, has tended to confirm this structure. A full discussion of this point would be out of place here, however, and should appear in a separate publication.

2.5 ml. of 1.0 *N* ethanolic KOH solution. After brief shaking 5.0-ml. portions of 1.0 *N* ethanolic HCl were added and the solutions diluted to 25.0 ml. Portions of the solutions were centrifuged and the spectra run against similarly prepared blanks.

D.—The double reverse was achieved by treating a 5.0-ml. aliquot of the reverse (acidic) solution with 5.0 ml. of 1.0 *N* ethanolic KOH, diluting to 25.0 ml., centrifuging and running against a similarly prepared blank.

Anaerobic Attempt to Recover Flavothebaone from Dilute Base.—A stock solution of flavothebaone was de-oxygenated with N_2 for 0.5 hour as was an ethanolic KOH solution. Some of the stock solution was pipetted into the KOH solution while continuing to sweep with N_2. The solution turned orange-yellow but became light yellow after a few minutes. An evacuated gas cell was attached to the system and a portion of the solution was thereby withdrawn. The ultraviolet spectrum of this yellow sample was the same as those of the red-brown solutions obtained without the above precautions. A portion of the alkaline solution was poured into ethanolic H_2SO_4, centrifuged and the spectrum taken. It was the same as the spectrum given by flavothebaone after acidification of the basic solution as listed in Table I.

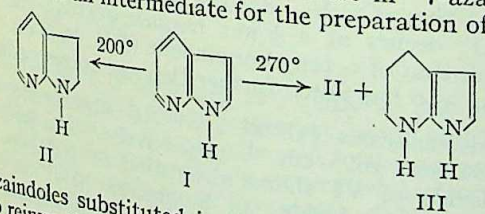
7-Azaindole. IV. The Hydrogenation of 7-Azaindole and Related Compounds[1,2]

BY MICHAEL M. ROBISON, FLORENCE P. BUTLER AND BONNIE L. ROBISON

RECEIVED DECEMBER 12, 1956

High-pressure hydrogenation of 7-azaindole (I) in neutral medium at 200° produces 2,3-dihydro-7-azaindole (II), while at higher temperatures the pyrroline ring is cleaved to yield 2-amino-3-ethylpyridine (IV). In acid medium, however, the ring is hydrogenated at atmospheric temperature and pressure to form 2,3,3a,4,5,6-hexahydro-1H-pyrrolo[2,3-b]pyridine (VI). The structure of this product was demonstrated by comparison with the corresponding hexahydro compounds obtained from the reductions of 1-methyl-7-azaindole (VII) and 7-methyl-7H-pyrrolo[2,3-b]pyridine (IX). 1,7-Dimethyl-1H-pyrrolo[2,3-b]pyridinium iodide (XV), on the other hand, reacts with five moles of hydrogen under similar conditions and 1-methyl-3-(2-methylaminoethyl)-piperidine hydroiodide (XVI) is formed. Miscellaneous derivatives of 7-azaindole including a number resulting from ring closure across the 1- and 7-positions are also described.

In 1943, Kruber[3] attempted to cleave the pyrrole ring of 7-azaindole (I) by high-pressure hydrogenolysis with a nickel catalyst in decalin solution. He reported that the pyrrolopyridine, unlike indole which can be cleaved to form *o*-ethylaniline,[4] reacts with one mole of hydrogen at 200° to form 2,3-dihydro-7-azaindole (II), and that at 250–270° a tetrahydroazaindole is produced as well. On the basis of its formation of a dibenzoyl derivative, Kruber proposed the structure 4,5,6,7-tetrahydro-7-azaindole (III) for the latter, but no conclusive evidence was offered for the structure of either hydrogenation product. An interest in "7-azaindoline" as an intermediate for the preparation of 7-azaindoles substituted in the pyridine ring led us to reinvestigate the course of these hydrogenations and to extend the investigation to related reductions.



Hydrogenation of 7-azaindole at the prescribed[3] temperature and pressure with an aged W-4 Raney nickel catalyst[5] afforded a dihydro compound apparently identical with that described by Kruber. Evidence in support of the azaindoline structure was obtained from the ultraviolet spectrum of the compound (Fig. 1). The absorption maxima in the

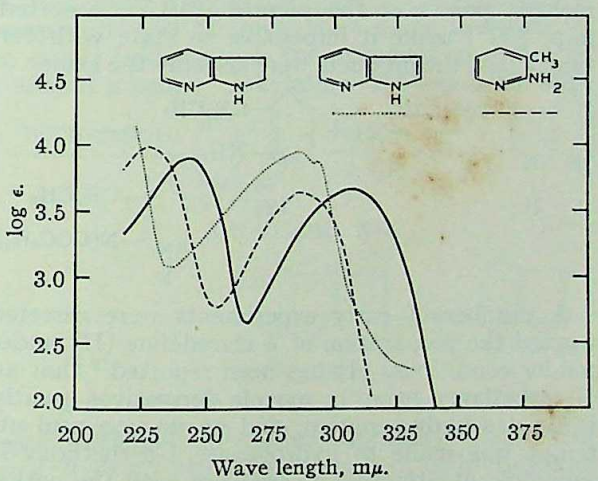


Fig. 1.

spectrum of the dihydro derivative show a bathochromic shift relative to the 7-azaindole absorption and the spectrum of II is more comparable to that of 2-amino-3-picoline, although the peaks in the latter spectrum also occur at a shorter wave length. Similar relationships are noted between the spectra of 2-methylindole,[6] 2-methylindoline[6] and *o*-toluidine[7] and between those of indene and hydrindene.[8] Although such a comparison does not provide conclusive evidence for the 2,3-dihydro structure, it does lend strong support to such a formulation. Attempts at substitution reactions in the pyridine ring of the dihydro compound are anticipated and these, if successful, will serve to confirm the structure.

In this Laboratory it was found that hydrogena-

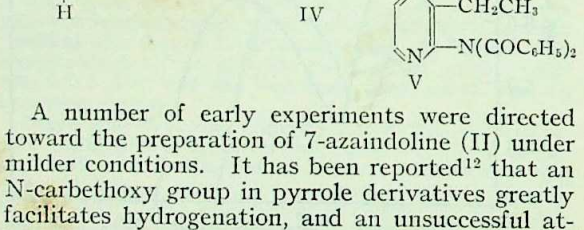
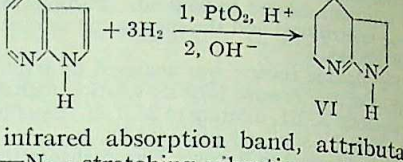
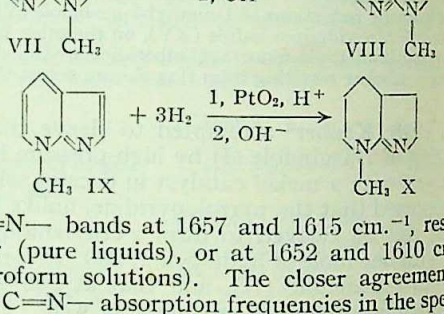
tion of azaindole at 250–270° afforded a mixture of the dihydro compound and a slightly more volatile material, as reported by Kruber.[3] Although distillation equipment capable of effecting a completely clean separation was not available, the ultraviolet spectra of the lower-boiling fractions were measured. These spectra were inconsistent with the pyrrole structure but corresponded very closely to the spectrum of 2-amino-3-picoline (see Fig. 1 and Experimental). The aminopyridine derivative likely to be formed in the reaction would be the known[9] 2-amino-3-ethylpyridine (IV) resulting from hydrogenolysis of the pyrrole ring and it was found that the low-boiling fractions did consist mainly of this "tetrahydro compound" contaminated by the 7-azaindoline. The identity of the purified crystalline material was demonstrated by mixture melting point of the amine and of its picrate with authentic samples of these compounds. Further, since 2-amino-3-picoline[10] and 2-aminopyridine[11] readily form dibenzoyl derivatives, it seemed possible that the "tetrahydro derivative" of Kruber was actually the hydrogenolysis product. The dibenzoyl derivative V melted at 166°, in fair agreement with the melting point (168°) reported by Kruber, but the discrepancies in the physical constants of the amine itself and in the melting points of the picrate (210.5°, reported[3] m.p. 200°) make it impossible to state with certainty that the products were actually the same.



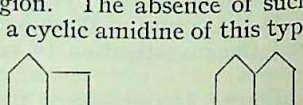
A number of early experiments were directed toward the preparation of 7-azaindoline (II) under milder conditions. It has been reported[12] that an N-carbethoxy group in pyrrole derivatives greatly facilitates hydrogenation, and an unsuccessful attempt was made to hydrogenate 1-carbethoxy-7-azaindole at atmospheric pressure with the active W-4 Raney nickel.[5] 7-Azaindole also was recovered unchanged after prolonged treatment with refluxing ethereal lithium aluminum hydride, in agreement with results observed with indole itself.[13] In a further search for mild reduction conditions hydrogenation in acid medium was tried, since the pyridine ring undergoes facile reduction in such circumstances.[14] It was found that 7-azaindole reacts with 3 moles of hydrogen at atmospheric temperature and pressure when stirred with Adams catalyst in aqueous ethanolic hydrochloric acid. The product, which is considered to be 2,3,3a,4,5,6 - hexahydro - 1H - pyrrolo[2,3 - b]pyridine (VI), is a strong base ($pK_b \sim 2.3$) and has an



intense infrared absorption band, attributable to the >C=N— stretching vibration, at 1652 cm.$^{-1}$ (KBr disk) or 1635 cm.$^{-1}$ ($CHCl_3$ solution). In an effort to provide closely-related spectral models to ascertain the position of the >C=N— bond, 1-methyl-7-azaindole (VII) and 7-methyl-7H-pyrrolo[2,3-b]pyridine (IX)[15] were also hydrogenated. The products were assigned the structures 1-methyl-2,3,3a,4,5,6-hexahydro-1H-pyrrolo[2,3-b]-pyridine (VIII) and 7-methyl-2,3,3a,4,5,6-hexahydro-7H-pyrrolo[2,3-b]pyridine (X) on the bases of the absence of >NH stretching absorptions in their infrared spectra and the occurrence of



>C=N— bands at 1657 and 1615 cm.$^{-1}$, respectively (pure liquids), or at 1652 and 1610 cm.$^{-1}$ (chloroform solutions). The closer agreement of the >C=N— absorption frequencies in the spectra of VI and VIII is at least strongly suggestive of the $\Delta^{7(7a)}$-structure, rather than the $\Delta^{1(7a)}$-structure corresponding to X. Further support for this formulation is to be found in a thorough-going series of investigations by Witkop,[16] who has found that the >C=N— absorption of hexahydroindole (XI) occurs at a lower frequency (1647 cm.$^{-1}$) than that of octahydroquinoline (XII, 1658 cm.$^{-1}$) and who has noted further that the corresponding hydrochlorides exhibit $>C{=}\overset{+}{N}H$ absorptions at 1684 and 1695 cm.$^{-1}$, respectively. The hydrochloride of VI shows absorption at 1684 cm.$^{-1}$ (KBr) and is lacking an "immonium band" in the 4.5–5.5 μ region. The absence of such a band is expected for a cyclic amidine of this type.[16c]



Further investigations of VI included dehydrogenation with palladium-on-charcoal. That the ring system had not been ruptured in the reduction was demonstrated by the formation of 7-azaindole. Early experiments also included benzoylation by several methods. From all of these a product was isolated whose analysis corresponded to the di-

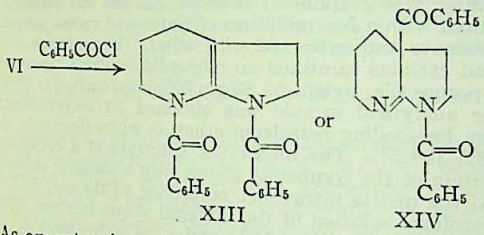
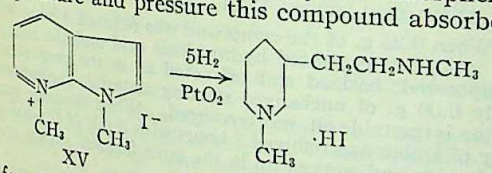
Digitized by Arya Samaj Foundation Chennai and eGangotri

benzoyl derivative of VI. In contrast to these results neither VIII nor X would form benzoyl derivatives under similar conditions. The structure of the acylation product is not clear. On the basis of structure VI, possibilities include either XIII or XIV for the derivative. On hydrolysis in concentrated hydrochloric acid an 87% yield of benzoic acid was obtained from the material, though the amine itself could not be isolated. Further experiments, however, demonstrated that the amine is relatively unstable to aqueous acid or base. The infrared spectrum of the dibenzoyl derivative provides no conclusive evidence for either structure, though it seems to favor structure XIV, since in the double-bond stretching region two strong absorptions are noted at 1635 and 1677 cm.$^{-1}$ as well as a shoulder at 1650 cm.$^{-1}$. On the basis of the available evidence, however, the exact structure must remain in doubt. In conjunction with the benzoylation studies, it may be noted that the amine was found to react in a 1:1 molar ratio with phenyl isocyanate. This result is in agreement with the proposed structure.

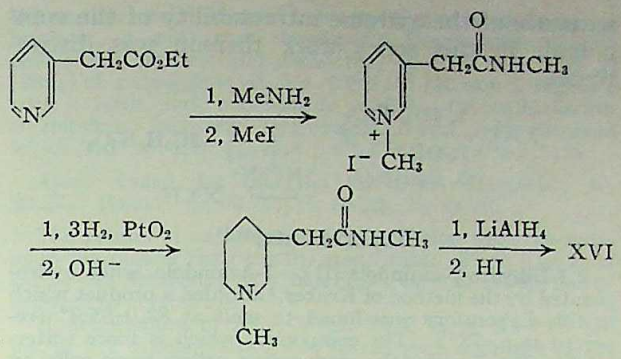


As an extension of the above reductions it was of interest to investigate the course of hydrogenation of 1,7-dimethyl-1H-pyrrolo[2,3-b]pyridinium iodide (XV). Rather surprisingly, at atmospheric temperature and pressure this compound absorbed

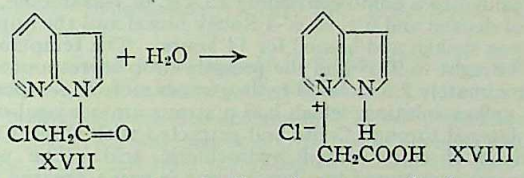


a fourth mole of hydrogen as rapidly as the first three and a fifth mole somewhat more slowly. Further, addition of hydriodic acid to the aqueous ethanol solutions completely prevented hydrogen uptake. The reaction of five moles of hydrogen indicated that one of the rings had been opened, and by analogy to the course of hydrogenation of compound IX in *neutral* medium,[15] it was expected that this would be the pyrrolidine ring. That the compound isolated was indeed the piperidine derivative XVI was demonstrated by comparison with an authentic sample, prepared by an unequivocal synthesis as shown below.

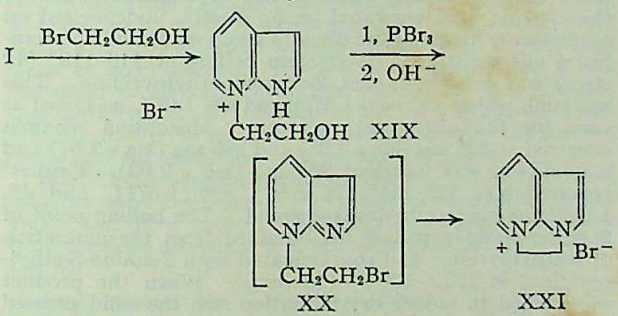
Some earlier experiments were directed to the preparation of tricyclic derivatives of azaindole by ring closure across the two nitrogen atoms, with the expectation of studying hydrogenations and other reactions in this series. Thus 1-chloroacetyl-7-azaindole (XVII) was prepared to attempt to form by intramolecular alkylation at the 7-position a product analogous to the imidazo[1,2-a]pyridine derivative obtained[17] on similar treatment of 2-



aminopyridine. On standing exposed to the atmosphere, or more readily on heating in water, the compound did undergo alkylation, but only with concomitant hydrolysis of the amide linkage to form the 7-carboxymethyl-1H-pyrrolo[2,3,-b]pyridinium chloride (XVIII).



Because of the facile cleavage of the amide linkage, work was discontinued on the chloroacetyl compounds and attempts were made to construct an *ethano* bridge across the nitrogens according to a second scheme. Alkylation of 7-azaindole with



2-bromoethanol proceeded normally[15] to form 7-(2-hydroxyethyl)-1H-pyrrolo[2,3-b]pyridinium bromide (XIX). Treatment of this salt with phosphorus tribromide apparently replaced the alcohol function by bromine to form the corresponding 2-bromoethyl salt and on basification a yellow color developed, indicating the formation of a 7-alkyl-7H-pyrrolo[2,3-b]pyridine.[15] When this was immediately extracted into ether and the solution warmed the color was largely discharged and a white salt, apparently impure XXI, was formed. Numerous attempts to purify this quaternary bromide were unsuccessful, however. Some analyses indicated the possibility of solvates, but the only satisfactory result obtained was that for the picrate corresponding to XXI. Several experiments were carried out on the hydrogenation of the crude bromide, with an apparent reaction of approximately four molar equivalents of hydrogen. From the reduction mixture a distyphnate was prepared whose analysis was satisfactory for XXII, but because of the large percentage of styphnic acid in the adduct these analytical data provided no conclusive information about the hydrogenation state. As a con-

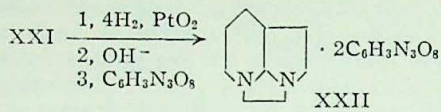
sequence of the extreme intractability of the compounds in this series work thereon was discontinued.



XXII

Experimental[18,19]

2,3-Dihydro-7-azaindole (II).—7-Azaindole, when hydrogenated by the method of Kruber,[3] afforded a product which in this Laboratory was found to melt at 83.0–85.0° (reported m.p. 78°). The compound, which is more water-soluble than 7-azaindole, gives only a yellow-green color on treatment with aqueous sodium nitroprusside and sodium hydroxide and the color changes to a pale green on acidification. These results are in contrast to the exceptionally strong blue-green → blue color reaction with azaindole.[9] The benzoyl derivative, prepared by the method of Kruber, melted at 119.5–121.5° (reported m.p. 120°).

2-Amino-3-ethylpyridine (IV).—Hydrogen at 78 atmos. was added to a bomb containing 22.4 g. of 7-azaindole, 100 ml. of decalin and 5 g. of W-4 Raney nickel and the apparatus was shaken and heated for 14 hours. The temperature was brought to 270° and the pressure-drop corresponded to approximately 2.5 moles of hydrogen per mole of compound. The yellow solution, which had a strong ammoniacal odor, was filtered through Celite and extracted with three 10-ml. portions of concentrated hydrochloric acid. The water layer was evaporated to a low volume *in vacuo*, treated with excess potassium carbonate and extracted with chloroform. The chloroform solution was dried over potassium carbonate and distilled. The product, together with some dihydro compound, was collected in four fractions (total 4.67 g.) boiling over the range 114° (12 mm.) to 135° (10 mm.). After the high-boiling fractions had crystallized partially, the crystals were separated (m.p. 78–82°, undepressed on admixture with authentic dihydro compound) and the combined oils redistilled. A fraction boiling at 116–118° (12 mm.) was relatively pure 2-amino-3-ethylpyridine. This material, which had $n^{24}D$ 1.5728 and d^{20}_4 1.047, was used as such for the ultraviolet spectrum. Absorption maxima occurred at 230 mμ (log ε 3.95) and 290 mμ (log ε 3.67) and a minimum was found at 258 mμ (log ε 2.93). Kruber[3] reported b.p. 133–134° (15 mm.), $n^{20}D$ 1.57117 and d^{20}_4 1.0891 for his tetrahydro compound. The boiling point of 2-amino-3-ethylpyridine[9] (as obtained from the amination of 3-ethylpyridine and contaminated with 2-amino-5-ethylpyridine) is 122.5–128.5° (18 mm.). When the product was chilled to induce crystallization and the solid pressed on porous tile and recrystallized from low-boiling petroleum ether, white plates were obtained, m.p. 41.0–41.5° alone and m.p. 41.5–43.5° on admixture with authentic 2-amino-3-ethylpyridine (reported[9] m.p. 43–45°).

2-Amino-3-ethylpyridine Picrate.—This adduct was prepared by reaction of the recrystallized amine with picric acid in 95% ethanol and recrystallization from the same solvent. There were obtained yellow needles, m.p. 210.0–211.0° dec. On admixture with picrate prepared from authentic amine (m.p. 209.0–210.5° dec.) these melted at 208.5–210.5° dec.

Anal. Calcd. for $C_7H_{10}N_2 \cdot C_6H_3N_3O_7$: C, 44.45; H, 3.73. Found: C, 44.61; H, 3.62.

2-(Dibenzoylamino)-3-ethylpyridine (V).—This derivative was prepared by the method of Huntress and Walter[11] for 2-(dibenzoylamino)-pyridine except that the crude product was washed with ethanol, with 5% hydrochloric acid and with 5% sodium bicarbonate to remove monobenzoyl compound and colored impurities. The yield of washed product, which had m.p. 159.5–162.5°, was 53%. It was found that recrystallization from ethanol[11] resulted in a material with a wide melting range, but recrystallization from 1:3 benzene–cyclohexane afforded white prisms, m.p. 165.5–166.5°.

Anal. Calcd. for $C_{21}H_{18}N_2O_2$: N, 8.48. Found: N, 8.40.

(18) Melting points are corrected, boiling points uncorrected.

(19) Analyses by Drs. Weiler and Strauss, Oxford, England, except for some nitrogen determinations carried out by a semimicro Kjeldahl technique in this Laboratory.

1-Carbethoxy-7-azaindole.—To a stirred solution of 5.90 g. of 7-azaindole and 3.95 g. of dry pyridine in 50 ml. of anhydrous ether a solution of 5.40 g. of ethyl chloroformate in 50 ml. of dry ether was added over a period of one hour. The mixture was refluxed for 3.5 hours, cooled and filtered from the precipitate of pyridine hydrochloride, which was washed with four 25-ml. portions of ether. The combined ether solutions were dried over sodium sulfate, the solvent was removed and the residue was chilled to form oily crystals which, after pressing on filter paper and washing with low-boiling petroleum ether, weighed 7.61 g. (80%), m.p. 42.0–48.5°. The analytical sample was recrystallized from the same solvent as long white filaments, m.p. 47.0–49.5°.

Anal. Calcd. for $C_{10}H_{10}N_2O_2$: C, 63.14; H, 5.31; N, 14.73. Found: C, 63.28; H, 5.28; N, 15.1.

Treatment of 7-Azaindole with Lithium Aluminum Hydride.—To a stirred solution of 145 mg. of lithium aluminum hydride in 15 ml. of dry ether was added a solution of 236 mg. of 7-azaindole in the same quantity of solvent. The mixture was refluxed 11 hours, the hydride decomposed and the ether dried and evaporated. Light-tan azaindole (0.21 g.) was recovered, m.p. 107.0–108.0°.

2,3,3a,4,5,6-Hexahydro-1H-pyrrolo[2,3-b]pyridine (VI).—A mixture of 2.36 g. of 7-azaindole, 50 ml. of 95% ethanol, 10 ml. of concentrated hydrochloric acid and approximately 0.5 g. of pre-reduced Adams catalyst was stirred with hydrogen for 12 hours, during which time about 103% of the theoretical hydrogen was absorbed. The colorless solution was evaporated *in vacuo* and the oily residue was treated with a few milliliters of water and excess potassium carbonate and extracted with ether. Evaporation of the dried extracts furnished an oily solid, which after pressing on porous tile, weighed 1.88 g. (76%) and melted at 88–96°. The analytical sample was obtained on recrystallization from low-boiling petroleum ether as white filaments, m.p. 103.5–104.5°. The ultraviolet spectrum of a cyclohexane solution of the compound shows only a shoulder extending into the quartz ultraviolet range, log ε (214 mμ) 3.72. A chloroform solution of the material shows infrared absorption at 3420 cm.$^{-1}$ (>NH) and a >C=N— band at 1635 cm.$^{-1}$ with a slight shoulder at 1665 cm.$^{-1}$ The pK_b, taken as equal to pOH at half-neutralization, is 2.3.

Anal. Calcd. for $C_7H_{12}N_2$: C, 67.68; H, 9.76; N, 22.56; neut. equiv., 124.2. Found: C, 67.70; H, 9.67; N, 22.52; neut. equiv., 125.1, 124.5.

When 0.25 g. of the compound was refluxed 4 hours with 10 ml. of concentrated hydrochloric acid and the solution evaporated, basified and extracted as in the preparation, only 0.06 g. of unchanged starting material, accompanied by an intractable oil, was recovered. When the same quantity of amine was refluxed 3 hours with 5 ml. of 5% sodium hydroxide and worked up in the same fashion, only a small quantity of oil was isolated.

Hydrochloride of Hexahydroazaindole.—After several unsuccessful attempts to precipitate this salt from anhydrous ether, the amine was treated with excess concentrated hydrochloric acid and the solution evaporated to dryness. The semi-liquid residue was dried at 60° (1 mm.) for 6 hours, during which period it became fairly hard. The exceptionally hygroscopic solid was quite soluble in most organic solvents. It could be recrystallized, albeit not satisfactorily, from dry benzene. The shiny white plates had m.p. 143.5–147.0°.

Anal. Calcd. for $C_7H_{13}N_2Cl$: C, 52.33; H, 8.15; N, 17.44. Found: C, 51.66; H, 8.10; N, 16.20.

Dehydrogenation of Hexahydroazaindole.—A mixture of 0.25 g. of the amine and 0.12 g. of 5% palladium-on-charcoal was heated at 250° for 3 hours in a nitrogen atmosphere. The mixture was extracted with hot cyclohexane and the extract was filtered through a bed of Darco and evaporated to yield 68 mg. of oily, yellow solid. This was pressed on porous tile and washed with cyclohexane, then dissolved in a few milliliters of 5% hydrochloric acid and treated with Darco. Precipitation with sodium bicarbonate afforded white solid, m.p. 105.0–106.0° both alone and on admixture with 7-azaindole. The product gave a positive sodium nitroprusside test.[9]

Dibenzoyl Derivative of VI.—Benzoyl chloride (1.12 g.) was added rapidly to a stirred mixture of 0.50 g. of amine, 10 ml. of anhydrous pyridine and 20 ml. of dry benzene and the solution was heated at 65° for 0.5 hour, during which

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

time a heavy oil layer separated. The mixture was then poured into 200 ml. of water and extracted as directed in Shriner, Fuson and Curtin.[20] Evaporation of the benzene layer left a residue which was dried *in vacuo* and washed with cold ethyl acetate. The resulting 0.79 g. (59%) of cream-colored solid had m.p. 140–144°, and was insoluble in dilute acid. The analytical sample was obtained on recrystallization from 1:3 ethanol–water as large leaves, m.p. 143.5–147.5°. No means of narrowing the melting range was found.

Anal. Calcd. for $C_{21}H_{20}N_2O_2$: C, 75.87; H, 6.08; N, 8.43. Found: C, 75.62; H, 5.93; N, 8.63.

When the reaction was carried out with equimolar quantities of benzoyl chloride and amine, only the dibenzoyl product was isolated, but in greatly reduced yield. Benzoylation in sodium hydroxide or in an ethereal suspension of potassium carbonate gave the same results.

When 664 mg. of the derivative was refluxed 5 hours with 5 ml. of concentrated hydrochloric acid and the cooled solution extracted with ether, 426 mg. (87%) of benzoic acid, m.p. 122.0–123.0° (undepressed on admixture with authentic acid), was obtained. Evaporation, basification and extraction of the water layer afforded only 23 mg. of oil.

1-Phenylcarbamyl-2,3,3a,4,5,6-hexahydro-1H-pyrrolo-[2,3-b]pyridine.—Equimolar quantities of the hydrogenation product and phenyl isocyanate were mixed and the solid product was dissolved in 5% hydrochloric acid and filtered to remove traces of diphenylurea. The amide was precipitated by base in 93% yield and recrystallized from *n*-hexane for analysis. The resulting fine, white needles had m.p. 86.5–89.0° (cloudy melt). A narrower melting range could not be attained.

Anal. Calcd. for $C_{14}H_{17}N_3O$: N, 17.27. Found: N, 17.20.

7-Methyl-2,3,3a,4,5,6-hexahydro-7H-pyrrolo[2,3-b]pyridine (X).—A solution of 3.085 g. of IX[15] in 50 ml. of 95% ethanol and 10 ml. of concentrated hydrochloric acid reacted with 105% of the theoretical volume of hydrogen when reduced under the conditions employed for 7-azaindole. The hydrogenation mixture was worked up by the usual method except that the base was extracted into chloroform and distilled. There was thus obtained a 68% yield of hygroscopic, colorless oil, b.p. 108° (22 mm.) to 109° (18 mm.). The redistilled analytical sample had b.p. 105–106° (18 mm.), $n^{25}D$ 1.5077 and $d^{23.5}{}_4$ 0.996. The pK_b, determined by titration, was found to be 2.5.

Anal. Calcd. for $C_8H_{14}N_2$: C, 69.52; H, 10.21; N, 20.27; neut. equiv., 138.2. Found: C, 69.42; H, 10.08; N, 20.80; neut. equiv., 139.1.

An attempt to benzoylate this amine by the pyridine method using a 1.5:1 molar excess of benzoyl chloride was unsuccessful. No oil layer separated during the reaction period and the product from the extracts consisted of a very small quantity of dark oil from which crystals of benzoic acid separated on standing.

1-Methyl-7-azaindole (VII).—It was found that this compound can be prepared in greatly improved yield by a modification of the method previously described.[15] 7-Azaindole (5.90 g.) was dissolved in 100 ml. of dry xylene and refluxed and stirred in a nitrogen atmosphere with 2.40 g. of sodium hydride for 3 hours. The suspension was cooled, 14.20 g. of methyl iodide in 25 ml. of xylene was added and the mixture was refluxed again for 1.5 hours. Excess hydride was then decomposed by the addition of ethanol after which the xylene layer was extracted with a mixture of 100 ml. of water and 25 ml. of concentrated hydrochloric acid in three portions. The acid solution was then made basic and steam distilled directly after which the procedure was as previously described.[15] The faintly-yellow product from one distillation had b.p. 114–122° (25 mm.) and $n^{19}D$ 1.5978, and weighed 4.10 g. (62%). Use of a still larger molar ratio of sodium hydride and methyl iodide was not tried, but it seems probable that such a procedure might further improve the yield.

1-Methyl-2,3,3a,4,5,6-hexahydro-1H-pyrrolo[2,3-b]pyridine (VIII).—When 5.766 g. of VII was hydrogenated in the same quantity of solvent and under the conditions described above, the theoretical quantity of hydrogen reacted. When the residue from the evaporation was made basic, however, a red color developed. Evaporation of the chloroform extracts and distillation afforded only 1.68 g. (28%) of pale-yellow oil, b.p. 108–113° (16 mm.), together with a large, red, non-volatile residue. On redistillation a colorless, intensely hygroscopic liquid was obtained which had b.p. 106° (15 mm.), $d^{26}{}_4$ 0.995 and $n^{24}D$ 1.5158.

Anal. Calcd. for $C_8H_{14}N_2$: C, 69.52; H, 10.21; N, 20.27. Found: C, 69.76; H, 10.32; N, 19.70.

The results of an attempted benzoylation were the same as in the case of the 7-methyl compound. From 0.55 g. of amine was obtained 0.31 g. of a brown oil which could not be induced to crystallize.

Hydrogenation of XV.—When 2.756 g. of XV[15] in 120 ml. of 5:1 ethanol–water was stirred with hydrogen in the presence of pre-reduced Adams catalyst from 0.5 g. of platinum oxide, four moles of hydrogen was taken up in 12 hours and a fifth mole reacted in another 15 hours. Filtration, evaporation and drying *in vacuo* left 2.7 g. of sticky, yellow solid which was recrystallized from acetonitrile under nitrogen. The recovery of white, crystalline material from the first recrystallization was typically only about 50%. The analytical sample of 1-methyl-3-(2-methylaminoethyl)-piperidine hydroiodide (XVI) had m.p. 140.0–142.0° (cloudy melt).

Anal. Calcd. for $C_9H_{21}N_2I$: C, 38.03; H, 7.45; N, 9.86. Found: C, 38.07; H, 7.51; N, 9.99.

N-Methyl-3-pyridineacetamide.—Ethyl 3-pyridineacetate[21] (24.78 g.) was dissolved in 50 ml. of aqueous methylamine which had been saturated at 0°, and the flask was stoppered tightly and allowed to stand for 71 hours. The solution was filtered to remove a small amount of insoluble impurity and evaporated to dryness *in vacuo*. On chilling, the residue crystallized affording a hygroscopic, slightly oily solid. This was boiled with cyclohexane and chilled to cause resolidification after which the hydrocarbon was decanted and the residue dried thoroughly *in vacuo*. The product (m.p. 56–64°) weighed 22.89 g. (theoretical yield 22.53 g.). No solvent was found from which the material could be recrystallized. For attempted purification it was subjected to several evaporative distillations in a sublimation apparatus at 140° (0.5 mm.), but the white product had m.p. 61–65°. No method was found to narrow the melting range and the analytical results were 1–3% low.

N-Methyl-3-pyridineacetamide Picrate.—This derivative was prepared by reaction of equimolar quantities of the amide and picric acid in 95% ethanol and recrystallization from the same solvent. The yellow needles had m.p. 177.5–178.5°.

Anal. Calcd. for $C_8H_{10}N_2O \cdot C_6H_3N_3O_7$: C, 44.33; H, 3.45; N, 18.47. Found: C, 44.49; H, 3.11; N, 18.40.

1-Methyl-3-(N-methylcarbamylmethyl)-pyridinium Iodide.—To 0.30 g. of amide was added 1.42 g. of methyl iodide and the mixture was allowed to stand overnight. The excess methylating agent was decanted and the crystalline product dried *in vacuo* to yield 0.59 g. (100%) of light-yellow solid, m.p. 117–125°. The analytical sample was obtained as pale-yellow needles from acetonitrile, m.p. 127.0–128.0°.

Anal. Calcd. for $C_9H_{13}N_2OI$: C, 37.00; H, 4.49; N, 9.59. Found: C, 37.44; H, 4.48; N, 9.66.

The reaction also was run on a 0.15 molar scale using only 0.5 mole of methyl iodide. With such quantities, however, efficient cooling is necessary to avoid overheating and loss of product.

N,N′-Dimethyl-3-piperidineacetamide.—The methiodide (30.73 g.) and approximately 1.5 g. of reduced Adams catalyst were added to 135 ml. of 80% ethanol and hydrogenated at an initial pressure of 3 atmospheres. After 34 hours, reaction had ceased and the pale-gold solution was filtered through Celite and evaporated to dryness. Water (25 ml.) and a small quantity of sodium bisulfite were added and the mixture was made strongly basic with potassium carbonate and extracted with chloroform. The extracts were dried over potassium carbonate and evaporated. The residue crystallized readily on drying *in vacuo* to yield 16.01 g. (89%) of a white solid, m.p. 76–79°. The

analytical sample was recrystallized from cyclohexane as white filaments, m.p. 82.0–83.0°.

Anal. Calcd. for $C_9H_{18}N_2O$: C, 63.47; H, 10.68; N, 16.45. Found: C, 63.33; H, 10.48; N, 16.10.

1-Methyl-3-(2-methylaminoethyl)-piperidine Hydroiodide (XVI).—To a stirred suspension of 1.5 g. of lithium aluminum hydride in 75 ml. of dry tetrahydrofuran, a solution of 3.41 g. of the piperidine amide in 25 ml. of tetrahydrofuran was added over a 20-minute period. The mixture was refluxed with stirring for 8 hours, 0.75 g. more hydride being added after 2 hours. The excess reducing agent was decomposed with ethanol, approximately 50 ml. of saturated aqueous potassium hydroxide was added and the layers were separated. The aqueous layer was washed with additional ether and the combined organic solutions were dried over potassium hydroxide. The solvent was evaporated and the product distilled, during which process an appreciable quantity of water-soluble solid residue separated. The distillation product weighed only 0.49 g. (16%) and had b.p. 68–74° (15 mm.). The amine was not investigated further as such but was converted directly to the hydroiodide XVI by addition of the theoretical quantity of aqueous hydriodic acid. Evaporation of the solution *in vacuo* afforded a white solid which after washing with acetonitrile weighed 0.83 g. and had m.p. 139.5–141.5°. Recrystallizations from this solvent in a nitrogen atmosphere produced the analytical sample, m.p. 141.5–143.0° (cloudy melt). On admixture with the hydrogenation product this melted at 142.0–143.5°.

Anal. Calcd. for $C_9H_{21}N_2I$: N, 9.86. Found: N, 9.87.

1-Chloroacetyl-7-azaindole (XVII).—To a stirred solution of 5.90 g. of 7-azaindole and 3.96 g. of anhydrous pyridine in 100 ml. of dry ether a solution of 5.55 g. of chloroacetyl chloride in 50 ml. of ether was added over a period of 35 minutes. During the addition the temperature was kept below −10°. Water (50 ml.) was then added to dissolve the yellow precipitate of pyridine hydrochloride, the layers were separated, the water layer was extracted with three 60-ml. portions of ether and the combined ether solutions were dried over magnesium sulfate. Evaporation of the solvent in a nitrogen stream at room temperature left a residue which crystallized partially on chilling. The crystals were separated from the oil by filtration and the latter was caused to deposit a small amount of additional solid on further cooling. The combined greenish-yellow crystals, after thorough pressing on filter paper, weighed 5.93 g. (61%) and melted at 102–105°. The analytical sample was obtained in the form of long, white needles from cyclohexane, m.p. 107.5–109.0.

Anal. Calcd. for $C_9H_7N_2OCl$: C, 55.53; H, 3.63; N, 14.40. Found: C, 55.91; H, 3.69; N, 14.52.

Attempted Cyclization of XVII.—When the chloroacetyl compound was allowed to stand exposed to the air for a month, it gradually liquefied, then resolidified. The resulting solid decomposed at about 212°. When 1.94 g. of the amide was heated 4 hours with 25 ml. of boiling water, the solid gradually dissolved and the solution became acidic. Evaporation of the colorless liquid *in vacuo* afforded an oil which, after drying over phosphorus pentoxide, was triturated with acetone to produce 1.02 g. (48%) of white solid, m.p. 216–218°. For analysis the strongly acidic compound was recrystallized from absolute ethanol through which gaseous hydrogen chloride was bubbled. The white 7-carboxymethyl-1H-pyrrolo[2,3-b]pyridinium chloride (XVIII) darkens at 190° and has m.p. 218.0–218.5° dec. The ultraviolet spectrum of a water solution has maxima at 224 mμ (log ε 4.30) and at 295 mμ (log ε 3.95) and a minimum at 252 mμ (log ε 2.70).

Anal. Calcd. for $C_9H_9N_2O_2Cl$: C, 50.83; H, 4.27; N, 13.18. Found: C, 51.28, 51.14; H, 4.40, 4.18; N, 12.99.

An attempt also was made to cyclize the amide in the absence of water. When the material was heated in refluxing xylene for 1.5 hours much decomposition ensued and no salt-like material separated from the solution. The polymeric products were not investigated further.

7-(2-Hydroxyethyl)-1H-pyrrolo[2,3-b]pyridinium Bromide (XIX).—A mixture of 5.90 g. of 7-azaindole and 31.2 g. of 2-bromoethanol was heated 1.5 hours on the steam-bath in a nitrogen atmosphere. The cooled mixture was poured into 300 ml. of ether and the white product was separated by filtration and dried *in vacuo*. There was thus obtained 10.69 g. (88%) of product with m.p. 161–168°. The analytical sample was prepared by recrystallization from *n*-propyl alcohol, m.p. 174.5–175.0°.

Anal. Calcd. for $C_9H_{11}N_2OBr$: C, 44.46; H, 4.57; N, 11.52. Found: C, 44.11; H, 4.84; N, 11.41.

Cyclizations of XIX.—To a stirred suspension of 2.43 g. of XIX in 50 ml. of dry toluene, which was maintained at 0°, a solution of 2.70 g. of phosphorus tribromide in 75 ml. of dry toluene was added over a period of 3 hours. Stirring was continued as the mixture was allowed to warm slowly to room temperature, after which it was allowed to stand overnight. The slurry was then refluxed gently for 2 hours, the toluene was decanted and the residue was covered with ether. Ice, followed by dilute sodium hydroxide solution, was added to the well-cooled mixture and the yellow ether layer was separated. The aqueous phase was then saturated with potassium carbonate and extracted with additional ether until the yellow color was removed completely. The extracts were dried briefly over magnesium sulfate and evaporated on the steam-bath to yield a yellow, oily solid. This was triturated with acetone and separated by filtration. The acetone solution was again evaporated to dryness to produce additional white solid which was separated in the same manner, the washings and evaporations being repeated until no additional product was obtained. The total yield of white solid, after one recrystallization from 1:4 absolute ethanol–carbon tetrachloride, was 0.82 g., m.p. 148.5–149.5° dec. Analytical results corresponding to a simple empirical formula were not obtained on recrystallization from this or other solvents. It was noted that after recrystallization the product *lost* weight on exposure to air while the weight remained *constant* on storing over phosphorus pentoxide. It was eventually determined that the material was a solvate containing carbon tetrachloride, for the desiccator-dried material gave a positive test for chlorine, on sodium fusion, as well as bromine. On exposure to air the carbon tetrachloride was lost, but was apparently replaced to some degree by water. Neither by this treatment nor on drying at elevated temperatures could a satisfactory sample be prepared. The ultraviolet spectrum of a water solution of a sample dried at 60° exhibits maxima at 230 mμ (log ε 4.20) and 292 mμ (log ε 3.94) and a minimum at 248 mμ (log ε (2.08), if the ε values are calculated on the basis of pure XXI.

From the supposed XXI, which can be named most simply as 1,7-ethano-1H-pyrrolo[2,3-b]pyridinium bromide, a picrate was prepared by reaction of 0.5 g. of the salt, 0.32 g. of sodium acetate trihydrate and 1.02 g. of picric acid in 30 ml. of water. Recrystallizations of the product from 95% ethanol produced the analytical sample, m.p. 146.0–147.0°.

Anal. Calcd. for $C_9H_9N_2 \cdot C_6H_2N_3O_7$: C, 48.26; H, 2.98; N, 18.76. Found: C, 48.42; H, 3.33; N, 18.3.

Hydrogenation of XXI.—A solution of 503 mg. of XXI in 25 ml. of 95% ethanol with Adams catalyst reacted with 3.64 molar equivalents of hydrogen in approximately 11 hours. The solution was filtered and evaporated to dryness and about one-third of the residue was treated with a solution of 0.49 g. of 2,4,6-trinitroresorcinol and 0.14 g. of hydrated sodium acetate in water. The resulting yellow precipitate was recrystallized from water and from methanol to produce the analytical sample of XXII, m.p. 195.5–196.0° dec.

Anal. Calcd. for $C_9H_{16}N_2 \cdot 2C_6H_3N_3O_8$: C, 39.26; H, 3.45; N, 17.44. Found: C, 39.14; H, 3.35; N, 17.7.

Absorption Spectra.—All ultraviolet spectra were measured on a Beckman model DU quartz spectrophotometer at concentrations varying from 10^{-4} to 5×10^{-5} *M*. The solvent was cyclohexane, unless otherwise specified. Infrared spectra were determined on either a Perkin–Elmer spectrophotometer or a Baird instrument by Dr. S. M. Nagy and associates at the Microchemical Laboratory, Massachusetts Institute of Technology.

Partial Esterification of Methyl 4,6-*O*-Benzylidene-α-D-glucopyranoside in Pyridine Solution[1]

BY ROGER W. JEANLOZ AND DOROTHY A. JEANLOZ

RECEIVED DECEMBER 17, 1956

Partial esterification of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside in pyridine solution with chlorides of carboxylic and sulfonic acids gave the monoester in position 2 in preponderant yield. When anhydrides were used for partial esterification, the carboxylic anhydrides gave the monoester in position 3 in preponderant yield, whereas the sulfonic anhydrides gave the monoester in position 2.

In order to study the influence of neighboring groups on the solvolysis of sulfonyl esters of glucose,[2] it has been necessary to prepare the various acetyl, benzoyl, methylsulfonyl and *p*-tolylsulfonyl derivatives of methyl 4,6-*O*-benzylidene-α-D-glucoside (I) reported in Fig. 1.

While this work was being completed, the preparation of some of the derivatives described here was reported either by different methods, or with quite different yields. Bourne, *et al.*,[3,4] have described the preparation of the partially substituted acetates III and IV and benzoates VI and VII using trifluoroacetyl intermediates. Since the preparation of the intermediates makes this method quite lengthy, the reagent is expensive and the yields starting from I are not excellent (III, 41%; IV, 38%; VI, 26%; VII, 41%), it seemed of interest to investigate the direct partial acetylation and benzoylation of I.

Monobenzoylation and mono-*p*-toluenesulfonylation of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I) using the acid chlorides in pyridine solution have been described previously. Although Ohle and Spencker[5] reported that the hydroxyls in position 2 and 3 reacted at the same speed, and that they could not obtain a monoderivative, Robertson and Griffith[6] obtained the 2-*O*-*p*-tolylsulfonyl derivative, isolated as derivative XIX, in a 20% yield. Bolliger and Prins,[7] using a chromatographic separation, were able to increase the yield of XVII to 60 to 70%. Robertson and Griffith[6] reported that monobenzoylation was difficult to control and gave poor and not reproducible yields. The 2-*O*-benzoyl derivative VI was obtained in a 9% yield, after isolation as 2-*O*-benzoyl-3-*O*-*p*-tolylsulfonyl derivative XXI. In both esterifications the reaction in position 2 was preponderant. After completion of the work described here, the preparation of the 2-*O*-methylsulfonyl derivative XI from I using two intermediate steps was reported.[8]

Repetition of Robertson and Griffith's procedure,[6] consisting of a partial benzoylation of I followed by a *p*-toluenesulfonylation, gave a mixture of products quite complex, as the known methyl 2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucoside (V) and methyl 2,3-di-*O*-*p*-tolylsulfonyl-4,6-*O*-benzylidene-α-D-glucoside (XVI) were isolated in addition to the 2-*O*-benzoyl-3-*O*-*p*-tolylsulfonyl derivative XXI already described by Robertson and Griffith. Consequently it was thought of interest to study separately each step of the reaction. The results of the monoesterification of I by various reagents under various conditions of temperature are reported in Table I.

When methyl 4,6-*O*-benzylidene-α-D-glucoside (I) was treated with acetic anhydride, most of the substitution took place in position 3 intead of position 2, as expected. From the 3-*O*-acetyl derivative IV, almost quantitative yields of the 2-*O*-methylsulfonyl XII and 2-*O*-*p*-tolylsulfonyl XVIII derivatives were obtained.

The preferential reaction of the carboxylic anhydride with position 3 as observed with acetic anhydride, was confirmed using benzoic anhydride, and from the 3-*O*-benzoyl derivative VII the 2-*O*-acetyl derivative VIII was obtained. However, all attempts at obtaining a 3-*O*-*p*-tolylsulfonyl derivative, using *p*-toluenesulfonic anhydride alone or in presence of bases like dimethylamine, were unsuccessful. Likewise, only the 2-*O*-methylsulfonyl derivative XI could be isolated, besides the dimesyl derivative X from the reaction of I with methanesulfonyl anhydride. In the latter case, the yields in crystalline material were much lower than when using methanesulfonyl chloride and in this case substitution of the anhydride for the chloride had not the advantage found by Linstead, Owen and Webb.[9]

Esterification with acid chlorides took place in position 2, as reported previously. However, acetylation with acetyl chloride did not afford a good yield in crystalline material and the best yield of 2-*O*-acetyl derivative III was obtained when the reaction was carried out at room temperature with acetic anhydride in presence of pyridinium chloride. From III, the 3-*O*-benzoyl VIII, the 3-*O*-methylsulfonyl XIV and 3-*O*-*p*-tolysulfonyl XX derivatives were obtained.

The best yield in 2-*O*-benzoyl derivative VI was

CH_3COCl	1.25	0	0	23	16		3
C_6H_5COCl	1.25[a]	0	0	35	24	6	12
CH_3SO_2Cl	1.1	0	20–30	16	68		

Reaction time one day, except for experiments marked [a] five days. [b] Crude material.

obtained when the reaction was started at −10°, carried out for some time at 0°, and finally at room temperature. Starting from VI, the 3-*O*-acetyl IX, 3-*O*-methylsulfonyl XV and 3-*O*-*p*-tolysulfonyl XXXI derivatives were prepared in an almost quantitative yield.

Methanesulfonylation was carried out with methanesulfonyl chloride added at 0° and the reaction left to proceed at room temperature. The results were very similar to the ones obtained by Bolliger and Prins[7] in the *p*-toluenesulfonylation procedure. Starting from the 2-*O*-methylsulfonyl derivatives XI, the 3-*O*-acetyl XIII and 3-*O*-benzoyl XIII derivatives were prepared in almost theoretical yield.

Bourne and co-workers[3,4] concluded that the 3-*O*-acetyl, 3-*O*-benzoyl and 3-*O*-trifluoroacetyl derivatives of I were stable, though the 2-*O*-*p*-tolylsulfonyl ester is formed preferentially. However, this finding was based on a reaction carried out in strongly alkaline aqueous solution. In dry or wet pyridine, the 2-benzoyl derivative was stable.

The experiments described here show that the relative reactivity of the positions 2 and 3 of I greatly depends on the number of protons present in the reaction medium, either by external addition, or by release during the reaction. When formed, the esters are stable under the conditions of the reaction, as no migrations of the 2-benzoyl under the action of pyridine,[4] or of the 3-acetyl under the action of pyridinium chloride are observed. However, displacement of the less stable ester by a competing grouping was observed in the isolation of some methyl 2-*O*-*p*-tolylsulfonyl-3-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucoside (XX) after reaction of methyl 2-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucoside (III), with *p*-toluenesulfonyl chloride. This result does not support Bourne's suggestion that acetic anhydride in presence of pyridine causes migration of ester whereas *p*-toluenesulfonyl chloride in the same medium is without effect. While displacement was observed with the latter reagent, as described above, no migration was ever seen during acetylation of the 2-*O*-benzoyl VI and 3-*O*-benzoyl VII derivatives.

While the influence of the other groupings (methyl and benzylidene) on the difference in reactivity of positions 2 and 3 cannot be estimated alone, conformation plays certainly a role. This is shown by the isolation in preponderant yield of the 3-*O*-*p*-tolylsulfonyl and 3-*O*-benzoyl esters after reaction of methyl 4,6-*O*-benzylidene-α-D-galactopyranoside with *p*-toluenesulfonyl chloride and benzoyl chloride respectively,[10] whereas benzoylation of methyl 4,6-*O*-benzylidene-α-D-altropyranoside with benzoic anhydride[2] gave only the 2-*O*-benzoyl derivative.

Studies on a number of different carbohydrates besides glucose, using a variety of conditions, should be undertaken before general concepts are evolved.

Experimental[12]

Acetylation of Methyl 4,6-*O*-Benzylidene-α-D-glucopyranoside (I) with Acetic Anhydride.—To a solution of 10.0 g. of I in 20 ml. of anhydrous pyridine was added 4.2 ml. (1.25 moles) of acetic anhydride. After standing at room temperature for 24 hours, ice was added and the mixture extracted with chloroform. The organic phase was washed five times with ice-cold 2 *N* sulfuric acid, three times with saturated sodium bicarbonate and then water, and dried over sodium sulfate. After evaporation *in vacuo*, the resulting partially crystalline sirup (12.2 g.) was dissolved in benzene, an equal volume of hexane added, and chromatographed on 250 g. of silicic acid. A mixture of benzene and ether 19:1 eluted methyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside (II). After recrystallization, it melted at 109–110°, showing a rotation of $[\alpha]^{24}D$ +72 ± 1° (in chloroform, *c* 1.04)[13] and weighed 3.36 g. (26%).

A mixture of benzene and ether 9:1 eluted 0.30 g. (3%) of a crystalline mixture in which methyl 2-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside (III) (see below) was predominant. Mixtures of benzene and ether 4:1, 2:1, 1:1 and pure ether, eluted **methyl 3-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside (IV).** Crystallization from a mixture of acetone, ether and pentane gave 4.78 g. (42%) of silk-like needles, m.p. 176–177°, $[\alpha]^{23}D$ +114 ± 1° (in chloroform, *c* 0.57).[15] *Anal.* Calcd. for $C_{16}H_{20}O_7$: C, 59.25; H, 6.22. Found: C, 58.95; H, 5.94.

Mixtures of methanol and ether eluted the starting material. After recrystallization, 0.71 g. (7%) was obtained, m.p. 163–165°, showing no depression in admixture with authentic material.

Acetylation of I with Acetyl Chloride.—To a solution of 2.0 g. of I in 5 ml. of anhydrous pyridine was added at 0° 0.63 ml. (1.25 moles) of acetyl chloride. After standing overnight at 0°, the mixture was extracted and purified as described above. After chromatography and crystallization, 0.73 g. (23%) of diacetyl derivative II was obtained and 0.06 g. (3%) of starting material. Elution with mixtures of ether and benzene 4:1 and 2:1 gave crystalline fractions of **methyl 2-*O*-acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside (III).** After crystallization from a mixture of ether and pentane, 0.37 g. (16%) of prismatic needles were obtained, m.p. 133–134°, $[\alpha]^{26}D$ +106 ± 2° (in chloroform, *c* 1.27).[15] *Anal.* Calcd. for $C_{16}H_{20}O_7$: C, 59.25; H, 6.22. Found: C, 59.17; H, 6.22.

Acetylation of I with Acetic Anhydride in Presence of Pyridinium Chloride.—To a solution of 1 ml. of anhydrous pyridine in 20 ml. of dry ether was added dry hydrochloric acid to saturation. After removal of the ether and excess hydrochloric acid, 20 ml. of anhydrous pyridine and 2.0 g. of I were added. After dissolution and cooling at 0°, 0.70 ml. (1.05 moles) of acetic anhydride was added and the solution left at room temperature overnight. After addition of ice, the reaction was worked as described above. The recrystallized 2,3-diacetyl II, 2-acetyl III, 3-acetyl IV derivatives and starting material I were recovered in 21, 30, 5 and 16% yields, respectively.

Benzoylation of I with Benzoyl Chloride.—To a solution of 5.0 g. of I in 5 ml. of anhydrous pyridine cooled at 0° was added slowly 2.0 ml. (1.25 moles) of cooled benzoyl chloride. The solution was left at 0° overnight, and, after addition of ice, was extracted as described above. The residual sirup (7.0 g.) was dissolved in benzene, four volumes of hexane were added, and the solution chromatographed on 200 g. of alumina. Pure benzene and mixtures of benzene and ether, 99:1, 49:1, 19:1 and 9:1, eluted crystalline fractions, which gave after crystallization from a mixture of acetone, ether and pentane 3.00 g. (35%) of methyl 2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (V), m.p. 154°, $[\alpha]^{26}D$ +94 ± 2° (in chloroform, *c* 1.51),[17] and showing no depression in admixture with authentic material.

Mixtures of benzene and ether 4:1, 2:1, 1:1 and pure ether eluted crystalline fractions; crystallization from a mixture of acetone, ether and pentane gave 1.63 g. (24%) of prismatic needles of **methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (VI)**, m.p. 169–170° (moistening at 165°), $[\alpha]^{26}D$ +111 ± 2° (in chloroform, *c* 1.64).[18] *Anal.* Calcd. for $C_{21}H_{22}O_7$: C, 65.28; H, 5.74. Found: C, 65.22; H, 5.79. Pure ether, mixtures of ether and ethyl acetate and pure ethyl acetate eluted 3-*O*-benzoyl derivative VII. After crystallization from a mixture of acetone, ether and pentane, 0.42 g. (6%) was isolated, melting at 218–219° and showing no depression with the product isolated below.

Mixtures of ethyl acetate and methanol eluted 0.60 g. (12%) of crude crystalline starting material.

The same reaction was carried out in mixing a solution of 10.0 g. of I in 10 ml. of anhydrous pyridine with a solution of 4.1 ml. of benzoyl chloride (1.0 moles) in 10 ml. of anhydrous pyridine, both previously cooled to −10°. After a few hours at 0°, and overnight at room temperature, the mixture was worked out as described above: 2.15 g. (12%) of crystalline V, 5.90 g. (43%) of crystalline VI, 1.70 g. (8%) of crystalline VII and 2.20 g. (22%) of crystalline starting material was obtained.

Benzoylation of I with Benzoic Anhydride.—A solution of 2.0 g. of I and 1.80 g. (1.1 moles) of benzoic anhydride in 10 ml. of anhydrous pyridine was heated at 50° for 24 hours under moisture protection. After cooling, the mixture was purified by extraction and chromatography, as previously described. After elution of 0.76 g. (22%) of crystallized dibenzoate V and 0.34 g. (12%) of crystallized 2-*O*-benzoyl derivative VI, crystalline fractions were eluted and gave, after crystallization from a mixture of acetone, ether and pentane, 0.61 g. (22%) of **methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (VII)** as long needles, m.p. 219–220°, $[\alpha]^{26}D$ + 34 ± 1° (in chloroform, *c* 1.10).[19] *Anal.* Calcd. for $C_{21}H_{22}O_7$: C, 65.28; H, 5.74. Found: C, 65.13; H, 5.60. In addition, 0.30 g. (15%) of crude starting material was recovered.

When the reaction was carried out at 70°, the yields obtained were approximately the same, whereas at room temperature (25–30°), 9% of V, 13% of VI, 25% of VII and 23% of I were obtained after crystallization.

Methanesulfonylation of I with Methanesulfonyl Chloride.—To a solution of 5.0 g. of I in 15 ml. of anhydrous pyridine, was added a solution of 1.75 ml. (1.3 moles) of methanesulfonyl chloride in 15 ml. of anhydrous pyridine. Both solutions had been previously cooled at 0°. After standing at room temperature for 24 hours, a small amount of ice was added and after 2 hours the solution was extracted with chloroform as described above. The residual sirup (7.15 g.) gave, after crystallization from a mixture of acetone, ether and pentane, 1.75 g. of **methyl 4,6-*O*-benzylidene-2-*O*-methylsulfonyl-α-D-glucopyranoside (XI)**, as prismatic needles, m.p. 135–136°, $[\alpha]^{24}D$ +73 ± 1° (in chloroform, *c* 2.22).[20] *Anal.* Calcd. for $C_{15}H_{20}O_8S$: C, 49.99; H, 5.59; S, 8.90. Found: C, 49.91; H, 5.67; S, 8.92.

The mother liquors dissolved in a 1:1 mixture of hexane and benzene were chromatographed on silicic acid. A 1:1 mixture of benzene and ether eluted 1.50 g. of sirupy **methyl 4,6-*O*-benzylidene-2,3-di-*O*-methylsulfonyl-α-D-glucopy-**

(12) R. W. Jeanloz, THIS JOURNAL, **76**, 555 (1954). "Silica Gel Davison" grade 923; 100–200 mesh was replaced by the less expensive grade 950; 60–200 mesh, without noticeable change in adsorption. In order to obtain good separations, a fully activated silicic acid was found necessary. When deactivation by contact with moist air occurred, reactivation was obtained by heating to 170–200° (Manufacturer's instructions). The proportion of weight of substance to be adsorbed to weight of adsorbent was 1 to 20–30 for alumina, and 1 to 50–100 for silicic acid. The proportion of weight of substance in g. to volume of fraction of eluent in ml. was 1 to 100. The ratio of diameter to length of the column was 1 to 5 for alumina and 1 to 20 for silicic acid.

(13) Mathers and Robertson[14] reported m.p. 108–109°, $[\alpha]D$ +75.5° (in chloroform).

(14) D. S. Mathers and G. J. Robertson, *J. Chem. Soc.*, 696 (1933).

(15) Bourne, *et al.*,[4] reported m.p. 174°, $[\alpha]^{14}D$ +110° (in chloroform).

(16) Bourne, *et al.*,[4] reported m.p. 133–134°, $[\alpha]^{19}D$ +112° (in chloroform, *c*, 0.86).

(17) Bourne, *et al.*,[4] reported m.p. 151–152°; Ohle and Spencker[6] m.p. 148°, $[\alpha]^{19}D$ +96.81° (in chloroform, *c*, 2.828).

(18) Bourne, *et al.*,[4] reported m.p. 165–166°, $[\alpha]^{21}D$ +109.5° (in chloroform, *c* 2.09).

Digitized by Arya Samaj Foundation Chennai and eGangotri

ranoside (X), which crystallized after a few days. Crystallization from a mixture of acetone, ether and pentane gave 1.22 g. (16%) of stout prisms, m.p. 188–190°, $[\alpha]^{26}D$ +49 ± 1° (in chloroform, *c* 1.46).[21] *Anal.* Calcd. for $C_{16}H_{22}O_{16}S_2$: C, 43.83; H, 5.02; S, 14.63. Found: C, 43.97; H, 5.18; S, 14.54.

Elution with a mixture of benzene and ether gave, after recrystallization, an additional crop of methyl 4,6-*O*-benzylidene-2-*O*-methylsulfonyl-α-D-glucopyranoside, 2.63 g., total yield 4.38 g. (68%).

Methanesulfonylation of I with Methanesulfonyl Anhydride.—To a solution of 500 mg. of I in 15 ml. of anhydrous dichloroethane was added 340 mg. (1.1 moles) of methanesulfonyl anhydride.[22] After cooling at 0°, 3 ml. of anhydrous pyridine was added and the mixture was left standing at 0° overnight. Ice was added and the solution was extracted with chloroform and purified by chromatography on silicic acid as previously described. Elution with 9:1 mixtures of benzene and ether gave methyl 4,6-*O*-benzylidene-2,3-di-*O*-methylsulfonyl-α-D-glucopyranoside (X), which after recrystallization from a mixture of acetone, ether and pentane weighed 45 mg. (6%), m.p. 186–188°, $[\alpha]^{24}D$ +51 ± 2° (in chloroform, *c* 1.33), and showed no depression in admixture with the product described above. Elution with mixtures of benzene and ether 4:1 gave 280 mg. of methyl 4,6-*O*-Benzylidene-2-*O*-methylsulfonyl-α-D-glucopyranoside (XI). After recrystallization from a mixture of acetone, ether and pentane, 255 mg. (40%) was obtained, m.p. 133–134°, $[\alpha]^{26}D$ +73 ± 2° (in chloroform, *c* 1.38). It showed no depression with the product described above. Elution with a mixture of ether and methanol 19:1 gave the starting material (15 mg., 3%, after recrystallization).

When mixing took place at 0°, and the reaction carried out at room temperature for 5 days, the yields were 8% for X, 34% for XI and 4% for the starting material. When the reaction was carried out in an excess of pyridine as solvent, extensive decomposition occurred at room temperature; when the mixture was made at −20° and the reaction carried out at 0° for 4 days, only slight decomposition occurred and the yields were 36% for X, 5% for XI and 22% for the starting material.

***p*-Toluenesulfonylation of I with *p*-Toluenesulfonic Anhydride.**—To a solution of 200 mg. of I in 2 ml. of anhydrous pyridine was added 280 mg. of *p*-toluenesulfonic anhydride (1.1 moles).[23] After standing at room temperature overnight and after addition of ice, the mixture was handled as previously described. Besides the 2,3-ditosyl derivative XVI isolated in a 15% crude yield, only methyl 4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (XVII) (crude yield 80–85%) could be obtained after recrystallization, melting at 151–153°[24] and not showing a depression in admixture with authentic material.

Attempts at *p*-toluenesulfonylation with *p*-toluenesulfonic anhydride in the presence of ethylamine, in pyridine or dichloroethane solution, were unsuccessful.

Methyl 2-*O*-Acetyl-3-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (VIII) from III.—To a solution of 105 mg. of III in 2 ml. of anhydrous pyridine cooled at −20° was added 0.055 ml. (1.5 moles) of benzoyl chloride. After standing overnight at 0° and 2 hours at room temperature, ice was added and the mixture handled as previously described. The crystalline residue was crystallized from a mixture of ether and pentane to give 133 mg. (95%) of typical rectangular or hexagonal prisms, m.p. 154–155°, $[\alpha]^{25}D$ +24 ± 2° (in chloroform, *c* 1.39). *Anal.* Calcd. for $C_{23}H_{24}O_8$: C, 64.48; H, 5.65. Found: C, 64.33; H, 5.79.

From VII.—To a solution of 100 mg. of VII in 1 ml. of pyridine was added 0.5 ml. of acetic anhydride. After standing overnight at room temperature, the mixture was worked up as usual and gave 106 mg. (95%) of prisms, m.p. 153–154°, showing no depression with the compound described above.

Methyl 3-*O*-Acetyl-2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (IX).—A solution of 100 mg. of VI in 1 ml. of anhydrous pyridine was treated with 0.05 ml. of acetic anhydride overnight at room temperature. After the usual work-up, crystallization from a mixture of ether and pentane gave 106 mg. (95%) of needles, m.p. 110–112°, $[\alpha]^{21}D$ +118 ± 2° (in chloroform, *c* 0.69). *Anal.* Calcd. for $C_{23}H_{24}O_8$: C, 64.48; H, 5.65. Found: C, 64.44; H, 5.71.

Methyl 3-*O*-Acetyl-4,6-*O*-benzylidene-2-*O*-methylsulfonyl-α-D-glucopyranoside (XII) from XI.—A solution of 0.75 g. of XI in 2.5 ml. of anhydrous pyridine was treated for one day at room temperature with 1.0 ml. of acetic anhydride. After the usual work-up, crystallization from a mixture of ether and pentane gave 0.79 g. (94%) of prismatic needles, m.p. 125–126°, $[\alpha]^{21}D$ +59 ± 1° (in chloroform, *c* 3.32). *Anal.* Calcd. for $C_{17}H_{22}O_9S$: C, 50.74; H, 5.51. Found: C, 50.29; H, 5.81.

From IV.—To a solution of 1.5 g. of IV in 5 ml. of anhydrous pyridine was added a solution of 0.5 ml. (1.4 moles) of methanesulfonyl chloride in 5 ml. of pyridine, both solutions previously having been cooled at 0°. After standing at room temperature overnight, the mixture was handled as previously described. Crystallization from a mixture of ether and pentane gave 1.82 g. (98%) of needles, m.p. 125–126°, showing no depression in admixture with the material described above.

Methyl 3-*O*-Benzoyl-4,6-*O*-benzylidene-2-*O*-methylsulfonyl-α-D-glucopyranoside (XIII).—To a solution of 0.94 g. of XI in 3 ml. of anhydrous pyridine cooled at 0° was added 0.45 ml. (1.5 moles) of benzoyl chloride. After standing for one day at 0°, the mixture treated as usual, gave after crystallization from a mixture of acetone, ether and pentane, 1.14 g. (94%) of prismatic needles, m.p. 174–175°, $[\alpha]^{21}D$ +39 ± 2° (in chloroform, *c* 2.13). *Anal.* Calcd. for $C_{22}H_{24}O_9S$: C, 56.89; H, 5.21. Found: C, 56.75; H, 5.09.

Methyl 2-*O*-Acetyl-4,6-*O*-benzylidene-3-*O*-methylsulfonyl-α-D-glucopyranoside (XIV).—To a solution of 0.50 g. of III in 5 ml. of anhydrous pyridine cooled at 0° was added 0.2 ml. (1.4 moles) of methanesulfonyl chloride. After standing at room temperature for a day, the mixture was treated as usual. Crystallization from a mixture of ether and pentane gave 0.59 g. (95%) of elongated prisms, m.p. 150–151°, $[\alpha]^{24}D$ +71 ± 2° (in chloroform, *c* 1.15). *Anal.* Calcd. for $C_{17}H_{22}O_9S$: C, 50.74; H, 5.51; S, 7.97. Found: C, 50.90; H, 5.67; S, 7.80.

Methyl 2-*O*-Benzoyl-4,6-*O*-benzylidene-3-*O*-methylsulfonyl-α-D-glucopyranoside (XV).—To a solution of 825 mg. of VI in 3 ml. of anhydrous pyridine previously cooled to 0° was added 0.23 ml. (1.4 moles) of methanesulfonyl chloride. After standing overnight at room temperature, the mixture was worked up as usual. Crystallization from a mixture of acetone, ether and pentane gave 930 mg. (94%) of prismatic needles, m.p. 169–171°, $[\alpha]^{26}D$ +123 ± 2° (in chloroform, *c* 1.06). *Anal.* Calcd. for $C_{22}H_{24}O_9S$: C, 56.89; H, 5.21; S, 6.90. Found: C, 56.93; H, 5.35; S, 6.97.

Methyl 3-*O*-Acetyl-4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (XVIII) from XVII.—A solution of 1.0 g. of XVII in 2.5 ml. of anhydrous pyridine was treated overnight at room temperature with 1.0 ml. of acetic anhydride. After addition of ice and extraction with chloroform, as previously described, crystallization from a mixture of acetone, ether and pentane gave 1.03 g. (95%) of shiny platelets, m.p. 161–162° (moistening at 158°), $[\alpha]^{26}D$ +50 ± 1° (in chloroform, *c* 2.20).[25]

From IV.—To a solution of 1.5 g. of IV in 5 ml. of anhydrous pyridine was added a solution of 1.25 g. of *p*-toluenesulfonyl chloride in 5 ml. of pyridine, both solutions having previously been cooled to 0°. After standing one day at room temperature, ice was added and the product isolated as previously described. Crystallization from a mixture of acetone, ether and pentane gave 2.17 g. (97%) of shiny platelets, m.p. 160–161°, and not showing a depression in admixture with the product described above.

***p*-Toluenesulfonylation of Methyl 2-*O*-Acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside (III).**—To a solution of 500 mg. of III in 5 ml. of anhydrous pyridine previously cooled at 0° was added 400 mg. (1.3 moles) of *p*-toluenesulfonyl chloride. After standing at room temperature for one week, the mixture was worked up as usual. The residual sirup was dissolved in benzene, an equal volume of hexane was added, and the solution was chromatographed on 20 g. of

(21) Honeyman and Morgan[3] reported m.p. 188–189°, $[\alpha]^{20}D$ +49° (in chloroform, *c* 1.4).

alumina. Mixtures of benzene and ether 19:1 and 9:1 eluted crystalline fractions. Crystallization from a mixture of acetone, ether and pentane gave 485 mg. (66%) of methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (XX), as stout prisms, m.p. 124–125°, $[\alpha]^{24}D$ +26 ± 2° (in chloroform, *c* 0.51).[26] *Anal.* Calcd. for $C_{28}H_{28}O_8S$: C, 57.73; H, 5.48; S, 6.70. Found: C, 57.93; H, 5.58; S, 6.53. From the mother liquors, 8 mg. (1%) of shiny platelets, m.p. 157–159°, were obtained. In admixture with methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (XVIII) described above no depression of the m.p. was observed.

Elution with 4:1, 2:1 and 1:1 mixtures of ether and benzene gave crystalline fractions. After crystallization from a mixture of acetone, ether and pentane, 125 mg. (25%) was obtained, melting at 133–134° and showing no depression in admixture with the starting material.

Action of Pyridinium Chloride on Methyl 3-*O*-Acetyl-4,6-*O*-benzylidene-α-D-glucopyranoside (IV).—A solution of 0.1 ml. of anhydrous pyridine in 5 ml. of dry ether was saturated with dry hydrogen chloride. After removal of the ether and excess hydrogen chloride, 5 ml. of anhydrous pyridine and 200 mg. of IV were added. After one day at room temperature, ice was added and the product was isolated as described above. Recrystallization from a mixture of ether and pentane gave 190 mg. (95%) of starting material, m.p. 176–177°.

Acknowledgments.—The authors wish to thank Mrs. Shirley Butterworth and Miss Anne Foley, for technical assistance.

BOSTON, MASS.

(26) Bourne, *et al.*,[3] reported a yield of 49%, m.p. 120–121°, $\alpha^{23}D$ +23.1° (in chloroform, *c* 0.78).

4-*O*-Methyl-D-glucosamine Hydrochloride (2-Amino-2-deoxy-4-*O*-methyl-D-glucose Hydrochloride)[1]

BY ROGER W. JEANLOZ AND CHARLES GANSSER[2]

RECEIVED DECEMBER 17, 1956

The synthesis of 4-*O*-methyl-D-glucosamine hydrochloride (2-amino-2-deoxy-4-*O*-methyl-D-glucose hydrochloride), a reference substance for structural studies of glucosamine-containing substances, is described. It was obtained in a sirupy state, starting from methyl 2-acetamido-2-deoxy-6-*O*-triphenylmethyl-α-D-glucopyranoside and from methyl 2-acetamido-3-*O*-tolylsulfonyl-α-D-glucopyranoside. It was transformed into the crystalline *N*-acetyl and *N*-(2′-hydroxynaphthylidene) derivatives.

In a previous paper[3] describing the methylation of methyl 2-acetamido-2-deoxy-6-*O*-triphenylmethyl-α-D-glucopyranoside (IV), a crystalline compound was isolated in addition to the known methyl 2-acetamido-2-deoxy-3-*O*-methyl-6-*O*-triphenylmethyl-α-D-glucopyranoside and methyl 2-acetamido-2-deoxy-3,4-di-*O*-methyl-6-*O*-triphenylmethyl-α-D-glucopyranoside. The structure of a methyl 2-acetamido-2-deoxy-4-*O*-methyl-6-*O*-triphenylmethyl-α-D-glucopyranoside (III) was ascribed to this product on the basis of its elementary analysis, of its mode of preparation, and because it was possible to prepare a monoacetyl derivative. It was of interest to ascertain this structure by an independent synthesis and at the same time synthesize the still unknown 4-*O*-methyl-D-glucosamine hydrochloride (VII), to complete the series of the known monomethyl derivatives of 2-amino-2-deoxy-D-glucopyranose.

The first attempt to obtain a 4-*O*-methyl-derivative, using as starting material a compound in which positions 3 and 6 were protected during methylation by methylsulfonyl groups, was unsuccessful, because such groupings could not be removed subsequently by reductive splitting.[4]

Another experiment in which the methylation of the methyl 2-acetamido-2-deoxy-3-*O*-*p*-tolylsulfonyl-6-*O*-triphenylmethyl derivative was attempted did not give conclusive results (see Experimental part).

Finally, the following route as shown in the accompanying diagram was successful: Controlled *p*-toluenesulfonylation of methyl 2-acetamido-2-deoxy-3-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (I)[5] gave, in excellent yield, the sirupy 3,6-di-*O*-*p*-tolylsulfonyl derivative II, characterized by a crystalline 4-*O*-acetyl derivative. Methylation with methyl iodide and silver oxide produced the sirupy 4-*O*-methyl derivative V. It was purified from the starting material by acetylation followed by chromatography. Although this product could not be obtained in crystalline form, and showed a rotation slightly different from the rotation of the product prepared by *p*-toluenesulfonylation of methyl 2-acetamido-2-deoxy-4-*O*-methyl-α-D-glucopyranoside (VI), it analyzed correctly and was used as such. Splitting of the *p*-tolylsulfonyl groups was accomplished by reduction and afforded in a 73% yield a crystalline methyl 2-acetamido-2-deoxy-4-*O*-methyl-α-D-glucopyranoside (VI) identical in all respects with the crystalline product obtained by weak acid hydrolysis of methyl 2-acetamido-2-deoxy-4-*O*-methyl-6-*O*-triphenylmethyl-α-D-glucopyranoside (III). Additional evidence for the identity of both compounds was obtained

by preparing III using as starting material the glycoside VI obtained through the route of the *p*-tolylsulfonyl derivatives. Attempts to characterize VI in preparing a crystalline 3,6-*O*-diacetyl derivative, were unsuccessful. Two different methods of preparation gave sirupy products, showing an identical rotation but with quite incorrect elementary analysis. The synthesis of methyl 2-acetamido-2-deoxy-3,4-6-tri-*O*-methyl-α-D-glucopyranoside[3,6] starting from VI showed that no shifting of the ring had occurred during methylation. Hydrolysis of VI gave the sirupy 2-amino-2-deoxy-4-*O*-methyl-D-glucosamine hydrochloride (VII), which was transformed into the crystalline N-acetyl (VIII) and N-(2′-hydroxynaphthylidene) (IX) derivatives.

Experimental[7]

Methyl 2-Acetamido-2-deoxy-4-*O*-methyl-α-D-glucopyranoside (VI) from III.—A solution of 105 mg. of methyl 2-acetamido-2-deoxy-4-*O*-methyl-6-*O*-triphenylmethyl-α-D-glucopyranoside (III)[3] in 4 ml. of glacial acetic acid was heated on the water-bath and 3 ml. of water was added dropwise. After one hour, the solution was cooled and diluted with 15 ml. of water. The triphenylcarbinol (47 mg.) was filtered off and the solution evaporated to dryness *in vacuo*. The crystalline residue, recrystallized from cold ethanol and from a mixture of ethanol and ether gave 43 mg. (85%) of elongated needles, m.p. 232–233°, $[\alpha]^{24}D$ +158 ± 5° (in methanol, *c* 0.58). *Anal.* Calcd. for $C_{10}H_{19}O_6N$: C, 48.18; H, 7.68. Found: C, 48.06; H, 7.84.

Methyl 2-Acetamido-2-deoxy-3,6-di-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (II).—To a solution of 500 mg. of methyl 2-acetamido-2-deoxy-3-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside[5] (I), in 1.5 ml. of dry pyridine was added 280 mg. (1.15 moles) of *p*-toluenesulfonyl chloride dissolved in 2.5 ml. of dry pyridine, both solutions having previously been cooled at −20°. The solution was kept at 0° overnight and at room temperature for one day; then the excess chloride was decomposed by addition of ice and the solution extracted with chloroform. The chloroform layer was washed three times each with ice-cold water, ice-cold 2 *N* sulfuric acid, saturated sodium bicarbonate solution, and water, dried over sodium sulfate and evaporated *in vacuo*. The residue was chromatographed on silicic acid. Elution with mixtures of ether and ethyl acetate afforded a quantitative yield of II as a colorless sirup; $[\alpha]^{24}D$ +62 ± 2° (in chloroform, *c* 1.30). *Anal.* Calcd. for $C_{23}H_{29}O_{10}NS_2$: C, 50.82; H, 5.38; S, 11.80. Found: C, 50.98; H, 5.50; S, 11.66.

Acetylation of 82 mg. of II with acetic anhydride and pyridine in the usual manner gave the 4-*O*-acetyl derivative which was purified by chromatography on silicic acid. Elution with pure ether and mixtures of ether and ethyl acetate gave crystalline fractions which after recrystallization from a mixture of acetone, ether and pentane afforded 62 mg. (80%) of prisms, m.p. 142°, $[\alpha]^{21}D$ +78 ± 2° (in chloroform, *c* 0.96). *Anal.* Calcd. for $C_{25}H_{31}O_{11}NS_2$: C, 51.27; H, 5.34. Found: C, 51.41; H, 5.47.

Methyl 2-Acetamido-2-deoxy-4-*O*-methyl-3,6-di-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside (V) from II.—Five hundred and five milligrams of II was refluxed for one day with 10 ml. of methyl iodide and 300 mg. of silver oxide; after another addition of 200 mg. of silver oxide, reflux was continued for another day. The silver residue was filtered and washed exhaustively with acetone, and the filtrate, evaporated *in vacuo*, was dissolved in benzene and chromatographed on silicic acid. Elution with mixtures of ether and ethyl acetate gave 430 mg. of a hygroscopic sirup. It was acetylated with acetic anhydride and pyridine in the usual manner to transform the unreacted II into its crystalline 4-*O*-acetyl derivative. After repeated evaporation *in vacuo* with toluene the remaining sirup was chromatographed on silicic acid. Elution with mixtures of ether and ethyl acetate (9:1 and 4:1) gave 412 mg. (80%) of V, as a colorless glass, $[\alpha]^{24}D$ +75 ± 2° (in chloroform, *c* 1.10). *Anal.* Calcd. for $C_{24}H_{31}O_{10}NS_2$: C, 51.69; H, 5.60; OCH_3, 11.13. Found: C, 51.60; H, 5.77; OCH_3, 11.04. The crystalline acetyl derivative of II was eluted with a mixture of ether and ethyl acetate 2:1.

From VI.—To a solution of 48 mg. of VI in 0.5 ml. of anhydrous pyridine was added 120 mg. of *p*-toluenesulfonyl chloride. After standing one day at 0° and another day at room temperature, ice was added and the solution was extracted with chloroform. The extract was washed with 2 *N* sulfuric acid, then with saturated sodium bicarbonate, and water and was dried over sodium sulfate. After removal of the solvent by distillation *in vacuo*, the sirupy residue was chromatographed on silicic acid. Elution with mixtures of benzene and ether afforded a first peak of substance, weighing 21 mg. (19%) which could not be induced to crystallize; $[\alpha]^{26}D$ +68 ± 2° (in chloroform, *c* 2.09). *Anal.* Calcd. for $C_{24}H_{31}O_{10}NS_2$: C, 51.69; H, 5.60; S, 11.33. Found: C, 51.99; H. 5.44; S, 11.33. The more polar fractions, some being partially crystalline, were not further investigated.

Methyl 2-Acetamido-2-deoxy-4-*O*-methyl-α-D-glucopyranoside (VI) from V.—To a solution of 275 mg. of V in 10 ml. of 0.05% methanolic sodium amalgam was added 4 g. of 2.5% sodium amalgam was

added and the mixture was shaken overnight. After addition of water, the solution was saturated with carbon dioxide, the mercury was filtered off through a layer of Celite and Darco G-60, and washed with methanol. The filtrate was evaporated to dryness *in vacuo*, dried by co-distillation with dry toluene, and the residue was extracted with acetone. After evaporation *in vacuo*, the crystalline residue was recrystallized from a mixture of methanol and ether, affording 90 mg. (73%) of prismatic needles, m.p. 232–233°, $[\alpha]^{22}D$ +157 ± 2° (in methanol, *c* 1.16). *Anal.* Calcd. for $C_{10}H_{19}O_6N$: C, 48.18; H, 7.68; OCH_3, 24.90. Found: C, 48.05; H, 7.60; OCH_3, 24.69. In admixture with the material described above, the m.p. was not depressed.

Acetylation of 50 mg. of VI with acetic anhydride and pyridine in the usual manner, gave, after chromatography on silicic acid, 58 mg. (87%) of the **3,6-di-*O*-acetyl** derivative as a homogeneous peak, eluted with mixtures of chloroform and ether. It failed to crystallize and showed $[\alpha]^{25}D$ +79 ± 2° (in chloroform, *c* 2.93). *Anal.* Calcd. for $C_{14}H_{21}O_8N$: C, 50.44; H, 6.96. Found: C, 51.27; H, 6.85.

Acetylation of 50 mg. of VI was carried out by heating with 2 ml. of acetic anhydride and 100 mg. of fused sodium acetate for 4 hours on the water-bath. After dilution with water, the solution was extracted with chloroform. After washing with water, the extract was dried over sodium sulfate, the solvent was removed by distillation *in vacuo* and the residue chromatographed on silicic acid, as described above. A quantitative yield of the sirupy **3,6-di-*O*-acetyl** derivative was obtained, $[\alpha]^{25}D$ +77 ± 2° (in chloroform, *c* 2.22). *Anal.* Calcd. for $C_{14}H_{23}O_8N$: C, 50.44; H, 6.96. Found: C, 51.43; H, 7.20.

Methylation of VI with dimethyl sulfate and sodium hydroxide[8] in the usual manner gave the methyl 2-acetamido-2-deoxy-3,4,6-tri-*O*-methyl-α-D-glucopyranoside. Purification was obtained by chromatography on silicic acid. Elution with mixtures of acetone and methanol (19:1) afforded a crystalline material. On recrystallization from a mixture of chloroform and pentane, long prismatic needles were obtained (yield about 40%), m.p. 166–168° (sublimation at 150°) $[\alpha]^{20}D$ +122 ± 4° (in chloroform, *c* 2.23). In admixture with authentic material,[3,6] the m.p. was not depressed.

Methyl 2-Acetamido-2-deoxy-4-*O*-methyl-6-*O*-triphenylmethyl-α-D-glucopyranoside (III) from VI.—A solution of 50 mg. of VI obtained from V and 115 mg. of triphenylchloromethane (2.0 equivalents) in 4.5 ml. of dry pyridine was left at 47° for 6 days. The pyridine was evaporated *in vacuo* at room temperature and the residue dried in a desiccator over calcium chloride and potassium hydroxide. After a new addition of 57 mg. of triphenylchloromethane (1.0 equivalent) and of 3.0 ml. of dry pyridine, the solution was left at 100° for four hours, the excess chloride decomposed by addition of ice and the solution extracted with chloroform. The chloroform layer was washed three times each with ice-cold saturated potassium bisulfate solution, sodium bicarbonate and water, dried over sodium sulfate and evaporated *in vacuo*. The residue was dissolved in benzene and chromatographed on silicic acid. Elution with mixtures of ethyl acetate and acetone afforded 36 mg. (36%) of crystalline fractions. Recrystallization from a mixture of acetone and ether gave 22 mg. (22%) of prisms (III), m.p. 210–212°, $[\alpha]^{24}D$ +59 ± 2° (in chloroform, *c* 0.81). In admixture with the material previously described[3] the m.p. was not depressed.

4-O-Methyl-D-glucosamine Hydrochloride (2-Amino-2-deoxy-4-O-methyl-D-glucose Hydrochloride) (VII).—A solution of 200 mg. of VI in 5 ml. of 3 *N* hydrochloric acid was heated for three hours on the steam-bath. After cooling it was diluted with 15 ml. of water, and the solution was evaporated *in vacuo*. The residue was dissolved in methanol, the solution was filtered through Celite and Darco G-60, and evaporated *in vacuo*. The colorless hygroscopic sirup (VII) was kept in a desiccator for several days over soda lime and obtained in a quantitative yield: $[\alpha]^{24}D$ +90 ± 2° (in water, *c* 1.70), $[\alpha]^{26}D$ + 108 ± 2° (in methanol, *c* 1.19). *Anal.* Calcd. for $C_7H_{16}O_5NCl$: C, 36.61; H, 7.02; Cl, 15.44; OCH_3, 13.51. Found: C, 36.43; H, 7.16; Cl, 15.30; OCH_3, 13.40.

2-Acetamido-2-deoxy-4-*O*-methyl-α-D-glucopyranose (VIII).—To a solution of 72 mg. of VII in 1 ml. of absolute methanol was added 58 mg. of silver acetate and 0.7 ml. of acetic anhydride. The mixture was left at 0° overnight, at room temperature for three hours, refluxed for five minutes, and filtered through Celite. The silver residue was washed with methanol and then with 1 ml. of hot water, and one drop of 0.1 *N* hydrochloric acid was added to the filtrate. After two hours the solution was filtered through Celite and Darco G-60 and the filtrate evaporated *in vacuo*. The residue was crystallized from a mixture of methanol and ether, and gave 41 mg. (56%) of prisms, m.p. 211–215° dec. The compound showed mutarotation from $[\alpha]^{24}D$ +79° (after 16 minutes) to $[\alpha]^{22}D$ +69 ± 2° (after 24 hours, in water, *c* 1.02). *Anal.* Calcd. for $C_9H_{17}O_6N$: C, 45.95; H, 7.28. Found: C, 45.77; H, 7.39.

2-Deoxy-2-(2′-hydroxynaphthylidenamino)-4-*O*-methyl-D-glucopyranose (IX).—A solution of 60 mg. of VII in 3 ml. of water was treated as previously described[3] with 110 mg. of 2-hydroxynaphthaldehyde and 30 mg. of sodium acetate trihydrate. The product was purified by chromatography on silicic acid. Elution with mixtures of ethyl acetate and acetone gave crystalline fractions. Recrystallization from a mixture of monomethyl glycol, methanol and ether gave 46 mg. (53%) of yellow, prismatic needles, m.p. 218–219° dec., $[\alpha]^{22}_{5461}$ +305 ± 10° (in methanol, at equilibrium, *c* 0.14). *Anal.* Calcd. for $C_{18}H_{21}O_6N$: C, 62.24; H, 6.09. Found: C, 62.28; H, 6.18.

Methyl 2-Acetamido-2-deoxy-3-*O*-*p*-tolylsulfonyl-6-*O*-triphenylmethyl-α-D-glucopyranoside.—To a solution of 550 mg. of methyl 2-acetamido-2-deoxy-3-*O*-*p*-tolylsulfonyl-α-D-glucopyranoside[5] (I) in 5 ml. of dry pyridine was added 400 mg. (1.05 moles) of triphenylchloromethane. After standing overnight at room temperature, the solution was heated at 100° for 2 hours. After cooling, ice was added, and the solution was extracted with chloroform. The organic phase was washed three times each, at 0° with a saturated solution of potassium bisulfate, at room temperature with a saturated solution of sodium bicarbonate and with water, then dried over sodium sulfate. After evaporation *in vacuo*, the residue was dissolved in benzene and chromatographed on silicic acid. Elution with mixtures of benzene and ether 2:1 and 1:1 and with pure benzene gave 600 mg. (67%) of a colorless sirup; $[\alpha]^{28}D$ +42 ± 2° (in chloroform, *c* 1.46). *Anal.* Calcd. for $C_{35}H_{37}O_8NS$: C, 66.54; H, 5.90; S, 5.08. Found: C, 66.43; H, 5.94; S, 5.24.

Acetylation of 43 mg. of the above sirup with acetic anhydride and pyridine in the usual manner gave, after purification by chromatography and recrystallization from a mixture of ether and pentane, 36 mg. (80%) of the **4-*O*-acetyl derivative**, as prismatic needles, m.p. 145–148°, $[\alpha]^{24}D$ +75 ± 3° (in chloroform, *c* 1.26). *Anal.* Calcd. for $C_{37}H_{39}O_9NS$: C, 65.95; H, 5.83; S, 4.76. Found: C, 66.04; H, 5.82; S, 4.92.

Attempts to methylate methyl 2-acetamido-2-deoxy-3-*O*-*p*-tolylsulfonyl-6-*O*-triphenylmethyl-α-D-glucopyranoside with methyl iodide and silver oxide gave only the starting material, identified by its crystalline 4-*O*-acetyl derivative.

Acknowledgment.—The authors wish to thank Mrs. Shirley Butterworth for her technical assistance.

BOSTON, MASS.

(8) Attempts with methyl iodide and silver oxide alone or in presence of dimethylformamide[9] gave unsatisfactory results.

3,4-Di-*O*-methyl-D-galactosamine Hydrochloride (2-Amino-2-deoxy-3,4-di-*O*-methyl-D-galactose Hydrochloride)[1,2]

BY ROGER W. JEANLOZ, DIETER M. SCHMID AND PIERRE J. STOFFYN

RECEIVED DECEMBER 17, 1956

The synthesis of 3,4-di-*O*-methyl-D-galactosamine hydrochloride (2-amino-2-deoxy-3,4-di-*O*-methyl-D-galactose hydrochloride), a reference substance for structural studies of galactosamine-containing substances, is described. It was prepared from 1,6:2,3-dianhydro-β-D-talopyranose, and was transformed into the crystalline *N*-acetyl and *N*-(2'-hydroxynaphthylidene) derivatives and into methyl 2-acetamido-2-deoxy-3,4-di-*O*-methyl-α-D-galactopyranoside. The latter compound was found identical to a similar product synthesized from the known methyl 2-acetamido-2-deoxy-α-D-galactopyranoside, prepared from D-galactosamine, obtained from a natural source.

Dimethyl derivatives of D-galactosamine are of special importance in the elucidation of the structure of derivatives of galactosamine isolated from natural sources, such as chondrosine,[3] and uridine diphosphate–acetylgalactosamine sulfate.[4] The synthesis of 4,6-di-*O*-methyl-D-galactosamine hydrochloride has been reported previously.[5,6] In this paper, the synthesis of a second dimethylgalactosamine, 3,4-di-*O*-methyl-D-galactosamine hydrochloride (XV), is described. Although the synthesis of 3,4-di-*O*-methyl-D-glucosamine hydrochloride successfully has been reported,[7] starting from D-glucosamine and using a 6-*O*-trityl derivative as an intermediate, an analogous synthesis in the galactosamine series was at first not considered, because of the unavailability of large amounts of D-galactosamine as starting material. Instead, the synthesis was started with a material obtained from lactose, which had been used for the preparation of 4-*O*-methyl-D-galactosamine hydrochloride, namely, 1,6:2,3-dianhydro-β-D-talose (II).[8]

The synthesis of the key compound, 2-acetamido-1,6-anhydro-2-deoxy-3,4-di-*O*-methyl-β-D-galactopyranose (VII), was investigated, using various intermediates and methylation procedures. In a first pathway, catalytic deacetylation of 2-acetamido-3,4-di-*O*-acetyl-1,6-anhydro-2-deoxy-β-D-galactopyranose[9] (VI) with barium methoxide gave 2-acetamido-1,6-anhydro-2-deoxy-β-D-galactopyranose (V). The same compound was obtained in acetylating 2-amino-1,6-anhydro-2-deoxy-β-D-galactopyranose (I), with acetic anhydride in methanol. Consideration of the spatial structure of 2-acetamido-1,6-anhydro-2-deoxy-β-D-galactopyranose shows that the hydroxyl in position 3 is in axial position and is considerably shielded by the 1,6-anhydro ring. Consequently, its reactivity is expected to be much lower than the reactivity of the vicinal equatorial group in position 4. This was indeed the case and methylation of the hydroxyl in position 3 was very slow.[10] From the treatment of V with methyl iodide and silver oxide, only the starting material could be recovered in crystalline form. Methylation in dimethylformamide solution[11] was not successful, no crystalline product being isolated. Methylation with methyl sulfate and sodium hydroxide afforded the best way to obtain, in a 35% yield, the dimethyl derivative VII, whereas the 4-*O*-methyl derivative VIII was isolated in a 40% yield. Direct methylation of the 3,4-di-*O*-acetyl derivative VI with methyl sulfate and sodium hydroxide did not proceed successfully and only 11% of the dimethyl derivative was obtained.

In the second pathway, methylation of 2-acetamido-1,6-anhydro-2-deoxy-4-*O*-methyl-β-D-galactose (VIII) and its 3-*O*-acetyl derivative IX[8] was studied. The starting material VIII was obtained either by catalytic deacetylation of IX or by acetylation of 2-amino-1,6-anhydro-2-deoxy-4-*O*-methyl-β-D-galactopyranose (III)[8] with acetic anhydride in methanol. Methylation of VIII with methyl iodide and silver oxide afforded the crystalline dimethyl derivative in a low yield of 15%, whereas reaction with methyl iodide after treatment with potassium in absolute ether or liquid ammonia did not lead to crystalline compounds. Methylation with methyl sulfate and sodium hydroxide was again the best method and dimethyl derivative VII and starting material VIII were isolated in yields of 35 and 45%, respectively.

The lack of reactivity of the hydroxyl in position 3 was also reflected in its very small contribution to the polarity of the molecule. Whereas in adsorption chromatography on silicic acid mono- and dimethyl ethers are generally eluted into two very distinct peaks, VIII and VII were eluted in a continuous peak, in which the middle fractions always contained a mixture of both.

Hydrolysis of VII with 2 *N* hydrochloric acid for 24 hours was carried out as described for the 4-*O*-methyl compounds.[8] From the resulting mixture, the crystalline 2-amino-1,6-anhydro-2-deoxy-3,4-di-*O*-methyl-β-D-galactose hydrochloride (XIV) was

isolated in an 8% yield. The remaining mother liquors were *N*-acetylated and after chromatography 22% of starting material was recovered, whereas the 3,4-di-*O*-methyl-D-galactosamine (XV) was isolated as its crystalline *N*-acetyl derivative XVI in a 23% yield. When XV was isolated as the crystalline *N*-(2′-hydroxynaphthylidenamino) derivative XVII, yields up to 41% were obtained. When the hydrolysis was followed by two methanolyses, a yield of up to 59% of crystalline α- and β-methyl glycosides X and XVIII was obtained, whereas only 9% of starting material was recovered.

The relatively low yields of free amino sugar hydrochloride XV obtained and the large amount of starting material recovered, compared to the nearly quantitative yield obtained in hydrolysis of methyl *N*-acetylglycoside derivatives, are easily explained on the basis of the relative speed of scission of the *N*-acetyl groups, and of the internal (1,6-anhydro) and external (methyl) glycosidic bonds. In the cases of 2-acetamido-1,6-anhydro-compounds and methyl 2-acetamidoglycosides, hydrolysis of the acetyl radical linked to the amino group proceeds concurrently with the hydrolysis of the glycosidic linkages. Studies in the glucose, galactose and mannose series have shown, however, the 1,6-anhydro internal glycosidic bond to be more resistant to hydrolysis than the glycosidically linked methoxyl. Consequently, the amount of free amino groups produced during hydrolysis of the internal glycosidic bond is much greater than that produced during the hydrolysis of the methoxyl glycosidic linkage. It has also been demonstrated a number of times that the presence of a vicinal free amino group inhibits completely the hydrolysis of a methoxyl bond by dilute acid and it is probable that a similar inhibition takes place in 1,6-internal glycosidic bond. The formation of free amino groups will thus control the degree of opening of the ring. The influence of the substitution at position 3 or 4 on the splitting of the acetyl group and consequently on the formation of substituted galactosamine with free aldehyde groups could not be

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

clearly established, as the results depended greatly on the isolation of the final products. When *N*-acetylated derivatives were prepared, a maximum yield of 23% of 3,4-di-*O*-methyl-D-galactosamine could be isolated and 30% of starting material recovered in the 3,4-dimethyl series, whereas a yield of 53% of 4-*O*-methyl-D-galactosamine (as crystalline hydrochloride) was obtained and 17% of starting material recovered in the 4-monomethyl series (ref. 8 and Experimental part). Concurrent inhibition of the opening of the anhydro ring by formation of the free amino group is quite large also in the non-methylated series. In a repetition of the work of James, *et al.*,[9] by one of us (P.J.S.) at the University of Brussels, it was observed during the hydrolysis of 2-acetamido-3,4-di-*O*-acetyl-1,6-anhydro-2-deoxy-β-D-galactopyranose (VI) with 2 *N* hydrochloric acid that the first product to crystallize from the mixture was 2-amino-1,6-anhydro-2-deoxy-β-D-galactopyranose hydrochloride, characterized by its transformation into V.[12]

The pure sirupy 3,4-di-*O*-methyl-D-galactosamine hydrochloride (2-amino-2-deoxy-3,4-di-*O*-methyl-D-galactose hydrochloride) (XV) was obtained by hydrolysis of the *N*-acetyl derivative XVI.

In order to correlate the dimethylgalactosamine XV prepared in such a way with a compound prepared from a natural source, the crude product of the hydrolysis of 2-acetamido-1,6-anhydro-2-deoxy-3,4-di-*O*-methyl-β-D-galactopyranose (VII) was fully acetylated and then glycosidified. After isolating some unreacted starting material, two crystalline compounds were obtained, to which the structures of α- and β-glycosides X and XVIII were attributed on the basis of their rotation. The residual mother liquors were subjected to a second glycosidification, and the total yields in crystalline material were 9% for the starting material, 53% for the α-glycoside X and 6% for the β-glycoside XVIII. These two compounds gave crystalline monoacetates XI and XIX.

The α-glycoside X and its 6-*O*-acetyl derivative XI did not show any depression in their melting points in admixture with identical products obtained by methylation of methyl 2-acetamido-2-deoxy-6-*O*-triphenylmethyl-α-D-galactopyranoside. This compound had been synthesized from methyl 2-acetamido-2-deoxy-α-D-galactopyranoside prepared from D-galactosamine (IV) which was isolated from a natural source.[13] In addition, the trityl derivative XIII was prepared from the α-glycoside X obtained *via* the route of the 1,6-anhydro derivatives and found to be identical with the same derivative synthesized from natural D-galactosamine. Such identity is not only evidence that galactosamine prepared from lactose and natural galactosamine are identical, but it also proves that X is really the α-anomer and possesses the pyranose configuration.

James, *et al.*, have proved in their work[9] the precise configuration of chondrosamine to be that of 2-amino-2-deoxy-D-galactose. The establishment of identity of the synthetic and the natural product was achieved by comparison of the X-ray powder diagrams and observation of the mutarotations. The β-pentaacetate derivative of the synthetic product was obtained in a yield not reported and found identical with the one from the natural product.

The present work presents further evidence for the identity of the two products, as three derivatives possessing definite melting point and rotation were compared and their mixed m.p.'s determined.

Preparation of the known 3,4,6-tri-*O*-methyl ether XII from X was additional proof of the identity of synthetic and natural product and of the α-anomerism and pyranose configuration of X.

Experimental[14]

2-Acetamido-1,6-anhydro-2-deoxy-β-D-galactopyranose (V) from I.—To a solution of 1.3 g. of 2-amino-1,6-anhydro-2-deoxy-β-D-galactopyranose[9] (I) in 40 ml. of methanol cooled at 0° was added 1.75 ml. of acetic anhydride. After 10 minutes, the solution was allowed to stand at room temperature for 3 hours, then evaporated under a stream of nitrogen and the residue dried in a desiccator overnight. Crystallization from a mixture of methanol and ether gave 1.48 g. (91%) of prisms, m.p. 207–208°, $[\alpha]^{25}D$ −5 ± 1° (in methanol, *c* 1.02). *Anal.* Calcd. for $C_8H_{13}O_5N$: C, 47.29; H, 6.45. Found: C, 47.20; H, 6.49.

2-Acetamido-1,6-anhydro-2-deoxy-β-D-galactopyranose (V) from VI.—To a solution of 2.90 g. of 2-acetamido-3,4-di-*O*-acetyl-1,6-anhydro-2-deoxy-β-D-galactopyranose[9] (VI) in 100 ml. of methanol was added 10 ml. of a 1.6 *N* barium methoxide solution. After refluxing for 10 minutes, the solution was cooled, diluted with a small amount of water and neutralized with a stream of CO_2. After filtration through Celite, it was evaporated *in vacuo*. The filtered material and the dry residue were extracted exhaustively in a Soxhlet apparatus with acetone. The combined extracts gave 1.92 g. of crystalline material, which after recrystallization from a mixture of methanol and ether afforded 1.89 g. (92%), melting at 204–207°. In admixture with the material previously described, the m.p. was not depressed.

2-Acetamido-1,6-anhydro-2-deoxy-4-*O*-methyl-β-D-galactopyranose (VIII) from III.—A solution of 95 mg. of 2-amino-1,6-anhydro-2-deoxy-4-*O*-methyl-β-D-galactopyranose[8] (III) in methanol was treated with acetic anhydride as described above for I. Crystallization from a mixture of acetone and ether gave 103 mg. (87%) of prismatic needles, m.p. 122–123°. When the melt was seeded with the material described below, crystallization in stout prisms occurred and a m.p. of 152–153° was observed, $[\alpha]^{24}D$ −53 ± 2° (in chloroform, *c* 0.98). *Anal.* Calcd. for $C_9H_{15}O_5N$: C, 49.76; H, 6.96. Found: C, 49.78; H, 6.84.

2-Acetamido-1,6-anhydro-2-deoxy-4-*O*-methyl-β-D-galactopyranose (VIII) from IX.—To a solution of 1.53 g. of 2-acetamido-3-*O*-acetyl-1,6-anhydro-4-*O*-methyl-β-D-galactopyranose[8] (IX) in 50 ml. of methanol was added 5 ml. of a 1.6 *N* barium methoxide solution. After refluxing for 10 minutes, the cooled solution was diluted with water, neutralized with a stream of CO_2 and filtered through Celite and charcoal. The filter was washed with water, the combined filtrates evaporated *in vacuo*, and the residue was extracted with boiling acetone. After evaporation, 1.30 g. of crude product was obtained; crystallization from a mixture of acetone and ether gave 1.16 g. (90%) of VIII, m.p. 120–122°. In admixture with the material described above, the m.p. was not depressed.

Methylation of V with Methyl Sulfate and Sodium Hydroxide.—To a solution of 2.21 g. of V in a minimum amount of water was added, with vigorous stirring and at room temperature, 33.3 ml. of methyl sulfate and 102.4 ml. of a 30% sodium hydroxide solution, in 20 portions each

(12) Using concentrated hydrochloric acid for 30 hours (2.2 *N* in the text of the Experimental part!) James, *et al.*,[9] were able to split the 1,6-anhydro ring in presence of a free amino group and obtain a yield of D-galactosamine hydrochloride greater than 50%. So great a concentration of acid was avoided in the treatment of methylated sugars in order to avoid demethylation.

at 15-minute intervals. The *p*H was checked frequently and always kept on the alkaline side. After the last addition, the mixture was stirred for a half-hour at room temperature, and then neutralized with CO_2. The precipitate was filtered off, and the filtrate was extracted several times with chloroform. The combined chloroform extracts were dried over sodium sulfate and evaporated *in vacuo*, giving 1.6 g. of crystalline residue. The water layer was evaporated *in vacuo* at 40°, and the residue dried in a desiccator. Combined with the filtered material, it was extracted with chloroform, in a Soxhlet apparatus. After drying over sodium sulfate, the chloroform was evaporated *in vacuo*, and the sirupy residue combined with the first residue gave 2.5 g. of crude product, which was chromatographed on silicic acid. Mixtures of ethyl acetate and acetone 4:1 eluted 940 mg. of crystalline fractions of **2-acetamido-1,6-anhydro-2-deoxy-3,4-di-*O*-methyl-β-D-galactopyranose (VII)**. After recrystallization from a mixture of acetone, ether and pentane, 880 mg. (35%) of stout prisms was obtained, m.p. 109–111°, $[\alpha]^{27}D$ −87 ± 2° (in chloroform, *c* 1.14). *Anal.* Calcd. for $C_{10}H_{17}O_5N$: C, 51.94; H, 7.41; N, 6.06; OCH_3, 26.84. Found: C, 52.04, 51.83; H. 7.56, 7.50; N, 6.18; OCH_3, 26.82.

The same mixture of ethyl acetate and acetone 4:1 eluted 300 mg., which could not be crystallized, and then 1.49 g. of partially crystalline fractions, which after recrystallization from a mixture of acetone and ether gave 935 mg. (40%) of VIII, melting at 119–121°. In admixture with the material described above, the m.p. was not depressed.

Methylation of VI with Methyl Sulfate and Sodium Hydroxide.—The methylation was carried out on 350 mg. of VI at 55° and 2.4 ml. of methyl sulfate and 7.1 ml. of a 30% solution of sodium hydroxide were introduced in 10 portions for two hours. After purification as described above, 32 mg. (11%) of VII was obtained, m.p. 108–110°, showing no depression in admixture with the compound described above; $[\alpha]^{25}D$ −82 ± 4° (in chloroform, *c* 0.60).

Methylation of VIII with Methyl Sulfate and Sodium Hydroxide.—A solution of 200 mg. of VIII in the minimum amount of water was methylated at room temperature with 1.3 ml. of methyl sulfate and 4.0 ml. of a 30% solution of sodium hydroxide, as described for V. After chromatography, 72 mg. (34%) of VII was obtained, melting at 108–110°, and showing no depression in admixture with the compound obtained above. In addition, 64 mg. (32%) of starting material, m.p. 120–121°, was obtained. In other experiments on a larger scale, the yield of VII varied from 25 to 37% and the yield in starting material was such as to give a total yield of crystalline products of 65 to 70%. The recovered starting material added to the non-crystallizable mother liquors gave again, after methylation, the same yield in VII.

Methylation of VIII with Methyl Iodide and Silver Oxide.—Five hundred mg. of VIII was methylated under reflux with 20 ml. of methyl iodide and four times 500 mg. of silver oxide, added over a 36-hour period. After 48 hours, the silver salts were filtered off and washed with acetone. The solution was evaporated *in vacuo*, and the residue chromatographed on silicic acid to give VII in a 15% yield, m.p. 103–105°, showing no depression with the material described above. No crystalline starting material could be recovered.

Methylation of IX with Methyl Sulfate and Sodium Hydroxide.—Two hundred mg. of IX was methylated at 55° with 1.4 ml. of methyl sulfate and 4.1 ml. of a 30% solution of sodium hydroxide as described for VI; 26 mg. (12%) of VII was obtained, m.p. 108–110°, showing no depression with the material described above.

3,4-Di-*O*-methyl-D-galactosamine Hydrochloride (2-Amino-2-deoxy-3,4-di-*O*-methyl-D-galactose Hydrochloride (XV) and 2-Acetamido-2-deoxy-3,4-di-*O*-methyl-α-D-galactopyranose (XVI).—A solution of 0.70 g. of VII in 50 ml. of 2 *N* hydrochloric acid in a sealed tube was heated for 24 hours in a boiling water-bath. After filtration through a layer of Darco G-60, the solution was evaporated *in vacuo* at 50° and the last traces of water and hydrochloric acid were removed by co-distillation with absolute ethanol. After a few weeks, the colorless sirup crystallized spontaneously, and was filtered after dilution with a mixture of methanol and acetone. Recrystallization from a mixture of methanol and acetone gave 55 mg. (8%) of **2-amino-1,6-anhydro-2-deoxy-3,4-di-*O*-methyl-β-D-galactose hydrochloride (XIV)**, as needles, subliming above 230° and decomposing above 250°, $[\alpha]^{27}D$ −26 ± 2° (in water, *c* 0.85). *Anal.* Calcd. for $C_8H_{16}O_4NCl$: C, 42.56; H, 7.15; Cl, 15.71; OCH_3, 27.50. Found: C, 42.48; H, 7.07; Cl, 15.68; OCH_3, 27.55. To a solution of 18 mg. of XIV in 1 ml. of methanol was added 14 mg. of silver acetate and 0.2 ml. of acetic anhydride. After standing a few hours at room temperature in the dark, the solution was filtered and one drop of 0.01 *N* hydrochloric acid was added to the filtrate. After one hour, the solution was filtered and evaporated *in vacuo* to dryness. The residue was dissolved in acetone, and filtered through a double layer of Celite and Darco G-60. Evaporation and crystallization of the residue in a mixture of acetone, ether and pentane gave 18 mg. (95%) of VII, m.p. 110–111°, $[\alpha]^{24}D$ −88 ± 2° (in chloroform, *c* 0.97); the m.p. showed no depression in admixture with the material described above.

The mother liquors of XIV (dry weight 0.72 g.) were subjected to a new hydrolysis by refluxing with 20 ml. of 3 *N* hydrochloric acid for 24 hours. After evaporation *in vacuo*, dissolution of the residue in water, filtration through a double layer of Celite and Darco G-60, and evaporation to dryness, 0.72 g. of a colorless sirup was obtained. Elementary analysis and rotation showed that it was composed approximately of 60% of XV and 40% of XIV, $[\alpha]^{27}D$ +62 ± 2° (in water, *c* 3.93). *Anal.* Found: C, 41.14; H, 8.18; O, 31.89. In order to separate those two components, 0.60 g. of the above sirup was dissolved in 10 ml. of methanol and 0.46 g. of silver acetate and 0.5 ml. of acetic anhydride were added. After standing for 2 days at room temperature in the dark, the solution was filtered, one drop of 0.1 *N* hydrochloric acid was added, and after a few hours the solution was filtered through a double layer of Celite and Darco G-60. After concentration *in vacuo*, 0.59 g. of a colorless sirup was obtained. Dissolved in chloroform, it was chromatographed on silicic acid. Elution with various mixtures of ethyl acetate and acetone gave 152 mg. (26%) of crude VII; recrystallization from a mixture of acetone, ether and pentane gave 134 mg. (22%), m.p. 110–112°, $[\alpha]^{25}D$ −86 ± 1° (in chloroform, *c* 1.18); the m.p. was not depressed in admixture with the compound described above.

Elution with mixtures of acetone and methanol gave 235 mg. (38%) of crude **2-acetamido-2-deoxy-3,4-di-*O*-methyl-α-D-galactopyranose (XVI)**; recrystallization from a mixture of methanol, ether and pentane gave 150 mg. (23%) of prisms, m.p. 199–200° (with slight decomposition). The product showed mutarotation from $[\alpha]^{27}D$ +114° (after 4 minutes) to $[\alpha]^{26}D$ +92 ± 2° (after 24 hours, in water, *c* 1.07). *Anal.* Calcd. for $C_{10}H_{19}O_6N$: C, 48.18; H, 7.68. Found: C, 48.07; H, 7.64.

The yields in crystalline materials showed that 30% of the starting material VII was recovered after *N*-acetylation, whereas 23% had its 1,6-anhydro ring opened and was transformed into the crystalline derivative XVI.

A solution of 110 mg. of XVI in 2 ml. of 2 *N* hydrochloric acid was heated on the steam-bath for 2 hours. After distillation *in vacuo* and co-distillation with absolute ethanol, the sirupy residue was left overnight in a desiccator over soda lime. It was dissolved in methanol, filtered through a double layer of Celite and Darco G-60 and evaporated to give 127 mg. (100%) of a colorless sirup, **3,4-di-*O*-methyl-D-galactosamine hydrochloride (XV)**, $[\alpha]^{24}D$ +108 ± 2° (in water, *c* 1.77). *Anal.* Calcd. for $C_8H_{18}O_5NCl$: C, 39.43; H, 7.44; Cl, 14.55; OCH_3, 25.47. Found: C, 39.27; H, 7.59; Cl, 14.51; OCH_3, 25.67.

2-Deoxy-2-(2′-hydroxynaphthylidenamino)-3,4-di-*O*-methyl-β-D-galactopyranose (XVII).—Hydrolysis of 200 mg. of VII gave 200 mg. of crude sirup. Dissolved in 2 ml. of water, it was treated as previously described[7] with 290 mg. of sodium acetate trihydrate and 440 mg. of 2-hydroxynaphthaldehyde dissolved in 20 ml. of methanol. On purification by chromatography, mixtures of ethyl acetate and acetone 4:1, 2:1, 1:1 and pure acetone eluted crystalline fractions. Crystallization from methanol and ether gave 130 mg. (41%) of yellow crystals, m.p. 203–204° (with slight decomposition). The product showed mutarotation from $[\alpha]^{26}_{5461}$ +107° (after 8 minutes) to $[\alpha]^{27}_{5461}$ +332 ± 5° (after 5 days, in methanol, *c* 0.15). *Anal.* Calcd. for $C_{19}H_{23}O_6N$: C, 63.15; H, 6.41. Found: 63.08; H, 6.52.

Methyl 2-Acetamido-2-deoxy-3,4-di-*O*-methyl-α-D-galactopyranoside (X) and Methyl 2-Acetamido-2-deoxy-3,4-di-*O*-methyl-β-D-galactopyranoside (XVIII) from VII.—The crude product of hydrolysis (534 mg.) of 475 mg. of VII was shaken for 60 hours with 15 ml. of acetic anhydride and

15 ml. of dry pyridine. After evaporation *in vacuo*, the last traces of reagents were removed by co-distillation with dry toluene. The amorphous residue was refluxed for two hours with 40 ml. of 2% hydrochloric acid in methanol. After cooling, the chloride ion was removed with silver carbonate, and the last traces of silver with hydrogen sulfide. After filtration through a double layer of Darco G-60 and Celite, the solvent was evaporated *in vacuo* and the crude crystalline residue, dissolved in chloroform, was chromatographed on silicic acid. Elution with ethyl acetate gave after recrystallization 37 mg. of starting material VII, m.p. 108–110°. Elution with a mixture of ethyl acetate and acetone 2:1 gave crystalline fractions, which after recrystallization from a mixture of methanol and ether afforded 185 mg. of **methyl 2-acetamido-2-deoxy-3,4-di-*O*-methyl-α-D-galactopyranoside (X)**, as prismatic needles, m.p. 219–220°, $[\alpha]^{25}D$ +146 ± 1° (in methanol, *c* 1.50). *Anal.* Calcd. for $C_{11}H_{21}O_6N$: C, 50.18; H, 8.04; OCH_3, 35.36. Found: C, 50.35; H, 8.17; OCH_3, 35.18. In admixture with material obtained by hydrolysis of methyl 2-acetamido-2-deoxy-3,4-di-*O*-methyl-6-*O*-triphenylmethyl-α-D-galactopyranoside, synthesized from natural D-galactosamine,[13] the m.p. was not depressed. Acetylation of 51 mg. of X with acetic anhydride and pyridine in the usual manner gave, after recrystallization from a mixture of acetone and ether, 51 mg. (90%) of the **6-*O*-acetyl derivative XI**, as fine needles, m.p. 203–204°, $[\alpha]^{27}D$ +123 ± 2° (in chloroform, *c* 0.70). *Anal.* Calcd. for $C_{13}H_{23}O_7N$: C, 51.14; H, 7.59. Found: C, 51.10; H, 7.71. In admixture with material prepared from natural D-galactosamine,[13] the m.p. was not depressed.

Elution with a mixture of ethyl acetate and acetone 1:1 gave a crystalline fraction. After recrystallization from a mixture of methanol and ether, 30 mg. (6%) of **methyl 2-acetamido-2-deoxy-3,4-di-*O*-methyl-β-D-galactopyranoside (XVIII)** was obtained as needles, m.p. 247–249°, $[\alpha]^{25}D$ −18 ± 3° (in methanol, *c* 0.76). *Anal.* Calcd. for $C_{11}H_{21}O_6N$: C, 50.18; H, 8.04. Found: C, 50.05; H, 8.09. Acetylation of 16 mg. of XVIII with acetic anhydride and pyridine in the usual manner gave, after recrystallization from a mixture of methanol and ether, 16 mg. (85%) of the **6-*O*-acetyl derivative (XIX)**, as prismatic needles, m.p. 247–248°, $[\alpha]^{26}D$ 0 ± 4° (in chloroform, *c* 0.63). In admixture with the starting material, the m.p. was depressed at 215–235°. *Anal.* Calcd. for $C_{13}H_{23}O_7N$: C, 51.14; H, 7.59. Found: C, 51.21; H, 7.73.

The residual mother liquors and non-crystalline fractions were refluxed with 25 ml. of 2% hydrochloric acid in methanol for 2 hours and the solution was treated as described above, but using lead carbonate instead of silver carbonate to remove the chloride ion. After chromatography, 40 mg. of crude starting material VII was recovered, from which only 6 mg. of crystalline product was obtained, giving a total yield of 43 mg. (9%). An additional yield of 84 mg. of crude crystalline α-glycoside X was isolated from which 50 mg. of pure compound was crystallized, to give a total yield of 285 mg. (53%).

In another experiment, in which a smaller amount of starting material was subjected to only one hydrolysis and one methanolysis, the yield in crystalline starting material VII recovered was 20%, whereas 24% of pure crystalline α-glycoside X and 3% of pure crystalline β-glycoside XVIII were isolated.

Fifty mg. of X was methylated under reflux for 48 hours with 10 ml. of methyl iodide and two additions of 100 mg. of silver oxide. After filtration of the silver salts and evaporation, the crystalline residue was crystallized from a mixture of acetone and ether to give 47 mg. (90%) of methyl 2-acetamido-2-deoxy-3,4,6-tri-*O*-methyl-α-D-galactopyranoside (XII), m.p. 189–192°, after a second recrystallization. In admixture with authentic material,[15] the m.p. was not depressed; $[\alpha]^{27}D$ +143 ± 2° (in methanol, *c* 0.79).

Methyl 2-Acetamido-2-deoxy-3,4-di-*O*-methyl-6-*O*-triphenylmethyl-α-D-galactopyranoside (XIII).—A solution of 36 mg. of X and 56 mg. (1.5 moles) of triphenylchloromethane in 0.5 ml. of anhydrous pyridine was heated at 55° for three days. After dilution with 10 ml. of ice-cold water, the precipitate was filtered off, dried in a desiccator and dissolved in a mixture of benzene and hexane 1:1. Chromatography on alumina afforded a large amount of triphenylcarbinol, eluted with pure benzene. A mixture of ether and methanol 9:1 eluted 40 mg. of crystalline XIII. Recrystallization from a mixture of acetone, ether and pentane gave 30 mg. (43%) of prismatic needles, m.p. 222–224°, $[\alpha]^{27}D$ +66 ± 4° (in chloroform, *c* 0.52). *Anal.* Calcd. for $C_{30}H_{35}O_6N$: C, 71.26; H, 6.98. Found: C, 71.29; H, 7.09. In admixture with material obtained by methylation of methyl 2-acetamido-2-deoxy-6-*O*-triphenylmethyl-α-D-galactopyranoside, synthesized from natural D-galactosamine (IV),[13] the m.p. was not depressed.

Hydrolysis of 2-Acetamido-3-*O*-acetyl-1,6-anhydro-2-deoxy-4-*O*-methyl-α-D-galactopyranose (IX).—In a preceding paper,[8] the hydrolysis of 300 mg. of IX with 2.5 *N* hydrochloric acid has been reported and 140 mg. of 4-*O*-methyl-α-D-galactosamine hydrochloride was isolated. The residual mother liquors were dissolved in 5 ml. of methanol and 165 mg. of silver acetate and 0.2 ml. of acetic anhydride were added. After standing at room temperature for 48 hours, in the dark, the solution was filtered and one drop of 0.1 *N* hydrochloric acid was added. After a few hours, the solution was filtered through Darco G-60 and Celite, evaporated *in vacuo* and the residue, dissolved in chloroform, was chromatographed on silicic acid. Mixtures of ethyl acetate and acetone eluted 50 mg. of crystalline fractions, 2-acetamido-1,6-anhydro-2-deoxy-4-*O*-methyl-β-D-galactopyranose (VIII). Recrystallization from a mixture of acetone and ether gave 43 mg. (17%) of stout prisms, m.p. 153–154°, $[\alpha]^{25}D$ −51 ± 2° (in chloroform, *c* 0.95). In admixture with the material described above (m.p. 122–123°) the m.p. was not depressed.

Elution with a mixture of acetone and methanol 49:1 gave 24 mg. of crystalline fractions, behaving like authentic 2-acetamido-2-deoxy-4-*O*-methyl-D-galactose.[16] However, recrystallization from a mixture of methanol and acetone afforded only 4 mg. of impure crystals. The remaining mother liquors were not further investigated.

Methyl 2-Acetamido-2-deoxy-4,6-di-*O*-methyl-3-*O*-*p*-tolylsulfonyl-α-D-galactopyranoside.—This compound had been previously obtained only in sirupy form.[5] After standing one year, it crystallized spontaneously. It was recrystallized from a mixture of ether and pentane to give prisms melting at 106–108°, $[\alpha]^{21}D$ +94 ± 2° (in chloroform, *c* 1.17). *Anal.* Calcd. for $C_{18}H_{27}O_8NS$: C, 51.78; H, 6.52. Found: C, 51.82; H, 6.53.

Acknowledgments.—The authors wish to thank Miss Ann Foley and Mrs. S. Butterworth for technical assistance.

The Synthesis of D-Allosamine Hydrochloride[1]

BY ROGER W. JEANLOZ

RECEIVED DECEMBER 17, 1956

Sirupy D-allosamine hydrochloride has been synthesized from methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranose and transformed into the crystalline N-acetyl and N-(2′-hydroxynaphthylidene) derivatives.

The increasing importance of glucosamine and galactosamine as components of biological systems and the recent isolations of new amino sugars from microorganisms[2] makes desirable the synthesis of 2-aminohexoses, to be used for reference or as biological substrates.

Fifty years ago, Fischer and Leuchs,[3] applied to D-arabinosimine the cyanohydrin method of lengthening the carbon chain and obtained impure D-glucosamine. In a series of papers, Levene later extended Fischer's work and prepared the eight possible 2-aminohexonic acids, but the yield was sometimes small and inconsistent.[4] Reduction of the aminohexonic acid generally gave poor yields and impure products. Only syntheses of D-glucosamine,[5] D-galactosamine[6] and D-mannosamine[7] were reported. A contaminated amino sugar was obtained from xylose. After treatment with phenylhydrazine it gave gulosazone, whereas benzoylation produced a crystalline pentabenzoate in small yield, not further identified.[5,8]

Recently catalytic hydrogenation of lactosazone led to the isolation of a 2-amino sugar in very minute amounts.[9]

The synthesis of 2-aminohexoses with the best yield takes place by addition of ammonia to 2,3-epoxy derivatives of hexoses.[10] However, only amino sugars with the 2,3-*trans* configuration are obtained and the final yield of the 2-amino isomer is controlled by the conformation of the molecule. Baker, *et al.*,[11] extending Winstein's work[12] on the influence of neighboring groups on the solvolysis of sulfonyl esters, have greatly increased the usefulness of the above described method. They were able to show, in the pentose series, that sulfonyl ester groups in transvicinal position to an acetylamino group can be split with concurrent Walden inversion, thus synthesizing 3-aminoribose from 3-aminoxylose. Application of the same method in the hexoses series to natural or synthetic 2-aminohexoses possessing *trans* configuration in positions 2,3 would make possible the preparation of the 2-aminohexoses possessing the 2,3-*cis* configuration. It is the aim of the present paper to describe this application to the naturally occurring D-glucosamine to obtain the new 2-amino-sugar, D-allosamine.

Methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside[13] treated with methanesulfonyl chloride in the presence of pyridine gave the 3-*O*-methylsulfonyl derivative II. When II was heated in the presence of sodium acetate in methyl Cellosolve solution, it yielded a small amount of I, and the crystalline methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-allopyranoside (III) characterized as its crystalline 3-monoacetate IV. Hydrolysis of III with 60% acetic acid afforded a crystalline methyl 2-acetamido-2-deoxy-α-D-allopyranoside (V), from which a crystalline 3,4,6-triacetate VI could be prepared. 2-Amino-2-deoxy-D-allose hydrochloride (D-allosamine hydrochloride) (IX) was obtained as a sirup by treatment of IV with hydrochloric acid. IX was characterized as two crystalline compounds, the 2-acetamido VII and the 2-(2′-hydroxynaphthylideneamino) (VIII) derivatives. Degradation with ninhydrin in presence of pyridine[14] gave rise to D-ribose (X). The latter compound, owing to lack of material, was identified by paper chromatography only. However, this additional evidence and the mode of preparation leaves little doubt as to the structure of the amino sugar.

Experimental[15]

Methyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methylsulfonyl-α-D-glucopyranoside (II).—To a solution of 11.5 g. of methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside[13] (I) in 50 ml. of anhydrous pyridine was added a solution of 6 ml. of methanesulfonyl chloride in 50 ml. of anhydrous pyridine, both solutions being previously cooled to 0°. After standing 8 days at 0°, ice was added, and after a few hr. the mixture was diluted with 2 l. of ice-cold water and left overnight in the refrigerator. The precipitate was filtered, washed well with ice-cold water and dried in a desiccator. After recrystallization from acetone, it yielded 13.0 g. (90%) of needles, m.p. 213–214°, with slight decomposition. The m.p. varied with the speed of heating. Very slow heating gave m.p. as low as 199–200°;

$[\alpha]^{24}D$ +42 ± 1° (in chloroform, *c* 1.33). *Anal.* Calcd. for $C_{17}H_{23}O_8NS$: C, 50.86; H, 5.77; S, 7.99. Found: C, 50.80; H, 5.92; S, 7.88.

Methyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-allopyranoside (III).—A solution of 450 mg. of II and 400 mg. of sodium acetate trihydrate in 10 ml. of 95% methyl cellosolve was heated under reflux for 40 hr. After cooling, the solution was extracted with 150 ml. of chloroform. The chloroform layer was washed three times with water and dried over sodium sulfate. After evaporation *in vacuo*, the residual crystalline mixture was dissolved in chloroform and chromatographed on 20 g. of silicic acid. Mixtures of chloroform and ether 4:1, 2:1, 1:1 and pure ether eluted fractions, which after crystallization from a mixture of acetone, ether and pentane gave 42 mg. (10%), m.p. 202–206° (with decomposition), which showed no depression in admixture with the starting material (II).

Mixtures of ether and ethyl acetate varying from 19:1 to 1:1 eluted fractions, which were crystallized from a mixture of acetone and pentane to give 236 mg. (66%) of fine needles III, m.p. 214–215°; $[\alpha]^{24}D$ +64 ± 2° (in chloroform, *c* 0.95). *Anal.* Calcd. for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55. Found: C, 59.31; H, 6.55. The test for S was negative.

Ethyl acetate eluted fractions weighing 50 mg. (14%) with a m.p. of 259–261° after crystallization from a mixture of chloroform, ether and pentane. When mixed with methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside,[13] the m.p. was not depressed.

The same reaction carried out with a tenfold amount gave an identical yield.

Acetylation of 35 mg. of III with acetic anhydride and pyridine in the usual manner gave, after crystallization from a mixture of acetone, ether and pentane, 28 mg. (70%) of the 3-*O*-acetyl derivative IV, as elongated prisms, m.p. 213–214°; $[\alpha]^{25}D$ +17 ± 3° (in chloroform, *c* 0.71). *Anal.* Calcd. for $C_{18}H_{23}O_7N$: C, 59.17; H, 6.34. Found: C, 59.13; H, 6.29. In admixture with methyl 2-acetamido-3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (m.p. 203–205°),[16] the m.p. was depressed to 175–205°. In admixture with III, the m.p. was depressed to 180–195°.

Methyl 2-Acetamido-2-deoxy-α-D-allopyranoside (V).—A solution of 1.0 g. of III in 50 ml. of 60% acetic acid was heated for 1 hr. on a water-bath. The benzaldehyde and the water were removed by distillation *in vacuo*, followed by codistillation with water, then with absolute toluene. After standing overnight in a desiccator, the residual sirup was crystallized from a mixture of ethanol and ether to give 0.71 g. (96%) of stout prisms, m.p. 155–156°; $[\alpha]^{23}D$ +92 ± 1° (in methanol, *c* 1.25). *Anal.* Calcd. for $C_9H_{17}O_6N$: C, 45.95; H, 7.29. Found: C, 45.98; H, 7.14.

Acetylation of 0.36 g. of V with acetic anhydride and pyridine in the usual manner gave, after recrystallization from a mixture of acetone, ether and pentane 0.51 g. (92%) of the 3,4,6-tri-*O*-acetyl derivative VI as stout, hexagonal prisms, m.p. 107–109°; $[\alpha]^{24}D$ +68 ± 1° (in chloroform, *c* 2.21). *Anal.* Calcd. for $C_{15}H_{21}O_9N$: C, 49.86; H, 6.42. Found: C, 49.76; H, 6.35.

D-Allosamine Hydrochloride (2-Amino-2-deoxy-D-allose Hydrochloride (IX)).—A solution of 1.0 g. of V in 5 ml. of 2 *N* hydrochloric acid was heated on the water-bath for 2 hr. After evaporation *in vacuo*, the last traces of hydrochloric acid, water and acetic acid were removed by codistillation *in vacuo* with absolute ethanol and benzene and storage of the residual sirup in a desiccator over soda lime and calcium chloride. After dissolving in methanol, the solution was filtered through a double layer of Darco-G-60 and Celite and evaporated *in vacuo*. A colorless sirup (yield 100%) was obtained which did not crystallize after three years; $[\alpha]^{25}D$ +29 ± 2° (in water, *c* 1.35). *Anal.* Calcd. for $C_6H_{14}O_5NCl$: C, 33.26; H, 6.48; N, 6.50; Cl, 16.44. Found: C, 33.42; H, 6.67; N, 6.43; Cl, 16.48. A small amount, deposited on paper and treated with ninhydrin and pyridine as previously described,[14] gave a spot with an R_f identical to that of D-ribose (X).

2-Acetamido-2-deoxy-β-D-allose (VII).—To a solution of 110 mg. of IX in 1 ml. of methanol was added 83 mg. of silver acetate and 0.1 ml. of acetic anhydride. After standing one day at 0° and 5 hr. at room temperature, the mixture was heated to boiling, filtered through Celite, and the precipitate was washed with 1 ml. of hot water. One drop of 0.1 *N* hydrochloric acid was added to the filtrate. After 2 hr., the solution was filtered through a double layer of Darco G-60 and Celite and concentrated. Crystallization from a mixture of ethanol, acetone and ether gave 87 mg. (77%) of VII, m.p. 205–207° (starting at 190°) with slight decomposition. Starting from room temperature the m.p. was 201–203°. The compound showed mutarotation, from $[\alpha]^{24}D$ −57 (after 6 minutes) to −48 ± 2° (after 16 hr., in water, *c* 0.51). *Anal.* Calcd. for $C_8H_{15}O_6N$: C, 43.44; H, 6.83. Found: C, 43.57; H, 6.85.

2-Deoxy-2-(2′-hydroxynaphthylidenamino)-D-allose (VIII).—A solution of 55 mg. of IX and 30 mg. of sodium acetate trihydrate in 1 ml. of water was treated as previously described[17] with 110 mg. of 2-hydroxynaphthaldehyde in 10 ml. of methanol. Purification was effected by chromatography; the substance was eluted by a mixture of acetone and methanol 49:1. Crystallization from a mixture of pyridine, methanol and acetone gave 32 mg. (38%) of small yellow prisms, m.p. 199–200° (with decomposition above 185°); $[\alpha]^{25}_{5461}$ −80 ± 5° (at equilibrium, in methanol, *c* 0.17). *Anal.* Calcd. for $C_{17}H_{19}O_6N$: C, 61.25; H, 5.75. Found: C, 61.09; H, 5.88.

Acknowledgments.—The author wishes to thank Miss Ann Foley and Mrs. Shirley Butterworth for technical assistance.

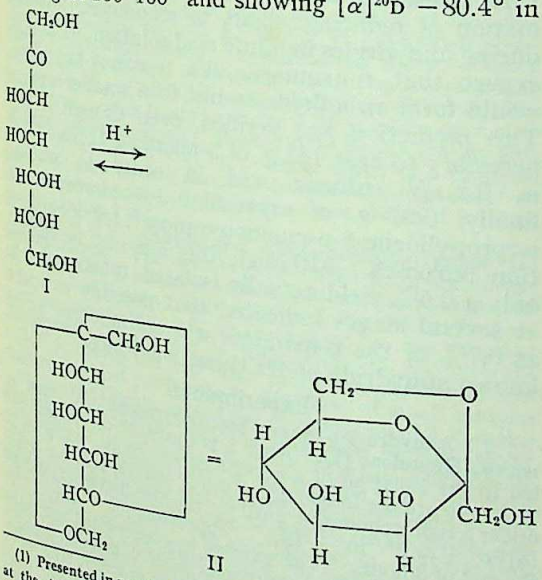
The Formation of 2,7-Anhydro-β-D-*manno*-heptulopyranose by the Action of Acid on D-*manno*-Heptulose and of Alkali on Phenyl α-D-*manno*-Heptulopyranoside; also 1,6-Anhydro-β-D-mannopyranose from D-Mannose in Acid Solution[1-3]

BY EMMANUEL ZISSIS, LAURA C. STEWART AND NELSON K. RICHTMYER

RECEIVED DECEMBER 14, 1956

D-*manno*-Heptulose has been converted by hot dilute acid in about 8% yield to 2,7-anhydro-β-D-*manno*-heptulopyranose, whose structure has been established through periodate oxidation methods. D-Mannose has been transformed similarly in about 0.6% yield to 1,6-anhydro-β-D-mannopyranose. Acetylation of D-*manno*-heptulose with acetic anhydride and pyridine forms first the 1,3,4,5,7-pentaacetate (described earlier as the α-hexaacetate) and then, much more slowly, the true α-D-*manno*-heptulopyranose hexaacetate (melting point 86–89°, $[\alpha]^{20}D$ +41.5° in chloroform). Condensation of both the penta-acetate and the hexaacetate with phenol in the presence of *p*-toluenesulfonic acid as catalyst yielded phenyl α-D-*manno*-heptulopyranoside pentaacetate. Deacetylation, and subsequent degradation of the phenyl α-D-*manno*-heptulopyranoside with hot aqueous alkali gave about a 15% yield of the same 2,7-anhydro-β-D-*manno*-heptulopyranose that was formed by the action of acid on D-*manno*-heptulose.

The conversion of aldohexoses, aldoheptoses and heptuloses in dilute acid solution to equilibrium mixtures containing one or more monomeric, non-reducing anhydrides has been studied extensively in this Laboratory. In general, heptuloses are transformed to a significantly greater extent than are the corresponding aldoses, and production of the 2,7-anhydroheptulopyranoses has been reported to occur to the following extents: *altro*, 91; *ido*, 85; *gulo*, 80; *allo*, 50; *talo*, 32; *gluco*, 2.[4] In extending these studies to the *manno* configuration we now find that D-*manno*-heptulose (I) is converted by dilute acids to an equilibrium mixture from which we could isolate a crystalline anhydride melting at 159–160° and showing $[\alpha]^{20}D$ −80.4° in water. Its structure was proved by periodate oxidation methods to be 2,7-anhydro-β-D-*manno*-heptulopyranose (II). No trace of other anhydrides, such as the 2,7-anhydro-β-D-*altro*-heptulofuranose derived from sedoheptulose[2] or the dimolecular dianhydride derived from D-*gluco*-heptulose,[3] was found.



In the equilibrium mixture of sedoheptulose (= D-*altro*-heptulose) and sedoheptulosan, the amount of anhydride varies with the temperature,[2] being 91% at 20° and only 84.5% at 80°. With D-*manno*-heptulose the equilibrium is shifted in the opposite direction with a change in temperature so that at 40° there is only 3% anhydride while at 80° there is about 7% anhydride (Table I). According to the principle of LeChatelier and Braun these results might not be unexpected, because the effect of heat is to displace the equilibrium in the direction of the thermodynamically less-favored component.

TABLE I

THE EFFECT OF TEMPERATURE ON THE AMOUNTS OF D-*manno*-HEPTULOSE (I) AND ITS ANHYDRIDE (II·H_2O) IN THE EQUILIBRIUM MIXTURE IN 0.2 *N* HYDROCHLORIC ACID

Time, hr.	Temp., °C.	$[\alpha]^{20}D$	% II·H_2O[a]	% I[b]	Mole % DHEF[c]
119	40	+25.9°	2.8	94.9	..
237	40	+25.9	2.8	94.6	0.11
16	60	+23.5	5.2	93.0	.26
40	60	+23.6	5.1	93.3	..
3	80	+21.2	7.4	89.8	.55
5	80	+21.3	7.3	89.8	.88

[a] Calculated from the specific rotation on the assumption that the solution contained only D-*manno*-heptulose (I) and 2,7-anhydro-β-D-*manno*-heptulopyranose (II) as its monohydrate of $[\alpha]^{20}D$ −73.5°; total concentration, 0.1 molar. [b] Determined by a ferricyanide titration method. [c] Calculated from the ultraviolet spectra on the assumption that the molecular absorption coefficient of DHEF [= 5-(1,2-dihydroxyethyl)-2-furaldehyde] is about the same as that of HMF [= 5-(hydroxymethyl)-2-furaldehyde]. For further details of the methods, see reference 2.

The acetylation of D-*manno*-heptulose by acetic anhydride and pyridine for 48 hours at 0° was reported by Montgomery and Hudson[5] to produce large prisms melting at 110° and showing $[\alpha]^{20}D$ +39.0° in chloroform. Carbon, hydrogen and acetyl analyses of their compound, as well as its

(3) For a recent paper on anhydro sugars that includes pertinent references to their preparation by both these methods, see L. C. Stewart, E. Zissis and N. K. Richtmyer, *Chem. Ber.*, **89**, 535 (1956).

(4) Although D-*altro*-heptulose appears to give the highest yield of anhydride yet reported, it should be noted that the 91% represents the amount as determined at the very favorable temperature of 20° whereas the values for the other sugars were obtained at 95–100°. It is expected that *ido*-heptulose and perhaps *gulo*-heptulose will generate more than 91% anhydride when they are allowed to stand in dilute acid solution at 20°.

transformation to an "acetobromo" compound and subsequent reaction of the latter to form the methyl glycoside pentaacetate, led them to designate it the α-hexaacetate. We find, however, that their product was actually a pentaacetate: it showed clearly a hydroxyl band in its infrared spectrum and upon further reaction with acetic anhydride and pyridine it yielded the true α-D-*manno*-heptulopyranose hexaacetate as small prismatic needles melting at 86–89° and showing $[\alpha]^{20}D$ +41.5° in chloroform. Our further studies have shown that acetic anhydride and pyridine at 25° convert D-*manno*-heptulose rapidly to the pentaacetate stage (65% yield isolated after one hour), whereas complete acetylation is achieved only after about 5 days. Comparable results with D-*gluco*-heptulose had been reported earlier by Wolfrom and Thompson[6] and by Frush and Isbell.[7] The first-named pair of investigators found that their "acetobromo" compound, with silver carbonate and aqueous acetone, yielded α-D-*gluco*-heptulose pentaacetate, and they thus established that the free hydroxyl group was at C2 in the pentaacetate. We have found, similarly, that penta-*O*-acetyl-α-D-*manno*-heptulopyranosyl bromide[5] is converted by gentle hydrolysis to the pentaacetate, which must, therefore, also be designated the 1,3,4,5,7-pentaacetate.

Acetylated glycosyl bromides are usually prepared from the fully acetylated sugars. We have found, in agreement with the experiment described by Montgomery and Hudson,[5] that the α-D-*manno*-heptulopyranose pentaacetate, in which the hydroxyl group at C2 is unsubstituted, is converted, readily and in high yield, by hydrogen bromide in glacial acetic acid to penta-*O*-acetyl-α-D-*manno*-heptulopyranosyl bromide. Likewise, the reaction of Helferich and Schmitz-Hillebrecht[8] is usually carried out with the fully acetylated sugar. We have found that the condensation of α-D-*manno*-heptulopyranose 1,3,4,5,7-pentaacetate with phenol, in the presence of *p*-toluenesulfonic acid as catalyst, can be effected although the yield in our only experiment was not so good as when we used the hexaacetate later. The product of these reactions was phenyl α-D-*manno*-heptulopyranoside pentaacetate, melting at 103–104° and showing $[\alpha]^{20}D$ +35.9° in chloroform; upon catalytic deacetylation it yielded phenyl α-D-*manno*-heptulopyranoside, melting at 181–183° and showing $[\alpha]^{20}D$ +89.6° in water.

In a recent paper[3] we reported that the reaction of phenyl α-D-*gluco*-heptulopyranoside with hot aqueous potassium hydroxide produced at least a 34% yield of 2,7-anhydro-β-D-*gluco*-heptulopyranose. Phenyl α-D-*manno*-heptulopyranoside appears to be degraded similarly to the extent of about 15%, and 8.4% of crystalline 2,7-anhydro-β-D-*manno*-heptulopyranose was isolated from the reaction mixture. In both cases there was extensive destruction of the remainder of the material. Earlier studies had shown that phenyl β-D-glucopyranoside is converted practically quantitatively to 1,6-anhydro-β-D-glucopyranose, and the reaction mechanism has been established satisfactorily.[9] Phenyl heptulosides, however, have a CH_2OH group attached to the glycosidic carbon atom (C2), and this situation tends to complicate the picture. Thus, we have suggested two possible, simple mechanisms for the degradation of phenyl α-D-*gluco*-heptulopyranoside to the anhydro sugar,[3] postulating inversion of configuration at the glycosidic carbon atom at each step. With phenyl α-D-*manno*-heptulopyranoside also, we may write similar one- and three-step reaction mechanisms. The first, delineated in the simplest manner, represents the reaction as involving elimination of the elements of phenol between C2 and C7, with inversion of configuraton at C2 (III → II). The alternate mechanism involves elimination of the elements of phenol between C2 and C3 and the formation of the 2,3-epoxide IV; this may be followed by rearrangement (reversible) to the 1,2-epoxide V, and a final rearrangement to the anhydro sugar II, which is stable to hot alkali. Other pathways may lead through the epoxide IV or through the isomeric 1,2-epoxide VI to free D-*manno*-heptulose (I), which is not stable to alkali and forms tarry decomposition products.

We hope that additional experiments now in progress on appropriately substituted heptuloses will contribute further to the study of these reaction mechanisms.

As a result of our earlier studies on the transformation of reducing sugars to monomeric, non-reducing anhydrides in dilute acid solution, we should expect that D-mannose, like D-*manno*-heptulose, would form an anhydride but to a smaller extent. This prediction was verified, even though it was necessary to heat 144 g. of D-mannose at about 83° in 0.2 *N* sulfuric acid in order to obtain, finally, 0.87 g. of crystalline 1,6-anhydro-2,3-*O*-isopropylidene-β-D-mannopyranose[10] for identification purposes. Although this amount represents only a 0.5% yield actually isolated, rotational data at several stages indicated that possibly as much as 0.7% of the D-mannose was transformed to its known anhydride under those conditions.

Experimental

2,7-Anhydro-β-D-*manno*-heptulopyranose (II) from D-*manno*-Heptulose (I).—After a preliminary experiment had led to the isolation of a crystalline anhydride, 100 g. of D-*manno*-heptulose in 800 ml. of 0.5 *N* sulfuric acid was boiled under a reflux condenser until the rotation had dropped from $[\alpha]^{20}D$ +29.2° to +18.5° (approximately constant) at the end of 3 hours. The solution was neutralized cautiously with aqueous barium hydroxide, filtered through carbon, and concentrated *in vacuo* to a sirup from which 60 g. of D-*manno*-heptulose was recovered by crystallization from ethanol. The remaining sugar was removed by heating its aqueous solution with excess barium hydroxide, neutralizing with sulfuric acid, filtering through carbon, and deionizing with Amberlite IR-120 and Duolite A-4 ion-exchange resins. The solution, upon concentration to a small volume, was levorotatory; it was concentrated further to a sirup that was crystallized from ethanol to yield a total of 3.3 g. of the anhydride. The 2,7-anhydro-β-D-*manno*-heptulopyranose separated as clusters of prisms from aqueous ethanol,

and after several recrystallizations melted at 159–160° and showed $[\alpha]^{20}D$ −80.4° in water (*c* 2.0).

Anal. Calcd. for $C_7H_{12}O_6$: C, 43.75; H, 6.30. Found: C, 43.54; H, 6.38.

After the experiments at 40, 60 and 80°, summarized in Table I, had been completed, a final run was made in which 21.02 g. of D-*manno*-heptulose in 1 liter of 0.2 *N* sulfuric acid was heated for 3 hours at 90°. The rotation $[\alpha]^{20}D$ +19.6° indicated the formation of 9.0% of 2,7-anhydro-β-D-*manno*-heptulopyranose, while an estimation of reducing sugar by the ferricyanide method indicated that 87.6% of the D-*manno*-heptulose remained. From an ultraviolet absorption spectrum of the very slightly colored solution we could estimate the presence of about 1.6 mole % of DHEF. The mixture was heated with excess barium hydroxide for 20 hours on the steam-bath, neutralized with carbon dioxide until the solution was no longer alkaline to phenolphthalein, filtered, deionized, and concentrated *in vacuo* to a small volume. At that point, the rotation of the solution corresponded to 1.73 g. (9.0%) of 1,6-anhydro-β-D-*manno*-heptulopyranose; crystallization from ethanol yielded 1.54 g. (8.0%) of material that upon recrystallization gave 1.38 g. (7.2%) of pure anhydride melting at 159–160°. The mother liquor from the 1.54 g., when examined by paper chromatography, showed only the anhydride and a trace of heptulose, with no evidence either of a furanose anhydride such as was obtained from D-*altro*-heptulose[2] or of a dimolecular dianhydride such as was obtained from D-*gluco*-heptulose.[3]

Oxidation of 2,7-Anhydro-β-D-*manno*-heptulopyranose (II) with Periodate.—The oxidation of 0.3865 g. of the anhydride with a 20% excess of sodium metaperiodate appeared to be complete within 1 hour at 20° as indicated by the constant rotation $[\alpha]^{20}D$ −17.3° (calculated as the expected dialdehyde). This value is comparable to the average −17.2° found for the four other anhydroheptuloses of this structure reported previously.[3] Titration of small samples at the end of 24 hours showed the consumption of 2.10 molar equivalents of oxidant and the liberation of 0.98 molar equivalent of formic acid. No formaldehyde could be detected. The remaining 90% of the solution was neutralized with barium hydroxide and enough additional barium ions were added as barium chloride to precipitate the iodate and periodate ions present. The solution (*p*H *ca.* 6.6) was concentrated *in vacuo* to dryness, and the dialdehyde extracted with 40 ml. of warm methanol. To the filtered solution was added 0.8 g. of 2,5-dichlorophenylhydrazine, and the mixture concentrated and heated on the steam-bath for 1 hour. Because inorganic material crystallized during this process, and especially when pentane was added to the methanol solution, it was necessary to concentrate finally on the steam-bath to a sirup and then extract the sirup with ether. Upon the addition of pentane to the clear ether solution, the product crystallized readily; wt. 0.6 g., m.p. 154–156°. After two recrystallizations, the m.p. was 157–158° and showed no depression when the material was mixed with an equal amount of 4-D-*glycero*-2-hydroxymethyl-1,3-dioxolane-2,4-*cis*-dicarboxaldehyde bis-2,5-dichlorophenylhydrazone derived in similar fashion from sedoheptulosan.[3] The rotation, $[\alpha]^{20}D$ +40.0° in chloroform (*c* 0.5), was in good agreement with the value +40.6° reported previously.

α-D-*manno*-Heptulopyranose 1,3,4,5,7-Pentaacetate and α-D-*manno*-Heptulopyranose Hexaacetate from the Acetylation of D-*manno*-Heptulose in Pyridine at 5°.—A suspension of 120 g. of D-*manno*-heptulose (powdered to pass through an 80-mesh sieve) in 600 ml. of dry pyridine was cooled in ice-water and to it was added 600 ml. of acetic anhydride. The mixture was shaken overnight at 5° and the resulting solution kept an additional 4 days at that temperature. The reaction mixture was then poured into 4 liters of cracked ice and water and left overnight in the refrigerator. The acetylated material was divided between the aqueous pyridine solution and the precipitated gum. The latter was dissolved in chloroform and the chloroform solution washed with ice-cold, dilute sulfuric acid and then with water, dried over sodium sulfate, filtered through a small amount of carbon, and concentrated *in vacuo* to a thin sirup. This was diluted with pentane and inoculated with seed crystals of "D-mannoheptulose α-hexaacetate" remaining from the earlier researches of Montgomery and Hudson.[5] The crystals grew slowly at room temperature into large prisms and after repeated additions of pentane during the next two weeks there was obtained 52.3 g. of product originally designated as the hexaacetate but now identified as α-D-*manno*-heptulopyranose 1,3,4,5,7-pentaacetate. After recrystallization from ether–pentane the pentaacetate melted at 105–106° and showed $[\alpha]^{20}D$ +39.4° in chloroform (*c* 2). Montgomery and Hudson[5] reported m.p. 110° and $[\alpha]^{20}D$ +39.0° in chloroform (*c* 2) for their "hexaacetate"; their original sample, now about 20 years old, melted at 99–103° and in admixture with our pentaacetate melted at 100–105°. After one recrystallization from ether, their sample melted at 104–106° with no depression of melting point when mixed with our pentaacetate. The infrared spectrum of their original sample in chloroform solution was practically identical with that of our pentaacetate, with both showing clearly a hydroxyl band at 3570 cm.$^{-1}$.

Anal. Calcd. for $C_{17}H_{24}O_{12}$: C, 48.57; H, 5.75; CH_3CO, 51.2. Found: C, 48.61, 48.49; H, 6.11, 5.93; CH_3CO, 52.6.

The chloroform–pentane mother liquor from the 52.3 g. of pentaacetate was concentrated to a sirup that was covered with about a liter of water and left at room temperature for two weeks with occasional stirring. At that time, small prismatic needles had begun to appear in the sirup and upon refrigeration for a week the sirup crystallized completely. The product was filtered, washed with water, and dried in the air; wt. 61.3 g. After recrystallization from 90 ml. of warm ethanol by the cautious addition of 90 ml. of water, the new, authentic α-D-*manno*-heptulopyranose hexaacetate melted at 85–88°, a value that was raised to 86–89° by additional recrystallizations in the same manner. The hexaacetate showed $[\alpha]^{20}D$ +41.5° in chloroform (*c* 1). Its ultraviolet absorption spectrum showed no absorption in the region of 280 mμ, indicating no ketone group and thus verifying the cyclic structure of the hexaacetate.

Anal. Calcd. for $C_{19}H_{26}O_{13}$: C, 49.35; H, 5.67; CH_3CO, 55.9. Found: C, 49.17; H, 5.51; CH_3CO, 56.1.

The original aqueous pyridine solution was extracted with chloroform, and the extract washed, dried and concentrated in the usual manner. Dilution of the residual thin

sirup with pentane afforded 62 g. of the pentaacetate. The mother liquor was concentrated to a sirup; extraction of this sirup by stirring with several liter portions of water removed the more soluble pentaacetate, which could then be extracted with chloroform. In this fashion an additional 9.3 g. of pentaacetate was isolated. The remaining, less soluble sirup yielded an additional 10.5 g. of hexaacetate. In summary, acetylation of 120 g. of D-*manno*-heptulose as described above furnished 123.6 g. (51.5%) of the 1,3,4,5,7-pentaacetate and 71.8 g. (27.2%) of the new hexaacetate.

Conversion of α-D-*manno*-Heptulopyranose 1,3,4,5,7-Pentaacetate to α-D-*manno*-Heptulopyranose Hexaacetate.—A solution of 5.4 g. of the pentaacetate in 25 ml. of pyridine and 25 ml. of acetic anhydride showed an initial rotation of $[\alpha]^{20}D$ +7°; after 5 days at 20° the rotation had become constant at $[\alpha]^{20}D$ +35°, calculated as the hexaacetate. The dark-colored solution was poured into ice-water and the mixture left in the refrigerator overnight. The crystalline hexaacetate was filtered, washed with cold water, and dried in the air. It weighed 4.7 g. (79%) and after recrystallization from aqueous ethanol melted at 85–88°.

Preparation of α-D-*manno*-Heptulopyranose Hexaacetate and of α-D-*manno*-Heptulopyranose 1,3,4,5,7-Pentaacetate at 20–25°.—When 21 g. of D-*manno*-heptulose was dissolved in 250 ml. of pyridine and 100 ml. of acetic anhydride added, the observed rotation at 20° in a 1-dm. tube dropped rapidly from +2.84 to +0.59° within an hour and then began to rise, with values of +1.97, +2.56, +2.98, +3.25 and +3.98° being observed at the end of 1, 2, 3, 4 and 7 days, respectively. The dark-colored reaction mixture was poured onto cracked ice and left at 5° overnight to crystallize. The resulting hexaacetate was filtered, washed with water, and dried; it weighed 21.2 g.; and an additional 17.4 g. was isolated by extraction of the aqueous pyridine solution with chloroform in the usual manner, giving a total yield of 38.6 g. (83.6%).

When the acetylation of D-*manno*-heptulose was interrupted near the point of minimum rotation, good yields of the 1,3,4,5,7-pentaacetate could be obtained. Preliminary experiments on 5-g. batches were run for 30, 45, 60, 75 and 90 minutes, and when these were poured onto cracked ice and left at 5° overnight, the portions of crystalline pentaacetate weighed 4.3, 5.3, 7.0, 6.6 and 5.5 g., respectively. The product thus obtained was a fairly unstable, pyridine-solvated form melting at 73–75°; it could be converted to the solvent-free modification by heating overnight at 55°, by longer standing at room temperature in the air or in an evacuated desiccator over concentrated sulfuric acid, or by recrystallization. In a final experiment, 10 g. of D-*manno*-heptulose was dissolved in 130 ml. of warm pyridine, the solution was cooled and to it was added 50 ml. of acetic anhydride. The reaction generated a small amount of heat. The solution was kept at 25° for 1 hour, poured into 500 ml. of ice-water, and the mixture allowed to stand for several hours at room temperature. Upon extracting with chloroform and washing the solution with cold acid in the usual manner, the resulting sirup weighed 18.7 g. Crystallization from ether–pentane afforded a total of 13.1 g. (65.5%) of D-*manno*-heptulose 1,3,4,5,7-pentaacetate

Penta-*O*-acetyl-α-D-*manno*-heptulopyranosyl Bromide from α-D-*manno*-Heptulopyranose 1,3,4,5,7-Pentaacetate.—Five grams of the pentaacetate was dissolved in 25 ml. of glacial acetic acid saturated with hydrogen bromide at 0°, the mixture left at room temperature for 2 hours, diluted with 60 ml. of chloroform, poured into ice-water, and the product isolated in the usual manner. The resulting sirup crystallized readily from ether, depositing 5.2 g. (90%) of prisms melting at 84–90°. After recrystallization from ether–pentane the bromide melted at 87–92° and showed $[\alpha]^{20}D$ +106° in chloroform (*c* 1), in good agreement with the values 92 and +104.0°, respectively, reported by Montgomery and Hudson.[5] In an unsuccessful attempt to condense 2.3 g. of the penta-*O*-acetyl-α-D-*manno*-heptulopyranosyl bromide with *p*-toluenethiol, 0.6 g. (30%) of D-*manno*-heptulopyranose 1,3,4,5,7-pentaacetate was recovered; it was undoubtedly formed as a result of hydrolysis of a portion of the bromide by the sodium salt of the thiol.

Phenyl α-D-*manno*-Heptulopyranoside Pentaacetate.—A fused mixture of 30 g. of α-D-*manno*-heptulopyranose hexaacetate, 27 g. of phenol and 1.5 g. of *p*-toluenesulfonic acid monohydrate was heated for 1 hour at 65–75° and 15 mm. pressure. The dark reaction mixture was dissolved in 450 ml. of chloroform and the solution washed twice with equal volumes of 3% aqueous sodium hydroxide and then with water, dried over sodium sulfate, filtered through decolorizing carbon, and concentrated to a thick sirup. Seed crystals were obtained by rubbing a small amount of the sirup with water and then allowing it to dry to a powdery residue. The remainder of the sirup was dissolved in warm ethanol and the solution cooled, seeded and diluted slowly with water. There was thus obtained 22.7 g. (70.5%) of shiny plates. After recrystallization in the same manner the phenyl α-D-*manno*-heptulopyranoside pentaacetate melted at 103–104° and showed $[\alpha]^{20}D$ +35.9° in chloroform (*c* 1); these values were unchanged by further recrystallizations. The same product was obtained when α-D-*manno*-heptulopyranose pentaacetate was used instead of the hexaacetate, but the yield was smaller.

Anal. Calcd. for $C_{23}H_{28}O_{12}$: C, 55.64; H, 5.69; CH_3CO, 43.4. Found: C, 55.83; H, 5.75; CH_3CO, 43.1.

Phenyl α-D-*manno*-Heptulopyranoside (III).—The catalytic deacetylation of 20.0 g. of phenyl α-D-*manno*-heptulopyranoside pentaacetate with sodium methoxide in methanol furnished 10.0 g. (87%) of the free glycoside. It separated as flat prisms from 3 parts of absolute ethanol and after two recrystallizations it melted at 181–183° and showed $[\alpha]^{20}D$ +89.6° in water (*c* 0.6).

Anal. Calcd. for $C_{13}H_{18}O_7$: C, 54.54; H, 6.34. Found: C, 54.63; H, 6.09.

2,7-Anhydro-β-D-*manno*-heptulopyranose (II) from Phenyl α-D-*manno*-Heptulopyranoside (III).—A solution of 9.9 g. of the phenyl glycoside in 250 ml. of *N* aqueous potassium hydroxide was boiled under a reflux condenser until the rotation became constant, after 3.5 hours, at $[\alpha]^{20}D$ −12° calculated as anhydroheptulose. On the assumption that the only optically active material present was the anhydro-*manno*-heptulose of $[\alpha]^{20}D$ −80.4°, the value $[\alpha]^{20}D$ −12° would correspond to a 15% yield. The dark-brown reaction mixture was made slightly acid with sulfuric acid to facilitate its decolorization with activated carbon; after that step the solution was neutralized to phenolphthalein with potassium hydroxide and concentrated *in vacuo*. The dry residue was extracted thrice by boiling with 100-ml. portions of absolute ethanol. The combined extracts were concentrated and an aqueous solution of the residual material was deionized by passage through Amberlite IR-120 and Duolite A-4 ion-exchange resins. The solution was concentrated *in vacuo* to a sirup whose solution in absolute ethanol deposited a total of 0.56 g. (8.4%) of chunky prisms. After one recrystallization from absolute ethanol the product melted at 156–159°, showed $[\alpha]^{20}D$ −77.9° in water, and suffered no depression of melting point when mixed with an equal amount of 2,7-anhydro-β-D-*manno*-heptulopyranose prepared by the action of acid on the sugar as described earlier in this paper.

2,7-Anhydro-β-D-*manno*-heptulopyranose Tetrabenzoate.—Benzoylation of 0.5 g. of the anhydride II in the usual manner yielded a sirup. This was dissolved in warm ethanol and left at 5° overnight. The gum that deposited was dissolved in chloroform and the solution clouded with pentane and left at −5° for several days. The thick prisms that separated were filtered and washed with pentane; wt. 1.0 g. The product appeared to melt at 38–39° to a viscous sirup, and the same melting point was observed after recrystallization from chloroform–pentane. However, attempts to obtain an analytical sample by drying in the air at 20–25° resulted in liquefaction and either chloroform or pentane of crystallization was suspected. The product showed no tendency to crystallize from ethanol. For analysis and rotation the sample was heated to constant weight at 77° in a high vacuum; $[\alpha]^{20}D$ −67° in chloroform (*c* 1.5).

Anal. Calcd. for $C_{35}H_{28}O_{10}$: C, 69.07; H, 4.64. Found: C, 68.94; H, 4.64.

2,7-Anhydro-β-D-*manno*-heptulopyranose Tetratosylate.—A mixture of 0.5 g. of the anhydride II and 4 g. of *p*-toluenesulfonyl chloride in 8 ml. of pyridine was kept at room temperature for 3 days and then poured onto cracked ice. A quantitative yield of the crystalline tosylate resulted. The product was recrystallized from 50 parts of absolute ethanol; it separated as fine needles that weighed 2.1 g. and melted at 145–147°. Recrystallization from chloroform–pentane then produced needles that melted at 85–100°, even after drying at 60° overnight, and the product may have

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

been solvated. A final recrystallization from ethanol gave the original, higher-melting form with m.p. 145–147° and $[\alpha]^{20}D$ +29.4° in chloroform (*c* 1.2).

Anal. Calcd. for $C_{35}H_{36}O_{14}S_4$: C, 51.97; H, 4.49; S, 15.85. Found: C, 52.24; H, 4.55; S, 15.65.

2,7-Anhydro-3,4-*O*-isopropylidene-β-D-*manno*-heptulopyranose.—A mixture of 1.0 g. of the anhydride II, 10 g. of anhydrous copper sulfate and 100 ml. of acetone was stirred mechanically for 48 hours, filtered and the solution concentrated to a sirup (1.26 g.) that crystallized spontaneously. From acetone–pentane there was obtained 0.85 g. of the *O*-isopropylidene derivative; it separated as clusters of acicular prisms and, after three recrystallizations, melted at 106–107° and showed $[\alpha]^{20}D$ −21.8° in water (*c* 2). Assignment of the *O*-isopropylidene group to the 3,4-positions is by analogy with 1,6-anhydro-β-D-mannopyranose and similar compounds.

Anal. Calcd. for $C_{10}H_{16}O_6$: C, 51.72; H, 6.95. Found: C, 51.70, 51.91; H, 6.91, 6.95.

1,6-Anhydro-β-D-mannopyranose from D-Mannose in Acid Solution and Isolation as Its 2,3-*O*-Isopropylidene Derivative.—Preliminary experiments showed that D-mannose suffered only negligible loss of rotatory power when a 0.1 *M* solution in 0.2 *N* hydrochloric acid was heated at 40° and at 60°. When a 0.2 *M* solution in 0.2 *N* hydrochloric acid was equilibrated overnight at 20° it showed $[\alpha]^{20}D$ +13.99°; after the solution had been heated at 80° for 3 and 6 hours, the rotations were +13.82 and +13.70°, respectively. For the attempted isolation of the expected very small amount of anhydride, three portions of D-mannose, totaling 144.13 g. and made to 4 liters at 20° in volumetric flasks with 0.2 *N* sulfuric acid, were allowed to stand overnight at that temperature. The rotations were $[\alpha]^{20}D$ +13.98, +13.96 and +14.06°. The first liter portion was heated 24 hours at about 70° and then showed $[\alpha]^{20}D$ +13.38°. The second liter portion was heated 32 hours at about 83° and then showed $[\alpha]^{20}D$ +13.24°. The third, 2-liter portion was heated 24 hours at about 83° and then showed $[\alpha]^{20}D$ +13.17°. These final values correspond to the presence of 0.5, 0.6 and 0.7%, respectively, of 1,6-anhydro-β-D-mannopyranose, calculated on the assumption that the solutions contained only D-mannose and its known anhydride. Reducing sugar determinations by the ferricyanide method indicated a small loss but the values were not considered reliable because the apparent change was less than the limit of accuracy of the method. Ultraviolet absorption data showed that less than 0.2% of 5-(hydroxymethyl)-2-furaldehyde was generated by heating D-mannose under these conditions.

The unchanged D-mannose in the 4 liters of solution was sacrificed by heating with excess barium hydroxide, and then neutralizing, filtering, deionizing and concentrating in the usual manner. The sirupy residue had a levorotation corresponding to 0.62 g. of the expected anhydride, but it weighed 9 g. and still contained material that reduced Fehling solution. Accordingly, it was treated again with barium hydroxide and the new sirup weighed 3.1 g. and had a levorotation corresponding to 0.91 g. (0.70%) of the expected anhydride. When an attempt to isolate 1,6-anhydro-β-D-mannopyranose by direct crystallization was unsuccessful, the sirup was extracted with 300 ml. of acetone at room temperature and the extract shaken with 10 g. of anhydrous copper sulfate for 42 hours. The filtered and concentrated solution crystallized readily. The product, isolated in two batches with the aid of 2-propanol and 1-butanol, weighed 0.87 g. (0.54%) and after one recrystallization from 1-butanol was identified as 1,6-anhydro-2,3-*O*-isopropylidene-β-D-mannopyranose[10] by melting point and mixed melting point of 160–161° and specific rotation $[\alpha]^{20}D$ −57.5° in water (*c* 1.8). Knauf, Hann and Hudson[10] reported m.p. 161–162° and $[\alpha]^{20}D$ −58.8° in water (*c* 2.08).

Acknowledgment.—The authors wish to thank Mr. John T. Sipes and Miss Rosemary Richtmyer, as well as several earlier workers in this Laboratory, for their preparations of D-*manno*-heptulose; Mr. William M. Jones and Mrs. Anne H. Wright for obtaining the infrared and ultraviolet absorption spectra, respectively; and Dr. William C. Alford and his associates of the Institutes' microanalytical laboratory for carrying out the microanalyses.

Crystalline 3-Deoxy-α-D-*ribo*-hexose. Preparation and Properties of 1,6-Anhydro-3-deoxy-β-D-*arabino*-hexopyranose, 1,6-Anhydro-3-deoxy-β-D-*ribo*-hexopyranose and Related Compounds[1,2]

BY JAMES W. PRATT AND NELSON K. RICHTMYER

RECEIVED DECEMBER 14, 1956

3-Deoxy-D-*arabino*-hexose and 3-deoxy-D-*ribo*-hexose have been shown to form their 1,6-anhydrides in aqueous acid to the extent of 29 and 10%, respectively. The 1,6-anhydrides were characterized as their di-*O*-acetyl derivatives. 3-Deoxy-α-D-*ribo*-hexopyranose and the phenyl 3-deoxy-α- and β-D-*ribo*-hexopyranosides have been obtained crystalline.

When LaForge and Hudson[3] established that hot aqueous acid acts on sedoheptulose (= D-*altro*-heptulose) to form a non-reducing anhydride, they were led to assume that this sugar is unique in this respect since their observation had no precedent, and, of course, many sugars had previously been subjected to such conditions on many occasions. An extension of this idea to include all sugars possessing the *altro* configuration was strongly suggested by the fact that D-altrose exhibits the same property.[4] Subsequently, the results of a number of investigations in this Laboratory have shown that although the amount of anhydride at equilibrium varies from more than 90% to less than 1%, the reaction is quite general among the aldohexoses, aldoheptoses and heptuloses.

Reeves[5] has sought to explain the ease of formation of the altrose[4] and idose[6] anhydrides in dilute aqueous acid in terms of the ring conformation of the parent aldohexose. His suggestion that the conformation of the β-D-pyranose ring exerts a con-

trolling influence should, perhaps, be broadened to include the α-D-pyranose ring as well, since we are dealing with a complex equilibrium and thus are concerned mainly with the question of thermodynamic stability. The stability of the anhydride itself is perhaps the most important factor; next in importance is the question of the relative stabilities of any and all of the tautomers, anomers and conformational isomers of the free sugar.

Since the generality of the reaction has been established, we are faced with the modified problem of evaluating the several steric factors which influence the extent to which the "forward" reaction proceeds (sugar ⇄ anhydride). Reeves' "instability factors"[7] serve as a useful guide in this area, but in the light of recent data they are somewhat inadequate except for idose and altrose at one end of the scale and glucose and mannose at the other.

From some recent data, particularly the amount of 1,6-anhydroallose[8] which resulted from this reaction, we have been led to the idea that the hydroxyl group on C3 plays a very prominent role in controlling the point of equilibrium. If this is true, a 3-deoxy sugar should react much more readily than the less reactive member of a 3-epimeric pair. A diminished reactivity compared with the more reactive epimer would be expected since a favorably situated hydroxyl not only would not interfere with bridge formation but, by introducing an "instability factor" in the opposite chair conformation, would increase the probability of the favorable orientation. In order to test this hypothesis we have prepared 3-deoxy-D-*arabino*-hexose, which is related to D-mannose and D-altrose, and 3-deoxy-D-*ribo*-hexose, related to D-glucose and D-allose. Our hypothesis is supported by the observations that at equilibrium in aqueous acid the amount of anhydride (molar basis) formed from 3-deoxy-D-*arabino*-hexose is 29% (*cf.* from D-mannose <1%[2]; from D-altrose 57%[4]); and from 3-deoxy-D-*ribo*-hexose 10% (*cf.* from D-glucose 2% or less[9]; from D-allose 14%[8]). We are at present engaged in extending this study to the remaining 3-deoxy-D-hexoses, and for this reason prefer not to argue too strongly for the hypothesis until the remaining data are available.

3-Deoxy-D-*arabino*-hexose (III), as its methyl 4,6-*O*-benzylidene-α-pyranoside derivative (I), was prepared uneventfully from methyl α-D-glucoside by the multistep method of Prins,[10] which employs as intermediates methyl 4,6-*O*-benzylidene-α-D-glucopyranoside, the corresponding 2-*p*-tolylsulfonyl ester, and the 2,3-anhydro-D-mannose derivative.[11] Hot, aqueous acid effected the hydrolytic removal of benzaldehyde and the aglycon, and continued heating resulted in the formation of an appreciable amount of the 1,6-anhydro sugar. The remaining free sugar was removed by heating the solution with excess barium hydroxide and subsequent deionization. Although the anhydride failed to crystallize, it was characterized through its crystalline dibenzoate and diacetate. The rotation ($[\alpha]^{20}D$ −156°) of the 1,6-anhydro-3-deoxy-β-D-*arabino*-hexopyranose (II) and the point of equilibrium between sugar and anhydride in the presence of acid were determined in solutions obtained by careful saponification of the pure diacetate. The free anhydride was not oxidized by periodate.

3-Deoxy-D-*ribo*-hexose (VII) was prepared, as its methyl 4,6-*O*-benzylidene-α-pyranoside derivative, from methyl 4,6-*O*-benzylidene-α-D-glucopyranoside also, but *via* the 2,3-di-*p*-tolylsulfonyl ester and the 2,3-anhydro-D-allose derivative.[11] Catalytic hydrogenolysis of the 2,3-anhydro compound[10,12] yielded methyl 3-deoxy-α-D-*ribo*-hexopyranoside as a sirup which was identified by the preparation of the crystalline 4,6-*O*-benzylidene derivative.

Acetylation of methyl 3-deoxy-α-D-*ribo*-hexo-

pyranoside followed by acetolysis produced a sirupy mixture of acetates (presumably tetraacetates). This mixture was heated with phenol in the presence of *p*-toluenesulfonic acid,[13] the product deacetylated, and phenyl 3-deoxy-β-D-*ribo*-hexopyranoside (V) obtained crystalline. Treatment of the phenyl glycoside with hot, strong caustic followed by appropriate purification afforded the desired 1,6-anhydride as a sirup which could not be induced to crystallize. A crystalline diacetate was readily obtained, however, and this derivative was used for subsequent studies in the manner outlined for the epimer. The rotation of the 1,6-anhydro-3-deoxy-β-D-*ribo*-hexopyranose (VI) is $[\alpha]^{20}D$ −79.9°. The anhydride was not oxidized by periodate.

We desired to obtain the sugar VII in as pure a form as possible, and so prepared the crystalline tetra-*O*-acetyl derivative first reported by Černý and Pacák.[14] Catalytic deacetylation of this material yielded the sugar as small needles melting at 105.5–107° and mutarotating in water from +102° (initial, extrapolated) to +32.2° (final, 3 hours); the rotatory data indicate that the 3-deoxy-*ribo*-hexose is the α-D-pyranose form. It is of interest to note that the equilibrium rotation of the sugar is in excellent agreement with the value +31.8° calculated from the data obtained by the equilibration of the anhydride in aqueous acid.

Experimental

Methyl 4,6-*O*-Benzylidene-3-deoxy-α-D-*arabino*-hexopyranoside (I).—Lithium aluminum hydride reduction of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside in the manner reported by Prins[10] led smoothly and in good yield to a product which after recrystallization, first from ether–pentane and then from aqueous methanol, melted at 111.5–113° and showed $[\alpha]^{20}D$ +95.5° in chloroform (*c* 2.2). Prins reports m.p. 111–112° and $[\alpha]^{20}D$ +107.3 ±2° in chloroform (*c* 0.941); Bolliger and Prins previously reported +95.0° (*c* 2.904) in chloroform.[15]

Anal. Calcd. for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81. Found: C, 63.22; H, 6.70.

Action of Dilute Aqueous Acid on Methyl 4,6-*O*-Benzylidene-3-deoxy-α-D-*arabino*-hexopyranoside (I).—A sample of I weighing 1.0163 g. was suspended in 0.2 *N* hydrochloric acid and allowed to stand at room temperature to effect solution. After 18 hours the volume was made to 50.0 ml. with water and the optical activity observed as $\alpha^{20}D$ +6.53° in a 4-dm. tube. The solution was heated to 100° and the rotation was observed to change in 3 hours to −0.72°, unchanged by heating an additional seven hours. This treatment was repeated with 5 g. of I. After a 3.5-hour heating period the solution was transferred to a silver flask, made strongly alkaline with barium hydroxide, and heated 2 hours to destroy the remaining sugar. The solution was neutralized with solid carbon dioxide, filtered, deionized by passage through Amberlite IR-120 and Duolite A-4, and concentrated *in vacuo* to a thick sirup of 1,6-anhydro-3-deoxy-β-D-*arabino*-hexopyranose (II) which weighed 1.2 g. The material has not as yet crystallized.

1,6-Anhydro-2,4-di-*O*-benzoyl-3-deoxy-β-D-*arabino*-hexopyranose.—The sirupy anhydride (II, 1.2 g.) was dissolved in 10 ml. of dry pyridine and 2.5 ml. of benzoyl chloride added. The mixture was allowed to stand four hours at room temperature and was then poured over a mixture of ice and solid sodium bicarbonate, and worked up in the usual manner. A few crystals were obtained from a chloroform solution of the benzoate by the addition of pentane, and these were used successfully to seed the ethanol solution of the sirup which yielded 1.5 g. of water-white, prismatic needles which on further recrystallization melted at 120–121.5° and showed a rotation $[\alpha]^{20}D$ −203.7° in chloroform (*c* 1.6).

Anal. Calcd. for $C_{20}H_{18}O_6$: C, 67.79; H, 5.13. Found: C, 67.88; H, 5.21.

1,6-Anhydro-2,4-di-*O*-acetyl-3-deoxy-β-D-*arabino*-hexopyranose.—The anhydride dibenzoate (18 g.) was debenzoylated catalytically and freed from methanol by evaporation in a stream of air and from methyl benzoate by extraction with ether. The sirupy anhydride was acetylated by the acetic anhydride–fused sodium acetate procedure and the resulting product (virtually quantitative) worked up in the usual way. Recrystallized first from ether–pentane and then from 10 parts of absolute ethanol, and dried overnight at 65° the white, prismatic needles melted at 99.5–101° and showed $[\alpha]^{20}D$ −139.2° in chloroform (*c* 0.37).

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13; CH_3CO, 37.4. Found: C, 51.88; H, 6.30; CH_3CO, 37.1.

Optical Activity of 1,6-Anhydro-3-deoxy-β-D-*arabino*-hexopyranose (II).—The anhydride diacetate (0.4260 g.) was saponified at room temperature with 5 ml. of *N* sodium hydroxide solution. After five hours, 5 ml. of *N* hydrochloric acid was added, the volume made to 25.0 ml. with water, and the rotation observed in a 4-dm. tube: $\alpha^{20}D$ −6.76°. From this value the specific rotation of the anhydride is calculated to be $[\alpha]^{20}D$ −156°.

Equilibrium in Acid Solution between 3-Deoxy-D-*arabino*-hexose (III) and its 1,6-Anhydride (II).—The anhydride diacetate (2.3092 g.) was saponified as before. After saponification, sufficient 5 *N* hydrochloric acid was added to make the final solution (50.0 ml.) 0.6 *N* in hydrochloric acid. The solution was allowed to stand 40 days at 41° during which time the observed rotation in a 4-dm. tube changed from −18.35° (extrapolated to zero time) to −0.94°; this value did not change during an additional 20 days. An estimation of aldose sugar by the iodine–alkali method[16] gave a value of 7.12 mmoles of aldose or 71.0% on a molar basis. It is assumed that the remaining 29.0% is the anhydride II. From these data the rotation of the 3-deoxy-D-*arabino*-hexose can be calculated as $[\alpha]^{20}D$ +46.8°. This is considerably higher than the value +17.7 ±2° reported by Bolliger and Prins[15] for their sirup. However, their material had been heated 3 hours at 100° in 0.75 *N* sulfuric acid and undoubtedly contained considerable levorotatory anhydride II.

Attempted Oxidation of 1,6-Anhydro-3-deoxy-β-D-*arabino*-hexopyranose (II) with Sodium Metaperiodate.—Di-*O*-acetyl-1,6-anhydro-3-deoxy-β-D-*arabino*-hexopyranose (0.2470 g.) was saponified by treatment with 5 ml. of *N* sodium hydroxide solution at room temperature for five hours. The alkali was neutralized by the addition of *N* sulfuric acid, 5 ml. of a 0.45 *M* solution of sodium metaperiodate added, and the volume made to about 20 ml. with water. After being allowed to stand in the dark at room temperature overnight, the solution was further diluted to a volume of 25.0 ml. and 5-ml. aliquots were tested for periodate consumption. The titration difference (0.08 ml.) was of the order of the limit of experimental error.

Phenyl 3-Deoxy-β-D-*ribo*-hexopyranoside (V).—Methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside was hydrogenolyzed at 110° under a hydrogen pressure of 2000 p.s.i. in the presence of Raney nickel. Rebenzylidenation of the sirupy methyl 3-deoxy-D-*ribo*-hexoside (IV) yielded methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*ribo*-hexopyranoside which showed a specific rotation in chloroform $[\alpha]^{20}D$ +121.5° (*c* 2), which is considered to be not significantly different from the reported value +115.8°.[12] In subsequent runs, the purified sirupy methyl glycoside was acetylated with acetic anhydride and sodium acetate and then acetolyzed with acetic anhydride containing 2% sulfuric acid by volume. The sirupy mixture of acetates was worked up in the usual way. To 100 g. of mixed acetates were added 100 g. of phenol and 2 g. of *p*-toluenesulfonic acid monohydrate and the fused mass was heated under reduced pressure at 65–75° for 1.5 hr.[13] The resulting product, isolated in the usual manner, failed to crystallize and so was deacetylated catalytically. On removal of solvents the mixture crystallized in part to yield 10.8 g. of material

which on recrystallization from 15 parts of hot water melted at 183–185° and showed $[\alpha]^{20}D$ −94.0° in water (*c* 0.27).

Anal. Calcd. for $C_{12}H_{16}O_5$: C, 60.00; H, 6.71. Found: C, 60.07; H, 6.84.

1,6-Anhydro-3-deoxy-di-*O*-acetyl-β-D-*ribo*-hexopyranose.—A suspension of 6.9 g. of phenyl 3-deoxy-β-D-*ribo*-hexopyranoside (V) in 200 ml. of 2.6 *N* aqueous sodium hydroxide was heated for 19 hours at 100° in a silver flask. The clear, pale-yellow solution was neutralized with 3 *N* sulfuric acid, concentrated *in vacuo* to a paste of sirup and crystals, and the slurry extracted thrice with 150-ml. portions of absolute ethanol. The extract was filtered, and the solvent removed *in vacuo* leaving 4.3 g. of sirup which failed to crystallize. Acetylation with acetic anhydride and sodium acetate resulted in the production of 4 g. (45% based on the phenyl glycoside) of crystalline material which on recrystallization from absolute ethanol melted at 114–116° and showed $[\alpha]^{20}D$ −74.0° in chloroform (*c* 0.7).

Anal. Calcd. for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13; CH_3CO, 37.4. Found: C, 52.00; H, 6.13; CH_3CO, 37.0.

Optical Activity of 1,6-Anhydro-3-deoxy-β-D-*ribo*-hexopyranose (VI).—The anhydride diacetate (0.2475 g.) was saponified in *N* sodium hydroxide at room temperature. After 3 hours an equivalent amount of *N* sulfuric acid was added, the volume made to 25.0 ml., and the rotation observed. By this procedure the anhydride VI was found to show $[\alpha]^{20}D$ −79.9°.

Attempted Periodate Oxidation of 1,6-Anhydro-3-deoxy-β-D-*ribo*-hexopyranose (VI).—To 20.0 ml. of the solution referred to in the paragraph above was added 5 ml. of a 0.45 *M* solution of sodium metaperiodate and the volume was made to 50.0 ml. After 20 hours in the dark at 20°, the solution was found to show $[\alpha]^{20}D$ −83.4°; after 9 days the specific rotation was −78.5°. These values do not differ significantly from that established for the anhydride. Periodate consumption in 20 hours was found to be 0.1 mole/mole.

Equilibrium in Acid Solution between 3-Deoxy-D-*ribo*-hexose (VII) and its 1,6-Anhydride (VI).—To 1.3953 g. of anhydride diacetate in a 50.0-ml. volumetric flask was added 6 ml. of 5 *N* sodium hydroxide solution. After 2 hours at room temperature, 10 ml. of 5 *N* hydrochloric acid was added, the volume made to the mark with water, and the solution placed in an oven at 60–62°. In five days the rotation became constant. The aldose content of the equilibrated solution, estimated by the alkali-iodine method,[16] was found to be 89.8% (molar basis). By the method given above for the epimeric system it can be shown that the specific rotation of 3-deoxy-D-*ribo*-hexose (VII) is $[\alpha]^{20}D$ +31.8°.

3-Deoxy-D-*ribo*-hexose.—Tetra-*O*-acetyl-3-deoxy-D-*ribo*-hexose was prepared from the sirupy product of the hydrolysis of methyl 3-deoxy-α-D-*ribo*-hexopyranoside (IV) using the sodium acetate in hot acetic anhydride procedure employed by Černý and Pacák.[14] After recrystallization from absolute ethanol our product melted at 129–130° in agreement with the literature value but showed $[\alpha]^{20}D$ −14° in chloroform (*c* 1) in contrast with the value −20° reported by the earlier authors.

Anal. Calcd. for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07. Found: C, 50.45; H, 6.06.

The acetate (1.0 g.) under 10 ml. of methanol was cooled to 3° and 0.2 ml. of *N* sodium methoxide in methanol was added. Solution was effected in four hours at that temperature. After two additional hours the base was destroyed by the addition of 2 drops of glacial acetic acid and the solvents were removed *in vacuo*. The sirupy product, taken up in absolute ethanol, was induced to crystallize and yielded 0.36 g. of material in the form of clusters of very small needles. Deposition of material was remarkably slow. On recrystallization from absolute ethanol the 3-deoxy-D-*ribo*-hexose melted at 105.5–107° and showed in water (*c* 1) $[\alpha]^{20}D$ +102° (initial, extrapolated) → +97.0° (2.5 min.) → +32.2° (3 hours; constant).

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 43.79; H, 7.24.

Phenyl 3-Deoxy-α-D-*ribo*-hexopyranoside (VIII).—An attempt was made to prepare the 1,6-anhydro-3-deoxy-β-D-*ribo*-hexopyranose by the alkaline hydrolysis of a mixture of the anomeric phenyl glycopyranosides. A crystalline product was obtained which on recrystallization from ethanol-ether melted at 136–138° and showed $[\alpha]^{20}D$ +172° in water. Rotational and analytical data as well as the method of preparation indicate that the compound is phenyl 3-deoxy-α-D-*ribo*-hexopyranoside which, as might be expected, was not affected by hot, aqueous alkali. The substance, unlike its anomer, is very soluble in water and alcohol.

Anal. Calcd. for $C_{12}H_{16}O_5$: C, 60.00; H, 6.71. Found: C, 60.33; H, 6.88.

Acknowledgment.—The authors wish to thank Mr. John T. Sipes for the preparation of both of the 2,3-anhydro intermediates, Mr. Edward W. Tracy for assistance with several steps of the procedures, and Dr. William C. Alford and his associates of the Institutes' Microanalytical Laboratory for the elemental analyses.

The Absence of an Amadori Rearrangement in Glucosazone Formation[1]

BY FELIX FRIEDBERG[2] AND LOUIS KAPLAN

RECEIVED JANUARY 21, 1957

Glucose-1-*t* is converted to its phenylosazone without loss of tritium. This observation invalidates any mechanism of osazone formation requiring an intermediate with two hydrogen atoms on carbon-1, including the Amadori rearrangement proposed by Weygand.

The classical scheme of Emil Fischer for osazone formation suffers from the difficulty of accounting for the oxidizing action of phenylhydrazine. In order to overcome this difficulty, Weygand[3] has proposed that the phenylhydrazone first formed rearranges, producing a carbonyl group at an adjacent carbon which then condenses with more phenylhydrazine. He has suggested two paths for the reaction, as shown by (A) and (B) in the chart. Path B, which involves an Amadori rearrangement,[4]

(1) Work performed under the auspices of the U. S. Atomic Energy Commission.

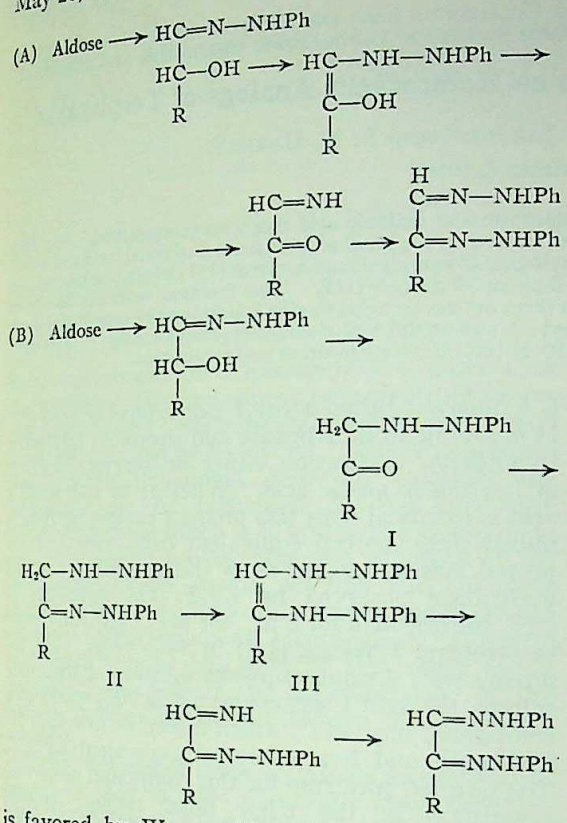
(2) College of Medicine, Howard University. Resident Research Associate, Argonne National Laboratory, 1956.

(3) F. Weygand, *Ber.*, **73**, 1284 (1940).

(4) Although the enolization involved in path A is sometimes referred to as an Amadori rearrangement (W. W. Pigman and R. M. Goepp, Jr., "Chemistry of the Carbohydrates," Academic Press, Inc., New York, N. Y., 1948, p. 405), J. E. Hodge (*Advances in Carbohydrate Chem.*, **10**, 169 (1955)) recommends that this designation be reserved for the complete conversion of a N-substituted aldosylamine to a 1-amino-1-deoxy-2-ketose.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri



is favored by Weygand,[5] and this mechanism is cited by several reviewers.[6,7]

The preparation of glucose-1-*t* in connection with another problem[8] has permitted a test of Weygand's mechanism B. In this scheme the hypothetical isoglucosamine intermediate I contains two hydrogen atoms on carbon atom 1, one of which is subsequently lost. Any osazone formed by way of this intermediate from glucose-1-*t* would therefore contain less tritium than the original glucose. Since, in fact, the phenylosazone had a molar activity identical with that of the glucose, it must be concluded that I is not an intermediate in glucosazone formation.

Experimental

D-Glucose-1-*t* was prepared by reduction[9] of δ-gluconolactone with sodium borohydride-*t*.[10] The details of the preparation and purification will be described elsewhere.[8] After crystallization in the α-form,[11] the material melted at 146° and had an initial specific rotation of +103°. A portion of the glucose was converted[12] to the β-pentaacetate, m.p. 129–131°. Another portion was heated with phenylhydrazine, acetic acid and sodium acetate to form[13] the phenylosazone, m.p. 202° dec., some of which was oxidized[13] with copper sulfate to the osotriazole, m.p. 195°. The derivatives were recrystallized to constant specific activity as listed in Table I. More than 99% of the tritium in the glucose was shown, by oxidation to calcium gluconate, to be on carbon atom 1.

Tritium assays were performed by ion-current measurement[14] on the gas obtained by the zinc fusion procedure.[15] Replicate determinations on each compound had an average deviation of less than 1%.

Discussion

The results in Table I show that, within an uncertainty of about 1%, there is no loss of tritium during the formation of the phenylosazone from glucose-1-*t*.[16] In the absence of an isotope effect, one-half of the tritium should have been lost if the phenylosazone had been formed from the isoglucosamine derivative I. It is extremely unlikely that the practically quantitative retention of tritium can be explained on the basis of an isotope effect, since an isotopic rate ratio, k_H/k_T, of at least fifty would have to be postulated for the hydrogen migration II → III. It must, therefore, be concluded that Weygand's path B cannot be the principal mechanism of osazone formation, at least in the case of glucose.

TABLE I

Compound	Activity μc./g.	Activity μc./mmole
α-D-Glucose	39.7	7.15
β-D-Glucose pentaacetate	18.0	7.03
Phenyl-D-glucosazone	19.9	7.13
Phenyl-D-glucosotriazole	26.7	7.08

Of the other mechanisms which have been proposed for osazone formation, Weygand's path A is not affected by the isotopic results reported here. It has, however, been challenged[17] (along with path B) on the ground that it does not explain why osazone formation is favored by an electron-attracting group on the phenylhydrazine. The mechanism of Braude and Forbes,[18] patterned after that of Kenner and Knight,[19] overcomes this objection and is consistent with the isotopic results. The alternative proposed[17] by Bloink and Pausacker for osazone formation from benzoin would, if applied to glucose, involve as an intermediate the isoglucosamine derivative I of Weygand's path B and cannot, therefore, be correct for this case.

2-Pyrones. XXV. 3,6-Diaryl-2-pyrones as Heterocyclic Analogs of Terphenyl

BY RICHARD H. WILEY,[1a] C. H. JARBOE[1b] AND F. N. HAYES[1c]

RECEIVED NOVEMBER 3, 1956

The synthesis of 6-phenyl-2-pyrone from phenylpropargyl aldehyde and malonic acid has been re-examined. Previous structural assignments for the products of the reaction have been revised on the basis of additional analytical data and infrared absorption characteristics. The principal product is 4-phenylbuten-3-yne-1,1-dicarboxylic acid (I) which can be cyclized to 3-carboxy-6-phenyl-2-pyrone (II). Decarboxylation gives 6-phenyl-2-pyrone (III). This reaction sequence has been extended to the condensation of phenylpropargyl aldehyde with three arylacetic acids to give 2,5-diphenylpenten-2-yne-4-oic acid (V), 3,6-diphenyl-2-pyrone (VI) and the related β-naphthyl-, *p*-biphenylyl and *p*-methoxyphenyl analogs. Introduction of the electron donor methoxy group results in lowered yields in both the condensation and cyclization.

The use of some of their heterocyclic analogs as replacements for *p*-terphenyl and *p*-quaterphenyl solutes in liquid scintillation counters has been sufficiently successful[2] to justify the continued exploration of related structural types. Such an effort is complicated by the fact that the *p*-polyphenyl structure, which is desired because the maximum scintillation response appears to be associated with the maximum resonance stabilization of the *para* structure, corresponds to a 1,4-diaryl heterocyclic structural type which is comparatively unknown. This study was undertaken to develop syntheses for a variety of 1,4-(*p*-)diaryl heterocycles to be examined in terms of their effectiveness as scintillators relative to *p*-terphenyl as a standard. In the present paper we wish to describe the preparation and characterization of a series of 3,6-diaryl-2-pyrones.

The possibility of preparing a 3,6-diaryl-2-pyrone by a modification of the synthesis originally described by Kalff[3] for the synthesis of 6-phenyl-2-pyrone was selected as the most attractive route to these structures. This synthesis as originally described involved the condensation of phenylpropargyl aldehyde with malonic acid to form an unstable compound, m.p. 208–218°, assigned the structure 6-phenyl-2-pyrone-3-carboxylic acid (II). This was reported to undergo decarboxylation in acetic acid at room temperature to give 6-phenyl-2-pyrone (III), m.p. 68°, and at steam-bath temperatures to give a compound, m.p. 218°, assigned the structure of a dilactone (IV) on the basis of its insolubility in bicarbonate, solubility in sodium hydroxide and stability toward decarboxylation.

On repeating the condensation we obtained only one product, m.p. 214–218°, regardless of the temperatures used, which could not possibly be II or IV on the basis of its characteristics. These include the presence of a strong maximum at 2210 cm.$^{-1}$ in the infrared absorption spectrum, which establishes that it is a disubstituted acetylene,[4] and a neutral equivalent of 108. Together these data indicate that the structure of this compound is 4-phenyl-1-buten-3-yne-1,1-dicarboxylic acid (I). It is soluble in bicarbonate and shows no tendency to undergo cyclization either on recrystallization or heating in acetic acid. Whether or not Kalff's acid is identical with this product cannot be determined since neutral equivalent data were not reported, but it does not show the instability toward cyclization observed by Kalff. On refluxing in 50% sulfuric acid for 3 hr., the acid I was converted to 6-phenyl-2-pyrone (III) in 54% yield. On refluxing with a dilute aqueous solution of mercuric sulfate, the acid I was converted in 80% yield to a compound, m.p. 214°, which is soluble in warm bicarbonate and has a neutral equivalent of 216. The infrared spectrum for this compound shows no absorption in the triple bond region, typical 2-pyrone carbonyl absorption at 1735 cm.$^{-1}$ and associated carboxyl carbonyl absorption at 1775 cm.$^{-1}$.[5] It shows absorption maxima in the ultraviolet at 240 mμ (log ε 3.73) and 345 mμ (log ε 4.17) as does also 6-phenyl-2-pyrone (235 mμ, log ε 3.92 and 330 mμ, log ε 4.12). It is readily converted in 67.5% yield to 6-phenyl-2-pyrone on refluxing with 50% sulfuric acid. On the basis of these data we believe this product to be 6-phenyl-2-pyrone-3-carboxylic acid (II). Again absence of a neutral equivalent for the compound obtained by Kalff makes it impossible to say definitely that the material he had is identical with ours.

In extending this reaction to the condensation of acrylacetic acids with phenylpropargyl aldehyde, it was found that this modification of the reaction proceeds best as a Perkin reaction. In acetic anhydride solution with sodium acetate as a catalyst 30–90% yields of the acetylenic acid V were obtained. Table I summarizes the yields obtained and the data characterizing the products from phenylacetic acid and the four substituted phenylacetic acids used. It can be seen that electron donor substituents in the aryl nucleus of the arylacetic acid decrease the yield significantly. The best yields and an increased reaction rate resulted using the *p*-biphenyl and α-naphthyl derivatives in which the *p*-biphenyl and α-naphthyl groups presumably are more effective electron-attracting groups than is the unsubstituted phenyl group. What little information is available[6] indicates that this is contrary to the effect usually produced by electron-attracting substituents in the aryl nucleus of the arylacetic acid in Perkin reactions.

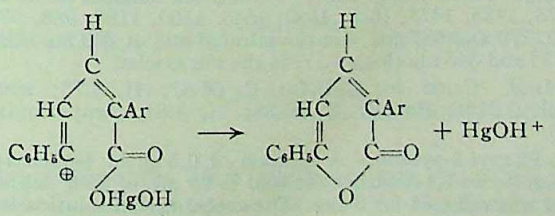
Such comparisons are of questionable validity since the available data are almost exclusively those for reactions using *o*-nitrobenzaldehydes in which steric effects must be important. Electron-attracting substituents should, however, facilitate the formation of the carbanion derived from the mixed anhydride which is to add to the aldehyde in accordance with usually accepted concepts of the mechanism of the Perkin reaction and therefore should, if this is an important factor, facilitate the reaction. This apparent inconsistency indicates that more precise data defining this effect would provide a more adequate understanding of the factors involved in the mechanism of the Perkin reaction.

The structures of these acetylenic acids are confirmed by their infrared absorption characteristics. They show typical disubstituted acetylene stretching absorptions of medium intensity between 2188 and 2205 cm.$^{-1}$, bonded hydroxyl stretching vibrations of medium intensity and very broad at 2800–3200 cm.$^{-1}$, C—O stretching or O—H deformation vibrations at 1412 and 1430 cm.$^{-1}$, and very strong carbonyl stretching vibrations at 1660–1680 cm.$^{-1}$, and the characteristic acid bands in the 1250–1268 cm.$^{-1}$ region.

Cyclization of the 2-aryl-5-phenylpenten-2-yne-4-oic acids (V) to the corresponding 3-aryl-6-phenyl-2-pyrones (V) takes place in aqueous organic solvents with mercuric sulfate catalyst. The choice of solvent and temperature and the role of the substituents in the aryl group are all important factors in the reaction. The phenyl analog is formed in 40–60% yields in 2.5 hr. in aqueous acetone or dioxane. Under otherwise similar conditions, 12.5-hr. reaction times are required to obtain similar yields of the β-naphthyl compound. A reaction time of 24 hr. and a much higher catalyst concentration are required to obtain at best 20% yields of the *p*-biphenyl derivative, and it is necessary to use aqueous methanol as the solvent for the cyclization of the *p*-methoxyphenyl derivative since only resins were obtained using dioxane or acetone. No satisfactory conditions could be found for the cyclization of the *m*-methoxyphenyl compound. A crystalline mercuric salt of the acid precipitated from all reaction media tried and could not itself be successfully cyclized. Because these conditions are obviously highly critical, the details of each reaction are given in the Experimental section. Data upon which the selection of these conditions was based will not be recorded here.

The pyrones isolated from these reactions are all yellow, crystalline materials with infrared absorption in the carbonyl stretching range at 1695 to 1712 cm.$^{-1}$. This displacement to frequencies below the 1720 cm.$^{-1}$ carbonyl frequency usually associated with the carbonyl stretching vibration in 2-pyrones[7] has been observed in other 3-substituted 2-pyrones.[8] This carbonyl absorption is displaced much too far toward higher frequencies to be confused with the β-substituted-5-membered lactone carbonyl absorptions.[9] This eliminates the possibility that cyclization has given a γ-lactone. In contrast to the acetylenic acids, absorption in the conjugated carbon–carbon unsaturation region is noted at 1620–1650 cm.$^{-1}$ as a band of medium intensity. The ultraviolet spectra of the 3-aryl-6-phenyl-2-pyrones show two maxima, as do other 2-pyrones,[10] but the frequencies are displaced to 245–265 mμ (log ϵ 4.00–4.27) and 360–370 mμ (log ϵ 4.10–4.56). This shift to longer wave lengths presumably is due to the additional conjugation.

The cyclization of these acids may be visualized as proceeding through initial hydration of the triple bond followed by lactonization or through cyclic addition of the carboxylic acid to the triple bond. The fact that the reactions require aqueous media suggests that hydration may be involved. In the addition of acetic acid to acetylene, traces of water result in acetaldehyde formation indicating a more rapid rate for the hydration reaction than for the addition of the acid. Initial attack by a proton at the γ-carbon atom followed by cyclization through displacement of the oxymercuri group offers a more direct mechanism, but this simplicity is perhaps misleading.



These compounds were examined by the Biomedical Research Group of the Los Alamos Laboratories of the University of California for activity as solutes in standard liquid scintillation counting systems. The results of this testing indicate that even though these materials are strongly fluorescent, they are not effective as scintillators. None

Experimental[11]

The phenylpropargyl aldehyde, malonic acid and arylacetic acids used in the following experiments were obtained from commercial sources. The *p*-biphenylacetic acid was prepared by a previously described procedure.[12]

4-Phenyl-1-buten-3-yne-1,1-dicarboxylic Acid (I).—A solution of 2.6 g. of phenylpropargyl aldehyde and 2.1 g. of malonic acid in 20 ml. of glacial acetic acid was allowed to stand for 48 hr. The entire reaction mass was poured into 200 ml. of ice-water. The solid precipitate was filtered, dissolved in bicarbonate solution and decolorized two times with activated charcoal. The solution was acidified with dilute hydrochloric acid to precipitate 2.8 g., 65.2%, of yellow 4-phenyl-1-buten-3-yne-1,1-dicarboxylic acid. m.p. 214–218°. Similar yields were obtained when the reaction mixture was refluxed for 4 hr. Infrared absorption maxima occur at 2210, 1730, 1645, 1580, 1485, 1450, 1250, 764 and 685 cm.$^{-1}$.

Anal. Calcd. for $C_{12}H_8O_4$: C, 66.67; H, 3.73; neut. equiv., 108. Found: C, 66.66; H, 3.69; neut. equiv., 108.

3-Carboxy-6-phenyl-2-pyrone.—A catalyst prepared by heating 0.5 g. of yellow mercuric oxide in 4 ml. of concd. sulfuric acid until the color was discharged was dissolved in 50 ml. of distilled water and added to 1 g. of 4-phenyl-1-buten-3-yne-1,1-dicarboxylic acid in a 125-ml. round-bottom flask. This mixture was refluxed for 4 hr., cooled to room temperature and filtered. The crude 3-carboxy-6-phenyl-2-pyrone thus obtained is soluble in bicarbonate solution on gentle warming. On recrystallization from glacial acetic acid there was obtained 0.8 g., 80%, of yellow-orange product, m.p. 218°. Absorption maxima occur at: 1775, 1735, 1675, 1630, 1580, 1545, 1500, 1180, 988, 934, 840, 770 and 687 cm.$^{-1}$ in the infrared and at 240 mμ (log ε 3.73) and 345 mμ (log ε 4.17) in the ultraviolet.

Anal. Calcd. for $C_{12}H_8O_4$: C, 66.67; H, 3.73; neut. equiv., 216. Found: C, 66.88; H, 3.84; neut. equiv., 216.

6-Phenyl-2-pyrone.—A solution of 0.5 g. of 4-phenyl-1-buten-3-yne-1,1-dicarboxylic acid in 20 ml. of 50% sulfuric acid was refluxed for 3 hr. The cooled turbid solution was poured into 200 g. of cracked ice to precipitate the crude 6-phenyl-2-pyrone. Recrystallization from petroleum ether gave 0.2 g., 54%, of light yellow plates, m.p. 68°. Absorption maxima occur at: 1725, 1635, 1580, 1545, 1506, 1460, 1410, 1343, 1118, 1076, 1009, 957, 844, 800, 768 and 687 cm.$^{-1}$ in the infrared and at 235 mμ (log ε 3.92) and 330 mμ (log ε 4.12) in the ultraviolet.

From 3-Carboxy-6-phenyl-2-pyrone.—A solution of 1 g. of 3-carboxy-6-phenyl-2-pyrone in 10 ml. of 50% sulfuric acid was refluxed for 1.5 hr. The cooled reaction mixture was poured into 100 ml. of ice-water to precipitate 0.5 g., 67.5%, of 6-phenyl-2-pyrone.

2,5-Diphenylpenten-2-yne-4-oic Acid.—A solution of 6.0 g. of phenylpropargylaldehyde and 6.0 g. of phenylacetic acid in 25 ml. of acetic anhydride was heated on a boiling water-bath. When temperature equilibrium was attained 3.0 g. of sodium acetate was stirred into the reaction mixture. The reaction was kept at water-bath temperature for 48 hr. The cooled solution was poured onto 300 g. of chipped ice and neutralized with bicarbonate to precipitate the crude product as a yellow brown solid. Recrystallization from ligroin (b.p. 66–75°) gave 9.0 g., 79%, of the product as yellow needles, m.p. 159°. Infrared absorption maxima occur at: 2900, 2200, 1680, 1600, 1580, 1562, 1490, 1440, 1415, 1300, 1280, 1268, 1180, 1070, 1038, 1006, 998, 918, 911, 887, 783, 773, 755, 699 and 687 cm.$^{-1}$.

Anal. Calcd. for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87; neut. equiv., 248. Found: C, 82.22, 82.22; H, 5.26, 5.38; neut. equiv., 247.

In the case of *p*-biphenylacetic acid and *β*-naphthylacetic acid the condensation was complete in 6 hr. Further details of the reaction with other arylacetic acids are given in Table I.

3,6-Diphenyl-2-pyrone.—A catalyst prepared by heating 0.1 g. of yellow mercuric oxide in 5 ml. of concd. sulfuric acid for 15 min. was dissolved in 20 ml. of distilled water. This solution was warmed on a water-bath and 20 ml. of *p*-dioxane containing 1.0 g. of 2-phenyl-5-phenylpenten-2-yne-4-oic acid gradually stirred in. The mixture was heated with agitation for 2.5 hr. The cooled reaction mass was poured onto 200 g. of cracked ice to precipitate the crude yellow product which on recrystallization from ethanol gave 0.4 g., 40%, of yellow needles, m.p. 161° (mixed m.p. with the starting acetylenic acid is 120°). The use of acetone in place of *p*-dioxane in this procedure results in yields of 60%. Absorption maxima occur at: 1712, 1625, 1600, 1575, 1550, 1490, 1450, 1355, 1258, 1110, 1085, 1078, 1046, 1023, 1002, 967, 944, 915, 901, 814, 784, 767, 754, 719, 691 and 685 cm.$^{-1}$ in the infrared and at 245 mμ (log ε 4.25) and 360 mμ (log ε 4.46) in the ultraviolet.

Anal. Calcd. for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87. Found: C, 82.12; H, 5.03.

3-(ε-Naphthyl)-6-phenyl-2-pyrone.—A catalyst prepared by heating 0.2 g. of yellow mercuric oxide in 10 ml. of concd. sulfuric acid for 15 minutes was dissolved in 20 ml. of distilled water and brought to 60°. To the hot mixture 0.5 g. of 2-(*β*-naphthyl)-5-phenylpenten-2-yne-4-oic acid in 75 ml. of acetone was added in a dropwise manner. Refluxing commenced immediately and was continued for 12 hr. The brown reaction mixture was filtered and upon cooling precipitated the crudely crystalline pyrone. Crystallization two times from benzene gave 0.2 g., 40%, of yellow plates, m.p. 197°. Absorption maxima occur at: 1695, 1620, 1598, 1540, 1490, 1450, 1363, 1325, 1273, 1117, 1145, 1023, 986, 917, 896, 863, 847, 824, 767, 750, 646 and 685 cm.$^{-1}$ in the infrared and at 250 mμ (log ε 4.24) and 365 mμ (log ε 4.31) in the ultraviolet.

Anal. Calcd. for $C_{21}H_{14}O_2$: C, 84.54; H, 4.73. Found: C, 84.54; H, 4.85.

3-(*p*-Biphenylyl)-6-phenyl-2-pyrone.—A catalyst prepared by heating 1.0 g. of yellow mercuric oxide with 10 ml. of concd. sulfuric acid for 0.5 hr. was dissolved in 20 ml. of distilled water. To this was added 0.5 g. of 2-(*p*-biphenylyl)-5-phenylpenten-2-yne-4-oic acid in 50 ml. of acetone. The mixture was refluxed for 24 hr., cooled to room temperature and the precipitate was extracted with

toluene in a Soxhlet apparatus for 2 hr. The product was precipitated by the addition of ligroin to the extracts and crystallized twice from toluene to give 0.1 g., 20%, of yellow needles, m.p. 268°. Absorption maxima occur at: 1705, 1650, 1600, 1550, 1487, 1448, 1355, 1110, 1142, 1120, 1103, 963, 890, 838, 813, 778, 753, 724 and 683 cm.$^{-1}$ in the infrared and at 265 mμ (log ε 4.27) and 365 mμ (log ε 4.56) in the ultraviolet.

Anal. Calcd. for $C_{23}H_{16}O_2$: C, 85.16; H, 4.97. Found: C, 85.46; H, 4.96.

3-(*p*-Methoxyphenyl)-6-phenyl-2-pyrone.—A catalyst mixture was prepared in the same manner as that used in the synthesis of 3,6-diphenyl-2-pyrone and diluted to 100 ml. with distilled water; 5 ml. of this catalyst was added to a solution of 0.5 g. of 2-(*p*-methoxyphenyl)-5-phenylpenten-2-yne-4-oic acid in 50 ml. of methanol. The reaction was kept at 45–50° for 48 hr. and the methanol evaporated. The precipitate was filtered, washed with distilled water and crystallized two times from ethanol to give 0.1 g., 20%, of yellow plates, m.p. 170°. Absorption maxima occur at: 1700, 1625, 1610, 1575, 1550, 1510, 1490, 1450, 1358, 1305, 1290, 1250, 1175, 1110, 1083, 1047, 1027, 965, 900, 840, 806, 777, 763 and 683 cm.$^{-1}$ in the infrared and occur at 250 mμ (log ε 4.00) and 370 mμ (log ε 4.10) in the ultraviolet.

Anal. Calcd. for $C_{18}H_{14}O_3$: C, 77.68; H, 5.07. Found: C, 77.50; H, 5.10.

Infrared absorption spectra were obtained on potassium bromide pellets using a Baird Associates double beam recording infrared spectrophotometer with sodium chloride optics. Ultraviolet absorption spectra were obtained using 1.00-cm. silica cells in a Beckman DU spectrophotometer. Absolute methanol was used as solvent except as noted.

Pyrolysis of Alkyl Phosphates

BY HENRY E. BAUMGARTEN AND ROBERT A. SETTERQUIST[1]

RECEIVED NOVEMBER 26, 1956

The preparation of amyl dimethyl, dimethyl hexyl, dimethyl octyl, dioctyl methyl and cyclohexyl dimethyl phosphates is described. These five alkyl phosphates and three others have been pyrolyzed to give olefins in high yield. The pyrolyses were accompanied by extensive rearrangement of the olefinic double bond.

In the preparation of olefins by the pyrolysis of esters, it is becoming increasingly apparent that a considerable variation in the nature of the acid moiety is allowable. A recent review[2] has cited numerous examples of olefin formation by pyrolysis in the liquid and vapor phases of esters of many different organic acids, and to these examples may be added the pyrolyses of esters of the inorganic acids, boric acid[3] and sulfurous acid.[4–6] Although no systematic study of the pyrolysis of the esters of phosphorus acids has been reported, isolated examples of the thermal decomposition of such substances to olefins have been described. For example, Gerrard[7] reported that *n*-octyl phosphorodichloridite decomposed to give octylene at 150°. Arbuzov and Valitova[8] obtained olefinic products by heating tertiary alkyl phosphites with methyl iodide in a sealed tube at 200°. Cronje[9] reported that the pyrolysis of dihydrogen dialkyl pyrophosphates at 180° yielded olefins. Other workers have reported obtaining olefinic by-products during the preparation or reaction of various organophosphorus esters but, in most instances, the immediate precursor of the olefin has not been identified and in many may not have been an organophosphorus compound. The present communication describes the preparation and pyrolysis of a number of alkyl phosphates and is the first of a series to be devoted to the pyrolysis of various phosphorus derivatives. From the many possible simple and mixed alkyl and aryl phosphates three types were selected for study: alkyl dimethyl phosphates (I), dialkyl methyl phosphates (II) and trialkyl phosphates (III).

$$\underset{\text{I}}{RCH_2CH_2OP(O)(OCH_3)_2} \longrightarrow RCH{=}CH_2 + HOP(O)(OCH_3)_2$$

$$\underset{\text{II}}{(RCH_2CH_2O)_2P(O)OCH_3} \longrightarrow 2RCH{=}CH_2 + (HO)_2P(O)OCH_3$$

$$\underset{\text{III}}{(RCH_2CH_2O)_3PO} \longrightarrow 3RCH{=}CH_2 + (HO)_3PO$$

Preparation of the mixed phosphates (I) was effected by treatment of the appropriate alcohol (IV) with phosphorus oxychloride in the presence of dimethylaniline followed by reaction of the intermediate alkyl phosphorodichloridate (V) with sodium methoxide.

$$\underset{\text{IV}}{RCH_2CH_2OH} + POCl_3 \xrightarrow{C_6H_5NMe_2} \underset{\text{V}}{RCH_2CH_2OP(O)Cl_2} \xrightarrow{CH_3ONa} \underset{\text{I}}{RCH_2CH_2OP(O)(OCH_3)_2}$$

The phosphates thus prepared are described in Table I. This procedure was more effective in our hands than the alternative treatment of dimethyl phosphorochloridate with the alkoxide of IV or with IV and a tertiary amine.[10]

Dioctyl methyl phosphate (II, R = C_6H_{13}) was prepared by treating the commercially available dioctyl phosphorochloridate with sodium methoxide in ether or, preferably, with methanol and tri-

[a] Based on total possible olefin obtainable. [b] L. J. Bellamy "(The Infrared Spectra of Complex Molecules," Methuen and Co., London, 1954, Chap. 3) quotes the average values for the C=C stretching vibration as, for $CHR{=}CH_2$ 1643 cm.$^{-1}$, for $CHR_1{=}CHR_2$ (*trans*) 1673 cm.$^{-1}$, for $CHR_1{=}CHR_2$ (*cis*) 1657 cm.$^{-1}$. [c] 9.8 g. (86%) of dimethyl *n*-hexyl phosphate recovered.

ethylamine in carbon tetrachloride. All of the simple trialkyl phosphates (III) used in this study were available from other sources.

The phosphates were pyrolyzed by dropping them through a 1-in. Pyrex or Vycor glass tube packed with 1/16-in. glass helices and heated to various temperatures by a tube furnace. The results of several typical pyrolyses are given in Table II. Inasmuch as a strong acid (phosphoric acid, its methyl or dimethyl ester or polymeric acids derived from these) should be formed in the elimination reaction, extensive isomerization of the double bond was expected in the olefin formed. Therefore, that part of the pyrolysate which boiled within the temperature range dictated by the boiling points of the expected olefins was collected as product.

In every run some darkening of the pyrolysis tube indicated that carbonization occurred in varying amounts, perhaps adding to the extent of isomerization.[11] As the temperature was increased the extent of the darkened area also increased.

The results of Table II indicate that alkyl phosphates pyrolyze readily at temperatures of 300° and above to give excellent yields of olefin. From many experiments the optimum temperature appeared to be around 350°, although occasionally good yields were obtained at 300°. It is interesting to note that in the attempted pyrolysis of dimethyl *n*-hexyl phosphate at 250°, no olefin was obtained and 85.5% of the starting material was recovered. Thus, the pyrolysis temperature of the phosphates is intermediate between those of the sulfites (170–260°) and of the acetates (400–550°).[6]

Essentially the stoichiometric amounts of olefin were obtained from II and III, two and three moles of olefin per mole of phosphate, respectively.

Although no attempt was made to determine quantitatively the composition of the olefinic products, the infrared spectra of all olefin fractions were examined for evidence of double bond migration. In all instances in which such migration would be expected, the infrared spectra indicated that migration had occurred. To illustrate, the frequencies of selected bands occurring in the spectrum of the product obtained from dimethyl *n*-hexyl phosphate at 350° are given in Table III together with the characteristic frequencies reported[12] for 1-hexene and *cis*- and *trans*-2-hexene. Comparison of these values indicates that a mixture of olefins was present in the pyrolysate. Inasmuch as the spectrum of the product obtained at 350° differed little from those of olefins formed at various temperatures from 300 to 400°, small variation in temperature apparently had little

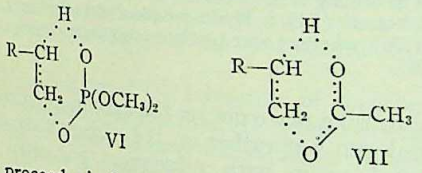
effect on the extent of isomerization, although the isomerization may have been in part thermal in origin. Of the other phosphates pyrolyzed, only cyclohexyl dimethyl phosphate appeared to give a single olefin, substantially free from rearrangement products.

Although a cyclic transition state (VI) can be written for the pyrolysis of alkyl phosphates which resembles that (VII) now commonly accepted for the pyrolysis of acetates and other esters of organic acids,[13] it seems more likely that the reaction



VI

VII

may proceed *via* ionic intermediates either to the exclusion of or in competition with the cyclic mechanism. Much of the argument offered by Berti[6] in support of an ionic type of cleavage for alkyl sulfites appears to be applicable to the cleavage of phosphates as well.

Experimental[14]

Alkyl Dimethyl Phosphates.—Equimolar amounts of the alcohol, phosphorus oxychloride and dimethylaniline and twice the molar amount of sodium methoxide were used. Special care was taken to maintain anhydrous conditions throughout each preparation.

A mixture of dry ethyl ether (100 ml. for each 10 g. of alcohol used), the alcohol and dimethylaniline was treated dropwise with stirring with phosphorus oxychloride in dry ether (100 ml. for each 20 g. of phosphorus oxychloride) while the temperature was maintained below −15°. After the addition was completed the mixture was allowed to stand and come to room temperature. The resulting ethereal solution of alkyl phosphorodichloridate was transferred from the precipitated dimethylaniline hydrochloride through a filter stick into another large, 3-necked, round-bottomed flask. The solid amine hydrochloride was washed with dry ether and the ethereal solution was added to the filtrate. Solid sodium methoxide (method A) or a 10% solution of sodium methoxide in methanol (method B) was added slowly while the cooled (in ice) ether solution was stirred rapidly. The reaction mixture was allowed to stand overnight at room temperature. The precipitated sodium chloride was separated by filtration and the ethereal solution was washed with 100 ml. of 5% aqueous sodium bicarbonate and then dried over anhydrous magnesium sulfate. The product was distilled under reduced pressure through an 18-in. by 0.5-in. Vigreux column.

Dioctyl Methyl Phosphate. (a) **From Sodium Methoxide.**—To a solution of 170.5 g. (0.5 mole) of dioctyl phosphorochloridate in 200 ml. of ether cooled in ice was added 27 g. (0.5 mole) of sodium methoxide in small portions. The reaction mixture was allowed to stand overnight and the sodium chloride was separated by filtration. The filtrate was washed with 5% aqueous sodium bicarbonate, then several portions of water and dried over magnesium sulfate. The ether was distilled from the product, giving 146 g. (87%) of crude dioctyl methyl phosphate, $n^{25}D$ 1.4400. Although purification by distillation was possible, in the presence of traces of acid, decomposition took place (even at 0.25 mm.) giving octene, which contaminated the distilled ester (*vide infra*).

(b) **From Methanol and Triethylamine.**—To a stirred solution of 10 g. (0.10 mole) of triethylamine and 3.5 g. (0.11 mole) of methanol in 200 ml. of dry carbon tetrachloride held at 0° in an ice-bath was added over a period of 1 hr. a solution of 33 g. (0.097 mole) of dioctyl phosphorochloridate in 50 ml. of carbon tetrachloride. The mixture was removed from the cold bath and allowed to stand at room temperature protected from moisture until no further precipitate of triethylamine hydrochloride formed.[15] The filtered carbon tetrachloride solution was washed successively with 5% hydrochloric acid, water, 5% aqueous sodium bicarbonate (twice) and water. The solution was dried over magnesium sulfate and then divided into two equal portions. The first half of the solution was distilled through a 24-in. column of the Podbielniak type.[16] Small fractions were collected at frequent intervals, a total of 9.5 g. (58%) of dioctyl methyl phosphate, b.p. 162–164° (1 mm.), $n^{25}D$ 1.4361–1.4362, being collected before the temperature at the take-off fell (to about 150°). On raising the bath temperature from about 210 to 230°, the remainder of the liquid in the still-pot suddenly and almost instantly decomposed forming octene, 2.5 g. (23%) (which was caught in the cold trap protecting the pump).

The second half of the solution was evaporated on the steam-bath under reduced pressure (down to 0.5 mm.), giving 14.2 g. (87%) of crude dioctyl methyl phosphate, $n^{25}D$ 1.4378. The infrared spectra of the crude product and of the distillate described above were not perceptibly different, indicating that for most practical purposes the crude material should suffice.

Pyrolysis Procedure.—The apparatus consisted of either a thick walled Pyrex or a Vycor glass tube, 25-mm. o.d. and 24 in. long, inserted in a vertically disposed FD303 Hoskins electric furnace. The tube was packed for 12 in. of its depth with 1/16-in. Pyrex glass helices (which were cleaned after each run with a solution of hot concentrated nitric and sulfuric acids and rinsed thoroughly with distilled water). A Hershberg-type dropping funnel,[17] modified to permit the pressure-equalized introduction of nitrogen into the system, was used to introduce the sample. The pyrolysate was collected in a large (50-mm. o.d.) side-arm test-tube immersed in a Dry Ice–methanol-bath. In some experiments the side-arm of the test-tube was connected to a U-tube immersed in Dry Ice–methanol as a precautionary measure, but normally this precaution was not necessary. A slow flow of nitrogen (about 1–2 l. per hour) was introduced into the tube during pyrolysis to sweep the vapors into the receiver and maintain a non-oxidizing atmosphere within the apparatus. All gases not condensed in the cold bath(s) were collected in a gas buret over water.

The temperature of the tube was determined using a Leeds and Northrup Model 8667 pyrometer and an iron–constantan thermocouple, the thermocouple leads being inserted in a

well extending about half-way into the packed section of the tube.[18] The temperature was controlled to ±6°.

The optimum rate of addition of phosphate during pyrolysis appeared to be about 0.3 g. of ester per minute, although little change in the yield of olefin occurred when the rate was varied from 0.06 to 0.3 g. per minute. The crude pyrolysate was purified by distillation through an 8-in. Vigreux column. The olefin fraction boiling in the range of temperatures given in the literature[19] for the expected olefin and isomerization products was collected for infrared analysis.[20] No attempt was made to identify other by-products. After a run the tube was usually clean throughout except for an approximately 2-in. area about 1 in. from the top of the packing, which was black. Etching of the tube in this area took place.

(18) A number of tube designs, including all-glass construction, have been employed to permit insertion of the thermocouple well and the dropping funnel into the relatively small tube opening. The simplest of these (and the easiest to disassemble and clean) was a tube terminating in an open cup of about 35-mm. o.d. The dropping funnel and thermocouple well were fitted into the cup with a clean rubber stopper. This device was very satisfactory provided that in inserting the pyrolysis tube into the apparatus it was first fitted with a 1.25-in. sleeve of 1-in. copper tubing and a fairly tight-fitting shield formed from a 2-in. square of asbestos cement board (Transite) (to conduct away the heat and to seal off the opening of the furnace, respectively). Otherwise, the rubber stopper charred badly at the higher temperatures.

Phosphonic Acids. IV.[1] Preparation and Reactions of β-Ketophosphonate and Enol Phosphate Esters[2]

BY HERBERT I. JACOBSON, MARTIN J. GRIFFIN, SEYMOUR PREIS AND ELWOOD V. JENSEN

RECEIVED JUNE 18, 1956

In contrast to α-chlorinated ketones which react with triethyl phosphite to form enol phosphate esters, α-iodoketones react "normally" with triethyl phosphite to yield β-ketophosphonate esters. Thus iodoacetone reacts with triethyl phosphite at room temperature to form diethyl β-ketopropylphosphonate (II). Diethyl β-ketopropylphosphonate also may be prepared by the acid-catalyzed ethanolysis of diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb), a substance which is obtained by the smooth reaction of two moles of triethyl phosphite with α,α′-dichloroacetone. Treatment of diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb) with sodium ethoxide in boiling ethanol results in the elimination of the elements of diethyl hydrogen phosphate to form diethyl propynylphosphonate (VI). Hydrogenation of diethyl isopropenyl phosphate (VIII) over palladium yields diethyl isopropyl phosphate (IX), whereas over platinum reductive cleavage of the enol ester linkage takes place to form diethyl hydrogen phosphate (X).

It has long been recognized that the reaction of α-chloroketones with sodium diethyl phosphonate[3] and with triethyl phosphite[4] gives rise to unusual products which, although originally formulated as β-ketophosphonates, do not react with the usual carbonyl reagents and which, on acid hydrolysis, undergo cleavage to produce a ketone and inorganic phosphate. The reason for this behavior became clear when it was demonstrated that the reaction of triethyl phosphite with α-chlorinated aldehydes[5] and ketones[6,7] takes place in a manner different from that of simple alkyl halides to yield predominantly enol phosphate esters rather than β-ketophosphonate esters. The most reasonable explanation proposed for this phenomenon is that the polarization induced by the electronegative halogen atoms causes the attack of triethyl phosphite to take place not on the carbon atom bearing the halogen but rather on the carbon atom of the carbonyl group with subsequent concerted rearrangement.[8]

In connection with the synthesis of phosphonate analogs of certain phosphorylated intermediates of metabolism,[1] a method was desired for the preparation of authentic β-ketophosphonate esters. If it is assumed that chloro and polyhaloketones react abnormally in the Arbuzov reaction because of the polarization induced on the carbonyl group by the electronegative halogen atoms, it was considered that an iodoketone might react normally since the less electronegative iodine atom would exert a smaller polarization effect as well as being more reactive toward simple displacement. Accordingly, the reaction of iodoacetone (I) with triethyl phosphite was investigated and found to proceed exothermically at room temperature to produce diethyl β-ketopropylphosphonate (II), with only a small amount of diethyl isopropenyl phosphate being formed.[9] This β-ketophosphonate (II) forms the expected 2,4-dinitrophenylhydrazone derivative, and its infrared spectrum shows strong carbonyl absorption at 1717 cm.$^{-1}$ and

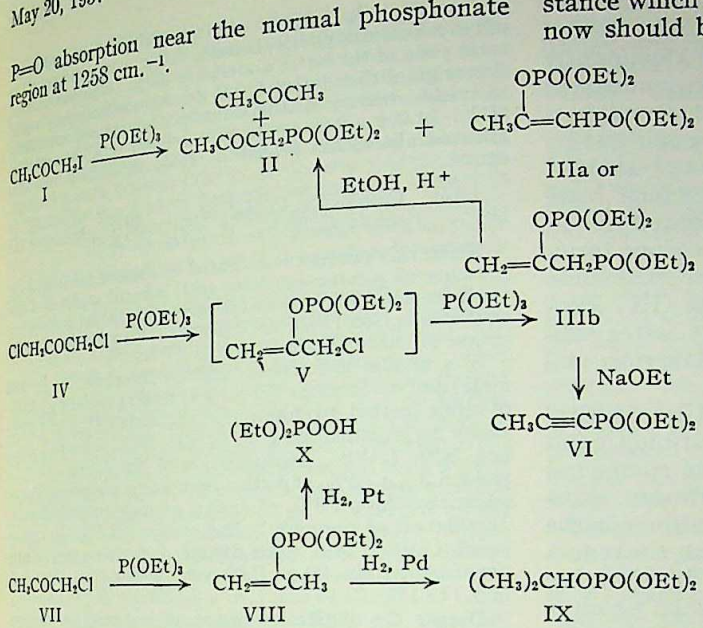
May 20, 1957



From the reaction of iodoacetone with triethyl phosphite, there was also isolated, besides ethyl iodide and a small amount of diethyl ethylphosphonate, significant amounts of acetone and of a higher boiling material which was shown to be a diethyl diethylphosphonoisopropenyl phosphate[10] (III). As described below, the latter substance can be transformed into diethyl β-ketopropylphosphonate by ethanolysis of the enol phosphate linkage.

The mechanism of the formation of acetone and the phosphate-phosphonate III presents an interesting problem. Inasmuch as the presence of a small amount of hydrogen iodide was noted during the distillation of the reaction product, it was considered that this material may act catalytically to reduce iodoacetone to acetone liberating iodine which then reacts either with iodoacetone or with the activated methylene group of the β-ketophosphonate II to regenerate hydrogen iodide and form either α,α′-diiodoacetone or diethyl α-iodo-β-ketopropylphosphonate. Either of these substances conceivably could react with triethyl phosphite to form III. However, in an experiment designed to eliminate the presence of hydrogen iodide by carrying out all steps under anaerobic conditions in the dark in the presence of solid potassium carbonate, substantial amounts of III again were produced, although in this case no hydrogen iodide was detectable. Therefore, the mechanism of the formation of the phosphate-phosphonate III remains uncertain.

Since an enol phosphate ester linkage represents a potential carbonyl group, an alternative route to diethyl β-ketopropylphosphonate was suggested. It has been reported[6a] that α,α′-dichloroacetone reacts with one mole of triethyl phosphite to form diethyl 3-chloroisopropenyl phosphate, a substance which still contains one chlorine atom which now should be capable of replacement by a phosphonate group in the normal Arbuzov reaction. Accordingly, the reaction of α,α′-dichloroacetone with excess triethyl phosphite was investigated and found to proceed smoothly with the evolution of two moles of ethyl chloride to produce diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb).[11] In contrast to its reaction with chloroacetone which requires a temperature of at least 150°, it is noteworthy that the reaction of the first mole of triethyl phosphite with α,α′-dichloroacetone took place at room temperature.

On prolonged heating with absolute ethanol in the presence of a catalytic amount of *p*-toluenesulfonic acid, ethanolysis of the enol phosphate linkage of IIIb took place affording a 63% yield of diethyl β-ketopropylphosphonate (II) accompanied by triethyl phosphate.

When an ethanolic solution of the phosphate-phosphonate IIIb was treated with one mole of sodium ethoxide at room temperature, the enol phosphate linkage was destroyed rapidly as indicated by the disappearance of the characteristic enol absorption band at 1640 cm.$^{-1}$. However, this base-induced cleavage gave not only triethyl phosphate and diethyl β-ketopropylphosphonate, but also substantial amounts of diethyl propynylphosphonate (VI) and, after acidification, diethyl hydrogen phosphate. When the reaction of IIIb with sodium ethoxide was carried out at elevated temperature, the elimination of the elements of diethyl hydrogen phosphate took place to the exclusion of the ethanolysis reaction affording diethyl propynylphosphonate (VI) in 69% yield.

The product from the reaction of sodium ethoxide with IIIb is assigned the structure of diethyl propynylphosphonate (VI) rather than the isomeric diethyl propargylphosphonate on the basis of its infrared spectrum (triple bond stretching at 2210 cm.$^{-1}$ typical of disubstituted acetylenes rather than 2100–2140 as in monosubstituted acetylenes as well as the absence of the characteristic ≡CH stretching absorption at 3300 cm.$^{-1}$) and the fact that it does not react with ammoniacal silver nitrate. The formation of VI from IIIb may involve the allene, $H_2C{=}C{=}CHPO(OEt)_2$, as an intermediate; investigations of this possibility are in progress and will be reported separately. An attempt was made to prepare authentic diethyl propargylphosphonate for comparison by the reaction of triethyl phosphite with propargyl bromide. This reaction did not proceed in a straightforward manner, but yielded chiefly a mixture of high boiling unstable products accompanied by a very small amount of a material apparently identical with VI.

(10) Inasmuch as there were minor differences between the infrared spectrum of this substance and that of the product obtained from dichloroacetone which undoubtedly possesses the structure IIIb, it is not yet certain whether structure IIIa or IIIb is the correct one in this case.

(11) Since the completion of this work, a similar preparation of diethyl 3-diethylphosphonoisopropenyl phosphate from dichloroacetone has been reported.[7b]

In confirmation of the observations of others,[6a,7] the reaction of chloroacetone (VII) with triethyl phosphite was found to produce predominantly diethyl isopropenyl phosphate (VIII) accompanied by small amounts of diethyl β-ketopropylphosphonate. The structure of VIII was confirmed by its unique infrared spectrum (enol band at 1646 cm.$^{-1}$ and phosphate-type P=O stretching band at 1270 cm.$^{-1}$ rather than phosphonate-type at 1240–1250 cm.$^{-1}$), by ozonolysis to produce formaldehyde and by hydrogenation over palladium to produce diethyl isopropyl phosphate (IX) identical with an authentic sample of the latter substance prepared by the method of Atherton and Todd.[12]

When the hydrogenation of diethyl isopropenyl phosphate was carried out using a platinum catalyst, two moles of hydrogen per mole of compound were absorbed to produce diethyl hydrogen phosphate (X) and presumably propane, although the latter substance was not isolated. Thus, the reductive cleavage of an enol phosphate bond under these conditions is similar to the cleavage which is known to take place when enol esters of carboxylic acids are hydrogenated with a platinum catalyst.[13]

An attempt was made to prepare diethyl β-ketopropylphosphonate from chloroacetone by blocking the carbonyl group as the ethylene ketal. It was found that the dioxolane of chloroacetone, prepared according to Kühn,[14] did not react with triethyl phosphite at 160° nor with sodium diethylphosphonate in boiling tetrahydrofuran.

Experimental[15]

Diethyl β-Ketopropylphosphonate (II) from Iodoacetone (I).—Freshly distilled iodoacetone (52.2 g., 0.28 mole), b.p. 68–69° (24 mm.), prepared by the reaction of potassium iodide with chloroacetone in aqueous ethanol,[16] was added[17] slowly with stirring to triethyl phosphite (47.3 g., 0.29 mole) held at 0–5°. After the addition was complete, the cold bath was removed, whereupon the reaction mixture warmed spontaneously to about 35° and remained at this temperature for 2 hr. when the temperature began to fall. Distillation of the reaction mixture at reduced pressure yielded, in addition to a forerun (13.6 g.) and a high boiling residue (15.0 g.), diethyl β-ketopropylphosphonate (II), 15.5 g., 30%, b.p. 83–84° (0.4 mm.), n^{25}D 1.4310, reported[7b] b.p. 126° (9 mm.), n^{20}D 1.4350, with characteristic infrared absorption peaks at 1165, 1258 and 1717 cm.$^{-1}$.

Anal. Calcd. for $C_7H_{15}O_4P$: C, 43.30; H, 7.79; P, 15.99. Found: C, 43.00; H, 7.94; P, 16.12.

Treatment of this product with 2,4-dinitrophenylhydrazine in methanol–sulfuric acid solution gave the 2,4-dinitrophenylhydrazone derivative, m.p. 104.9–105.5°.

Anal. Calcd. for $C_{13}H_{19}O_7N_4P$: N, 14.96. Found: N, 15.11.

Redistillation of the 13.6 g. of forerun yielded crude diethyl isopropenyl phosphate, 7.2 g., 14%, b.p. 60–68° (1.5 mm.), n^{25}D 1.4136, plus an additional amount of diethyl β-ketopropylphosphonate, 6.2 g., 12%, bringing the total yield of the latter material to 42%. The residue from the original distillation (15.0 g.) was molecularly distilled to yield diethyl diethylphosphonoisopropenyl phosphate (III), 14.0 g., 0.04 mole, n^{25}D 1.4469, with characteristic infrared absorption peaks[18] at 1149, 1252, 1290 and 1650 cm.$^{-1}$.

Anal. Calcd. for $C_{11}H_{24}O_7P_2$: C, 40.00; H, 7.32; P, 18.77. Found: C, 39.93; H, 7.41; P, 18.50.

When this product was heated in absolute ethanol in the presence of *p*-toluenesulfonic acid, infrared analyses of test portions showed a progressive decrease in the intensity of the enol absorption (1648 cm.$^{-1}$) with the appearance and increase of carbonyl absorption (1717 cm.$^{-1}$).

In a similar experiment, triethyl phosphite (74 g., 0.45 mole) and iodoacetone (77 g., 0.42 mole) gave 29.2 g., 38%, of crude diethyl β-ketopropylphosphonate (II), n^{25}D 1.4300, which on redistillation gave 21.9 g., 28%, of purified product, n^{25}D 1.4340. Redistillation of the forerun (7.1 g.) yielded 3.7 g., 5%, of diethyl isopropenyl phosphate plus an additional 2.0 g., 3%, of diethyl β-ketopropylphosphonate. Distillation of the high boiling residue (32.5 g.) through a small Claisen flask gave diethyl diethylphosphonoisopropenyl phosphate, 30 g., 0.09 mole, boiling from 125° (0.10 mm.) to 136° (0.14 mm.), n^{25}D 1.4465.

During the distillation of the original reaction mixture, 86.5 g. of volatile material collected in the −80° trap, and one gram of a fuming substance which appeared to be hydrogen iodide collected in a subsequent trap cooled in liquid nitrogen. Redistillation of the volatile product through a Fenske column yielded acetone, 6.4 g., 0.11 mole, b.p. 55–56°, n^{25}D 1.3850, m.p. of dinitrophenylhydrazone derivative, 123.5–124.5°; ethyl iodide, 40.7 g., 0.26 mole, b.p. 71–72°, n^{25}D 1.5074; and a third product which appeared to be diethyl ethylphosphonate, 5.2 g., 0.03 mole, b.p. 78–88° (16 mm.), n^{25}D 1.4120.

In an attempt to prevent the formation of the high boiling product (III) by eliminating the presence of hydrogen iodide in the reaction system, iodoacetone (26.5 g., 0.14 mole), freshly distilled in subdued light into a receiver containing a small amount of solid potassium carbonate, and triethyl phosphite (22.8 g., 0.14 mole) were allowed to react in the dark in an atmosphere of nitrogen in the presence of a little potassium carbonate. As before, the mixture warmed spontaneously to 35° for about 2 hr. On distillation of the reaction mixture in subdued light, no trace of hydrogen iodide was noticeable in the liquid nitrogen-cooled trap, but the yield of diethyl β-ketopropylphosphonate, 7.8 g., 33%, was approximately the same as in previous experiments, and 7.0 g., 0.021 mole, of the high boiling product (III) was obtained.

Diethyl 3-Diethylphosphonoisopropenyl Phosphate (IIIb) from α,α′-Dichloroacetone.—To recrystallized α,α′-dichloroacetone (10.0 g., 0.079 mole) one molar equivalent of triethyl phosphite (13.1 g., 0.079 mole) was added at such a rate that the temperature of the stirred reaction mixture which warmed spontaneously, and evolved ethyl chloride was maintained at about 50°. When the addition was complete and the temperature began to drop, an additional equivalent of triethyl phosphite (13.1 g., 0.079 mole) was added in one portion and the reaction mixture heated at 160° for 2 hr. After the evolution of ethyl chloride (8.3 g., 82%) had ceased, the mixture was cooled, and the small amount of unreacted triethyl phosphite was removed at reduced pressure. The residue (14 g.) was molecularly distilled to yield diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb), 12.9 g., 50%, n^{25}D 1.4429, reported[7c] n^{20}D 1.4435, with characteristic infrared absorption peaks at 1164, 1272 and 1650 cm.$^{-1}$.

(17) If the triethyl phosphite is added to excess iodoacetone, the reaction mixture turns dark.

(18) The infrared spectrum of this substance was identical with that of diethyl diethylphosphonoisopropenyl phosphate (IIIb) obtained from the reaction of triethyl phosphite with α,α′-dichloroacetone except for a slight modification and broadening of the P=O bands at 1252 and 1290 cm.$^{-1}$ and the presence of an additional moderately strong band at 1149 cm.$^{-1}$ which obscures partially the POEt band at 1165 cm.$^{-1}$.

May 20, 1957

Anal. Calcd. for $C_{11}H_{24}O_7P_2$: C, 40.00; H, 7.32; P, 18.77; neut. equiv., 165. Found: C, 39.73; H, 7.27; P, 18.20; neut. equiv., 169.[19]

A subsequent experiment was carried out in a similar fashion except that a 50% excess of triethyl phosphite was employed. Thus, from α,α′-dichloroacetone (97 g., 0.76 mole) and triethyl phosphite (378 g., 2.28 moles) there was obtained a crude product (238 g., 95%, $n^{25}D$ 1.4432) which on distillation in a Claisen flask yielded purified diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb), 210 g., 84%, b.p. 118–120° (0.05 mm.), $n^{25}D$ 1.4459, with an infrared spectrum identical with that of the analyzed sample of this substance.

Diethyl β-Ketopropylphosphonate (II) from IIIb.—A solution of diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb, 25.4 g.; 0.077 mole) and *p*-toluenesulfonic acid (250 mg.) in 100 ml. of absolute ethanol was heated under reflux for 24 days until infrared analysis of test portions showed complete disappearance of enol absorption and no further increase in the carbonyl absorption. The reaction mixture was deacidified by passage through a column containing 100 g. of Amberlite IRA-410 (OH) resin which had been washed thoroughly with ethanol. The eluate was stirred with 2.0 g. of barium hydroxide whereupon 4.8 g. of a solid precipitate slowly formed and was removed by filtration. Recrystallization of this solid from 80% alcohol gave barium diethyl phosphate derived from the triethyl phosphate produced in the ethanolysis reaction.

Anal. Calcd. for $C_8H_{20}P_2Ba$: C, 21.66; H, 4.54; P, 13.97. Found: C, 21.69; H, 4.73; P, 14.31.

The alcohol was evaporated from the above filtrate, and the residue (16.8 g.) was distilled at reduced pressure to yield, after a small forerun, diethyl β-ketopropylphosphonate (II), 9.4 g., 63%, b.p. 80–89° (1.0 mm.), $n^{25}D$ 1.4300, with an infrared spectrum identical with that of the analyzed sample of this material prepared from iodoacetone. The 2,4-dinitrophenylhydrazone of this product melted at 105.0–105.7°, not depressed by admixture with the derivative of the authentic diethyl β-ketophosphonate, m.p. 104.9–105.2°.

Reaction of IIIb with Sodium Ethoxide at Room Temperature.—A solution of crude diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb, 66 g., 0.20 mole) in 80 ml. of absolute ethanol was added to 200 ml. of absolute ethanol in which metallic sodium (4.6 g., 0.20 mole) had been dissolved. After standing 1 hr. at room temperature, infrared analysis of a neutralized test portion indicated complete disappearance of enol absorption (1640 cm.$^{-1}$) with the appearance of strong carbonyl absorption (1717 cm.$^{-1}$), was well as a sharp, fairly strong peak at 2222 cm.$^{-1}$ typical of acetylenic compounds. After 2 hr., the reaction mixture was freed of alkali by passage through a column of Amberlite IR-120 resin which had been washed with ethanol. The alcohol was evaporated from the eluate at reduced pressure, and the residual oil was distilled through a small Vigreux column to yield triethyl phosphate, 16.7 g., b.p. 56.5–59° (0.5 mm.), $n^{25}D$ 1.4060, reported[20] $n^{25}D$ 1.4039.

Anal. Calcd. for $C_6H_{15}O_4P$: C, 39.62; H, 8.24; P, 17.00. Found: C, 39.62; H, 8.09; P, 16.86.

This was followed by a series of fractions (total wt. 24.9 g.) boiling from 63 to 86° (0.5 mm.), $n^{25}D$ 1.4200 to 1.4350, which, from their infrared spectra, appeared to be mixtures of diethyl alkylphosphonates possessing both carbonyl and alkyne absorption. There remained a high boiling, acidic residue, 16.1 g., the infrared spectrum of which was practically identical with that of the analyzed sample of diethyl hydrogen phosphate (X) described below.

Fractionation of a portion of the combined mixture of the phosphonate esters through a Podbielniak Heliband column yielded a small amount of diethyl β-ketopropylphosphonate (II), b.p. 65° (0.8 mm.), $n^{25}D$ 1.4307, several larger fractions showing progressively less carbonyl and more alkyne absorption and, finally, a small fraction of apparently pure diethyl propynylphosphonate (VI), b.p. 73° (0.8 mm.), $n^{25}D$ 1.4432.

Anal. Calcd. for $C_7H_{13}O_3P$: C, 47.73; H, 7.44. Found: C, 47.34; H, 7.56.

Diethyl Propynylphosphonate (VI) from IIIb.—Diethyl 3-diethylphosphonoisopropenyl phosphate (IIIb, 33 g., 0.10 mole) was added over a 0.5-hr. period to a refluxing solution of sodium (2.28 g., 0.099 mole) in 70 ml. of absolute ethanol with stirring in an atmosphere of dry nitrogen. The cooled orange-colored reaction mixture was then both neutralized and freed of diethyl hydrogen phosphate by passage through a column of 750 ml. of Amberlite MB-1 resin which had been previously washed with 750 ml. of 95% ethanol followed by 300 ml. of absolute ethanol. The ethanol was evaporated from the eluate and the residue (21.6 g.) distilled at reduced pressure. After a 6-g. forerun, there was obtained diethyl propynylphosphonate (VI), 12.0 g., 69%, b.p. 108–110° (2.1 mm.), $n^{25}D$ 1.4449, with characteristic infrared absorption peaks at 1168, 1270 and 2210 cm.$^{-1}$.

Anal. Calcd. for $C_7H_{13}O_3P$: C, 47.73; H, 7.44; P, 17.59. Found: C, 47.73; H, 7.59; P, 17.36.

Reaction of Triethyl Phosphite with Propargyl Bromide.—A mixture of propargyl bromide (31.7 g., 0.266 mole) and triethyl phosphite (43.2 g., 0.26 mole) was heated to 90° whereupon a vigorous exothermic reaction took place. After this reaction had subsided (30 minutes) the mixture was heated under reflux for 1 hr. An additional amount of triethyl phosphite (21.6 g., 0.13 mole) was added and heating continued for another hour. Ethyl bromide (17.9 g., 0.16 mole) was collected in a cold trap. Distillation of the red-brown residue under reduced pressure yielded, after a forerun of triethyl phosphite, a substance apparently identical in its properties and infrared spectrum with diethyl propynylphosphonate (VI), 2.3 g., 5%, b.p. 98–103° (2 mm.), $n^{25}D$ 1.4453.

Anal. Calcd. for $C_7H_{13}O_3P$: C, 47.73; H, 7.44; P, 17.59. Found: C, 47.65; H, 7.59; P, 17.33.

The major distillable product (13 g.) was a higher boiling material, b.p. 150–152° (0.2 mm.), $n^{25}D$ 1.4756, which was unstable on storage. The structure of this material has not as yet been determined.

Anal. Found: C, 45.24; H, 7.61; P, 16.45.

A non-volatile residue (27 g.) remained in the still-pot.

Diethyl Isopropenyl Phosphate (VIII).—A mixture of redistilled chloroacetone (25 g., 0.27 mole) and triethyl phosphite (50 g., 0.30 mole) was heated for 4 hr. at 165°. During this time ethyl chloride (17.1 g., 0.26 mole) and 1 g. of higher boiling material were evolved and collected in a cold trap. The reaction mixture was cooled and distilled at reduced pressure. Crude diethyl isopropenyl phosphate (45 g.) was collected at 56–65° (0.1 mm.). A portion of this product was redistilled through a Podbielniak Heliband micro-column to yield pure VIII, b.p. 57° (0.6 mm.), $n^{25}D$ 1.4158; reported b.p. 72–73° (1 mm.),[6a] 96° (12 mm.),[7b] $n^{35}D$ 1.4135,[6a] $n^{20}D$ 1.4190,[7b] with characteristic infrared absorption peaks at 1165, 1270 and 1646 cm.$^{-1}$.

Anal. Calcd. for $C_7H_{15}O_4P$: C, 43.30; H, 7.79; P, 15.96. Found: C, 42.55; H, 7.93; P, 16.13.

In a similar experiment, the reaction product of chloroacetone (50 g., 0.54 mole) and triethyl phosphite (100 g., 0.60 mole) gave, on distillation through a Vigreux column, diethyl isopropenyl phosphate (VIII), 84 g., 80%, b.p. 98–101° (11 mm.), $n^{25}D$ 1.4187, and diethyl β-ketopropylphosphonate, 9.5 g., 9%, b.p. 87–97° (1.5 mm.), $n^{25}D$ 1.4324, with an infrared spectrum similar to that of the product (II) obtained from the reaction of triethyl phosphite and iodoacetone.

Treatment of diethyl isopropenyl phosphate with 2,4-dinitrophenylhydrazine in ethanol or in ethanol–acetic acid solution did not yield any derivative. When this reaction was carried out in methanol–sulfuric acid solution, yellow needles were obtained which, after two recrystallizations from ethanol, melted at 123–124.5° and did not depress the melting point of the 2,4-dinitrophenylhydrazone prepared from acetone.

Anal. Calcd. for $C_9H_{10}O_4N_4$: N, 23.5. Found: N, 23.3.

Ozonolysis of Diethyl Isopropenyl Phosphate.—A solution of VIII (508 mg., 2.62 mmoles) in 500 ml. of ethyl ace-

(19) For the determination of the neutral equivalent, a weighed sample of the ester was hydrolyzed by refluxing overnight with 6 *N* hydrochloric acid, and most of the hydrogen chloride was removed by azeotropic distillation with two portions of benzene. The residue was diluted with water and titrated electrometrically. The titration curve found was that of phosphoric acid; the neutral equivalent was calculated on the basis of the alkali required to raise the *p*H from the first inflection point at 4.2 to the second inflection point at 8.5.

tate was treated with ozone at −80° at the rate of 0.5 mmole per minute. After five minutes, unreacted ozone was present in the effluent gases whereupon ozonization was halted and the mixture concentrated to 20 ml. under reduced pressure. This residue was diluted to 250 ml. with water, and after standing for several days aliquot samples were removed and analyzed for formaldehyde. Colorimetric determination with chromotropic acid indicated a 14.6% yield of formaldehyde whereas gravimetric determination as the methone derivative gave a 12.2% recovery.

Diethyl Isopropyl Phosphate (IX) from VIII.—A solution of VIII (1.54 g., 7.9 mmoles) in 20 ml. of ethyl acetate was hydrogenated in the presence of 210 mg. of 10% palladium-on-charcoal. At the end of 42 minutes, 8.4 mmoles of hydrogen had been absorbed and further uptake ceased. After removal of the catalyst and the solvent, the residue was distilled to yield diethyl isopropyl phosphate (IX), 1.1 g., 70%, b.p. 84–86° (20 mm.), $n^{25}D$ 1.4038. This material is quite hygroscopic; a hydroxyl peak was observed in the infrared absorption spectrum unless determined in carbon tetrachloride solution immediately after drying over magnesium sulfate, in which case the infrared spectrum (characteristic peaks at 1167 and 1262 cm.$^{-1}$) was identical with that of a similarly dried solution of authentic diethyl isopropyl phosphate. Analytical results on a sample of the pure liquid IX dried with magnesium sulfate were not quite correct, but they were similar to those found with the authentic material (see below). Phosphorus analyses were low and varied widely on duplicate samples of this substance.

Anal. Calcd. for $C_7H_{17}O_4P$: C, 42.86; H, 8.67; neut. equiv., 196. Found: C, 41.50; H, 8.78; neut. equiv., 200.[19]

Diethyl Isopropyl Phosphate (IX) from Diethyl Phosphonate.[12]—A solution of diethyl phosphonate (13.8 g., 0.10 mole), dry isopropyl alcohol (20 ml.), bromotrichloromethane (20 ml.) and 2,6-lutidine (20 ml.) in 100 ml. of dry ether was allowed to stand overnight at room temperature whereupon a copious precipitate of amine hydrobromide was formed. This was removed by filtration, and the filtrate was washed with 15 ml. of water, dried and evaporated under reduced pressure. Distillation of the residue yielded diethyl isopropyl phosphate, 3.9 g., 24%, b.p. 101–103° (20 mm.), $n^{25}D$ 1.4042. The infrared spectrum of this compound (in CCl_4) showed characteristic peaks at 1167 and 1262 cm.$^{-1}$. As mentioned previously, because of the hygroscopic nature of this substance, it was necessary to dry the solution before determination of the spectrum, and the results obtained on microanalysis were not quite correct even after drying the sample with magnesium sulfate.

Anal. Calcd. for $C_7H_{17}O_4P$: C, 42.86; H, 8.67; P, 15.76; neut. equiv., 196. Found: C, 41.65; H, 8.92; P, 13.26; neut. equiv., 207.[19]

Diethyl Hydrogen Phosphate (X) from VIII.—Preliminary investigations of the hydrogenation of diethyl isopropenyl phosphate (VIII) using reduced platinum oxide in ethyl acetate indicated that two moles of hydrogen were absorbed to form a strongly acidic product. In one experiment VIII (186 mg., 0.96 mmole) in 15 ml. of ethyl acetate was hydrogenated using 45 mg. of platinum oxide, whereupon 1.69 mmoles of hydrogen were absorbed in 15 minutes. After filtration, the entire reduction mixture was titrated electrometrically with standard alkali to *p*H 7.9. In this way an equivalent weight of 202 was obtained for VIII as compared to the calculated value of 194.

To isolate the reduction product, a solution of VIII (3.5 g., 0.018 mole) in 35 ml. of absolute ethanol was hydrogenated in a Parr apparatus with 400 mg. of platinum oxide for 90 minutes. After filtration and evaporation of the solvent, the residue was distilled in a molecular still to yield diethyl hydrogen phosphate (X), 1.66 g., 60%, $n^{25}D$ 1.4170, reported[21] $n^{25}D$ 1.4152.

Anal. Calcd. for $C_4H_{11}O_4P$: C, 31.20; H, 7.14; P, 20.15. Found: C, 31.30; H, 7.37; P, 20.20.

Phosphonic Acids. V.[1] An Improved Method for the Preparation of Sodium Diethyl Phosphonate and a Study of its Comparative Reactivity with Alkyl Halides and *p*-Toluenesulfonates[2]

BY RONALD G. HARVEY, TERRELL C. MYERS, HERBERT I. JACOBSON AND ELWOOD V. JENSEN

RECEIVED JUNE 18, 1956

Sodium diethyl phosphonate is prepared rapidly and conveniently by treatment of a solution of diethyl phosphonate with an excess of sodium hydride. In tetrahydrofuran solution, the relative reaction rates of primary alkyl halides and *p*-toluenesulfonates with sodium diethyl phosphonate are RBr > ROTs > RCl. The reaction of sodium diethyl phosphonate with trimethylene chlorobromide gives diethyl γ-chloropropylphosphonate, which on hydrolysis yields γ-chloropropylphosphonic acid.

Sodium diethyl phosphonate, or sodium diethyl phosphite, a reagent commonly used for the preparation of phosphonic acid esters, generally has been prepared[3] by treatment of a solution of diethyl phosphonate with either an equivalent amount of sodium ethoxide (or methoxide) or else with metallic sodium which dissolves with the evolution of hydrogen. Since alcohol and diethyl phosphonate probably do not differ greatly in their acid strengths the former method has the disadvantage that some sodium ethoxide may remain in the mixture either to compete with sodium diethyl phosphonate in its nucleophilic reactions or to react with the products formed. The latter procedure has the disadvantage that metallic sodium dissolves rather slowly in solutions of diethyl phosphonate so that many hours or even days may be required for completion of the reaction. Moreover, the dissolving metal acts as a reducing agent, and solutions of sodium diethyl phosphonate prepared in this way invariably are contaminated with phosphine compounds as indicated by the characteristic odor.[4]

It was found that the undesirable features of either procedure could be avoided by the use of sodium hydride as the basic reagent according to the equation

$$HPO(OEt)_2 + NaH \longrightarrow NaPO(OEt)_2 + {}^1/_2H_2$$

May 20, 1957

A suspension of this substance reacts rapidly with a tetrahydrofuran solution of diethyl phosphonate with the evolution of hydrogen to produce a solution of sodium diethyl phosphonate free from phosphine odors.

Recently it was observed that primary and secondary alkyl esters of *p*-toluenesulfonic and methanesulfonic acids react with sodium diethyl phosphonate in a manner similar to that of alkyl halides to produce the corresponding diethyl alkylphosphonate esters.[5] In order to evaluate the potential usefulness of this reaction, a comparison was made of the relative reactivity of alkyl chlorides, bromides and tosylates toward sodium diethyl phosphonate. In this study, freshly prepared sodium diethyl phosphonate[6] was allowed to react at 20° in tetrahydrofuran solution with a threefold excess of *n*-butyl bromide, *n*-butyl chloride and *n*-butyl tosylate, respectively. The progress of these reactions was followed by measurement of the bromide, chloride or tosylate ions produced at various time intervals. As indicated by the data of Fig. 1, the relative reactivities are in the order Br > OTs > Cl with the initial rates in the approximate order of 280:70:1.

$$ROTs + NaPO(OEt)_2 \longrightarrow RPO(OEt)_2 + NaOTs$$

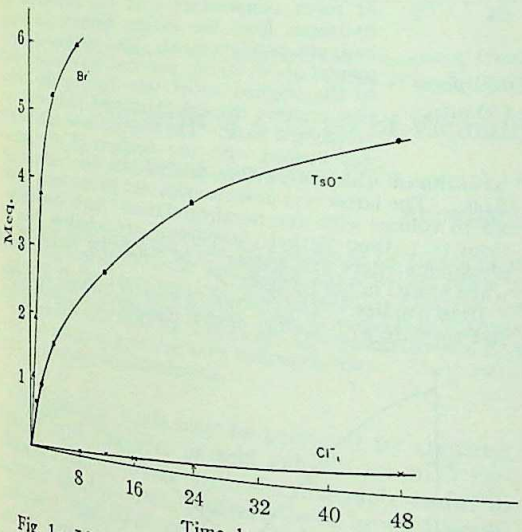

Fig. 1.—Liberation of ions from the reaction of sodium diethyl phosphonate (10 meq. from Na) with either *n*-butyl bromide, *n*-butyl tosylate or *n*-butyl chloride (30 meq.) at 20°.

When sodium diethyl phosphonate is allowed to react with a mixture of excess *n*-butyl bromide and *n*-butyl tosylate at 30°, bromide ion is liberated at about 4 times the rate of tosylate (Fig. 2). The concentration of bromide ion reaches a maximum in about 2 hr., whereupon it begins to disappear rapidly with an accompanying increase in the rate of appearance of tosylate ion. Similarly, when sodium diethyl phosphonate is allowed to react with a mixture of butyl chloride and butyl tosylate, chloride ion reaches a maximum concentration and then disappears (Fig. 3).

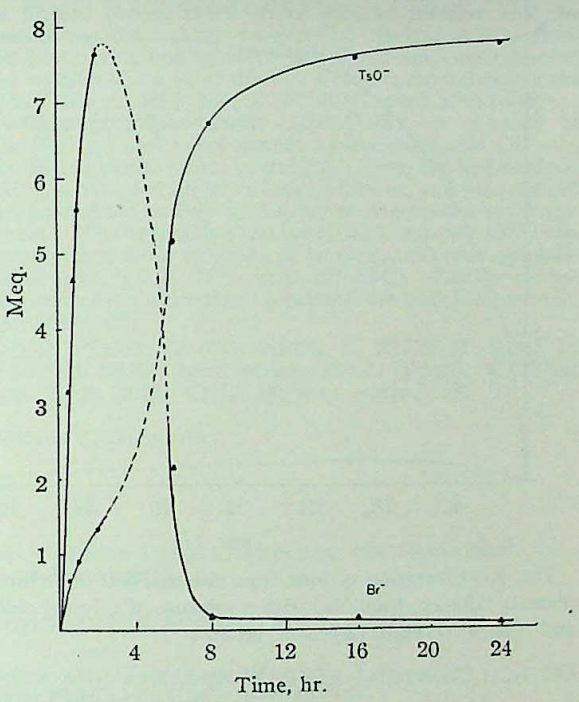

Fig. 2.—Liberation of ions from the reaction of sodium diethyl phosphonate (10 meq. from NaH) with a mixture of *n*-butyl bromide (30 meq.) and *n*-butyl tosylate (30 meq.) at 30°.

The disappearance of bromide (and chloride) ion probably results from a reaction with butyl tosylate in the following manner

$$ROTs + Br^- \longrightarrow RBr + TsO^-$$

However, a suspension of finely pulverized sodium bromide in tetrahydrofuran shows little tendency to react with butyl tosylate. It would appear that the sodium bromide produced from the reaction of sodium diethyl phosphonate with alkyl bromides may be in an extremely finely divided or otherwise reactive form. That this reactivity is gradually lost is indicated by an experiment in which sodium diethyl phosphonate was allowed to react with butyl bromide for 15 hr. at 30° and then butyl tosylate added. As is shown in Fig. 4, again there is a disappearance of bromide ion accompanied by an appearance of tosylate ion, but in this case it is much less rapid or complete than when the butyl tosylate is present during the liberation of the sodium bromide.

In all the reactions studied, using sodium diethyl phosphonate prepared both from sodium and from sodium hydride, the amount of halide or tosylate ions liberated was never greater than 70 to 80% of that calculated on the basis of the diethyl phosphonate employed, even after very long reaction

(5) T. C. Myers, S. Preis and E. V. Jensen, THIS JOURNAL, **76**, 4172 (1954).

(6) A number of these experiments were carried out previous to the development of the sodium hydride method for the preparation of sodium diethyl phosphonate, and in these studies metallic sodium was employed for the preparation of this reagent. However, the rates of liberation of sodium bromide from *n*-butyl bromide at 30° with sodium diethyl phosphonate prepared by either method were found to be similar. The results obtained with a mixture of butyl bromide and butyl tosylate illustrated in Fig. 2 for sodium diethyl phosphonate prepared with sodium hydride are entirely analogous to those obtained with the reagent prepared from metallic sodium.

periods. These results indicate either that excess sodium or sodium hydride does not convert diethyl phosphonate completely to the sodium derivative or, more probably, that sodium diethyl phosphonate does not react completely with excess alkyl halide or tosylate. Evidence suggesting the latter possibility has been obtained by other investigators.[7]

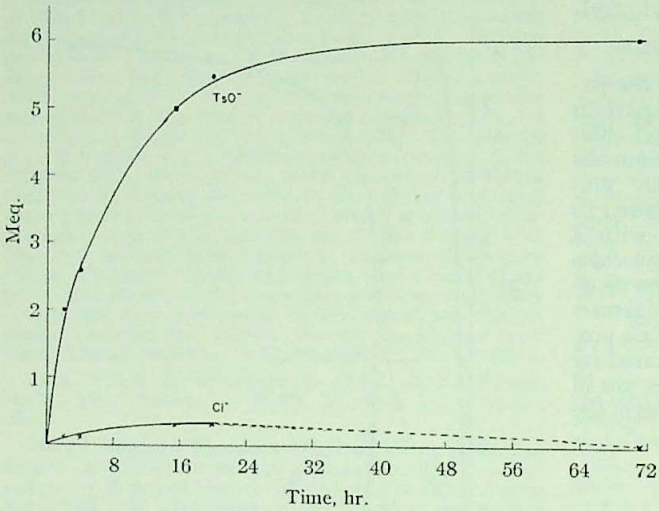

Fig. 3.—Liberation of ions from the reaction of sodium diethyl phosphonate (10 meq. from Na) with a mixture of *n*-butyl chloride (30 meq.) and *n*-butyl tosylate (30 meq.) at 30°.

b, R = H

When sodium diethyl phosphonate was allowed to react in tetrahydrofuran with an equimolar amount of trimethylene chlorohydrin tosylate (I), diethyl γ-chloropropylphosphonate (IIIa) was isolated in 22% yield; with two molar proportions of trimethylene chlorobromide (II) the yield of IIIa was 54% based on sodium diethyl phosphonate. Hydrolysis of IIIa with concentrated hydrochloric acid gave crystalline γ-chloropropylphosphonic acid (IIIb).

Experimental

Reagents.—Commercial diethyl phosphonate, *n*-butyl chloride, *n*-butyl bromide and *n*-butyl tosylate[8] were redistilled before use. Tetrahydrofuran was dried by distillation from calcium hydride and stored over sodium. The sodium hydride used was a bluish material obtained from the du Pont Co.; the gray product obtained from Metal Hydrides, Inc., was found unsatisfactory in that it produced brown solutions and formed gelatinous material which prevented filtration of the final solution. It was found convenient to weigh out several 4-g. portions of du Pont sodium hydride in a dry-box and store these in stoppered bottles in a desiccator. The entire contents of one bottle then was used for an individual preparation of sodium diethyl phosphonate as described below without further need for the dry-box.

In the competition experiments which were carried out previous to the development of the sodium hydride method for the preparation of sodium diethyl phosphonate, this reagent was prepared in the conventional manner[3] by dissolving metallic sodium in a tetrahydrofuran solution of diethyl phosphonate. The method of preparation of sodium diethyl phosphonate is specified for each experiment.

Preparation of Sodium Diethyl Phosphonate with Sodium Hydride.—The reaction of diethyl phosphonate with sodium hydride was carried out conveniently in a dry 300-ml. 2- or 3-necked flask equipped with a dropping funnel with pressure equalizer and an outlet protected by a drying tube. In the bottom of the flask was sealed a medium porosity fritted glass disk[9] through which the final solution could be filtered through an all-glass connection into a 250-ml. volumetric flask. A continuous stream of dry helium or nitrogen at about 5 cm. pressure was introduced through this disk both to flush out the system and to stir the contents of the flask during the reaction.

Approximately 100 ml. of dry tetrahydrofuran was placed in the flask and a bottle of sodium hydride containing a 10% molar excess over the diethyl phosphonate to be used was opened and quickly emptied into the tetrahydrofuran. This mixture was cooled to −12° by immersion in a Dry Ice–chloroform–carbon tetrachloride mixture, and then diethyl phosphonate was added from the dropping funnel at such a rate that the evolution of hydrogen did not become too vigorous. After addition was complete the mixture was allowed to stand at room temperature until the evolution of hydrogen from the sodium hydride particles had practically ceased. The helium stream, now at about 20 cm. pressure, was transferred to the original outlet tube forcing the reaction mixture through the fritted disk into the volumetric flask. The residual sodium hydride was washed with two portions of dry tetrahydrofuran which were then filtered into the volumetric flask. The latter was now removed and its contents made up to volume with dry tetrahydrofuran. Such stock solutions of sodium diethyl phosphonate are colorless, free of phosphine odors and appear to be stable for several days when stored in the refrigerator.

Rate Studies.—The reaction of *n*-butyl chloride, bromide and tosylate with sodium diethyl phosphonate were carried

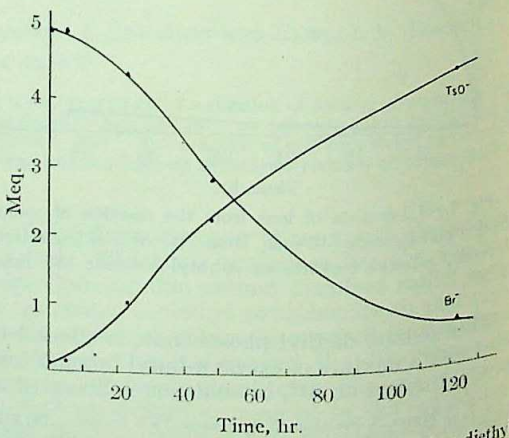

Fig. 4.—Ionic composition of a mixture of sodium diethyl phosphonate (10 meq. from NaH) and *n*-butyl bromide allowed to react for 15 hr. at 30° and then treated (at 0 time) with *n*-butyl tosylate (30 meq.) at 30°.

out in 250-ml. volumetric flasks agitated on an Eberbach shaking machine. Reactions at 20 ± 1° were carried out in air conditioned room; reactions at 30 ± 0.2° were immersed in a constant temperature water-bath. In each flask there was placed 30 millimoles of the butyl halide or tosylate dissolved in 10 ml. of dry tetrahydrofuran. At zero time there was added 10 ml. of a tetrahydrofuran solution containing sodium diethyl phosphonate (prepared from 10 millimoles of diethyl phosphonate). After shaking for the appropriate time period, the reaction was stopped by the addition of 150 ml. of water and 60 ml. of pentane. After thorough mixing, the pentane layer was removed; the aqueous layer was diluted to volume and aliquot portions were analyzed for halide ion by the Volhard titration and for tosylate ion by comparison of the ultraviolet absorption at 261 mμ with that of a standard solution of sodium tosylate.

Diethyl γ-Chloropropylphosphonate (IIIa) from Trimethylene Chlorohydrin Tosylate (I).—A solution of I (14.9 g., 0.06 mole) and sodium diethyl phosphonate, prepared by the action of excess sodium on diethyl phosphonate (8.57 g., 0.06 mole), in tetrahydrofuran (50 ml.) was stirred at room temperature for 72 hr. Then dry pentane (70 ml.) was added and the mixture filtered. The solid residue (9.41 g.) contained chlorine (6.0%), sulfur (13.1%) and phosphorus (2.6%). The filtrate was concentrated under reduced pressure and the residue (14.2 g.) distilled. The fraction (4.3 g.) boiling at 59–78° (0.04 mm.) was redistilled to yield diethyl γ-chloropropylphosphonate (IIIa), 2.1 g., 16%, b.p. 68–70° (0.05 mm.), n^{25}D 1.4423.

Anal. Calcd. for $C_7H_{16}O_3PCl$: C, 39.16; H, 7.51; P, 14.44. Found: C, 38.53; H, 7.80; P, 14.10.

The higher boiling fraction (6.7 g.) appeared to be a mixture from which no pure substances could be isolated.

Repetition of the above reaction on a 0.4 molar scale yielded similar results with diethyl γ-chloropropylphosphonate isolated in 22% yield.

From Trimethylene Chlorobromide (II).—To a stirred solution of sodium diethyl phosphonate, prepared by the action of excess sodium on diethyl phosphonate (27.6 g., 0.20 mole) in tetrahydrofuran (400 ml.), trimethylene chlorobromide (63.0 g., 0.40 mole) was added. After 15 minutes a white solid began to separate. After stirring at room temperature for 4 hr. the reaction mixture was filtered, the filtrate concentrated under reduced pressure and the residue distilled. After recovery of the excess chlorobromide, a fraction boiling at 85–100° (0.32 mm.) was collected and redistilled to yield diethyl γ-chloropropylphosphonate (IIIa), 23.2 g., 54%, b.p. 97–99° (0.25 mm.), n^{25}D 1.4429.

γ-Chloropropylphosphonic Acid (IIIb).—A mixture of IIIa (3.0 g.) and concentrated hydrochloric acid (30 ml.) was heated under reflux overnight. Then the hydrochloric acid was removed under reduced pressure, and benzene (10 ml.) was added and distilled away to remove the last traces of acid. The crystalline residue (2.0 g., m.p. 95–102°) was recrystallized from chloroform to give γ-chloropropylphosphonic acid, 1.7 g., 76%, m.p. 101–104°. Further recrystallization from chloroform furnished the analytical sample, m.p. 104–105°.

Anal. Calcd. for $C_3H_8O_3PCl$: C, 22.72; H, 5.08; P, 19.55; Cl, 22.37; neut. equiv., 158.6. Found: C, 23.12; H, 5.12; P, 19.60; Cl, 22.14; neut. equiv., 158.

Synthesis of a Series of Vicinally Substituted Hydroxamic Acids[1]

BY MARVIN A. STOLBERG,[2] WILLIAM A. MOSHER AND THEODOR WAGNER-JAUREGG

RECEIVED JULY 17, 1956

A series of hydroxamic acids were prepared by standard procedures from the corresponding esters with the exception of *o*-methoxybenzohydroxamic acid which was obtained from the acid chloride. Compounds which have not been previously reported in the literature are: *o*-nitrobenzohydroxamic, *o*-methoxybenzohydroxamic, *o*-dimethylaminobenzohydroxamic, *cis*-hexahydrophthalohydroxamic and *exo-cis*-3,6-endoxohexahydrophthalohydroxamic acids. *cis*-N-Hydroxyhexahydrophthalamide and *endo-cis*-N-hydroxy-3,6-endomethylene-Δ⁴-tetrahydrophthalimide were obtained from the reaction of the corresponding anhydrides with hydroxylamine. Their infrared spectra were compared to that of N-hydroxyphthalimide and N-hydroxyisophthalimide.

Hydroxamic acids may be prepared by treating esters, acid chlorides or acid anhydrides with hydroxylamine.[3] Other methods, although useful in certain specific cases, generally have limited application. The hydroxamic acids described in this paper were prepared from the corresponding esters with the exception of *o*-methoxybenzohydroxamic acid which was obtained from the acid chloride. Since difficulties were encountered in the isolation and purification of the hydroxamic acids and prime attention was paid to the purity of the products, the yields reported do not necessarily reflect efforts to reach a maximum. A good general method for the separation of certain hydroxamic acids from the corresponding carboxylic acids which are frequent impurities is by treatment of an alkaline aqueous solution with carbon dioxide, which results in precipitation of the hydroxamic acid. This method is applicable to water-insoluble hydroxamic acids that have a pK_a above 9.0.

Compounds prepared for this investigation which have not been previously reported in the literature are: *o*-nitrobenzohydroxamic,[4] *o*-methoxybenzohydroxamic,[4] *o*-dimethylaminobenzohydroxamic, *cis*-hexahydrophthalohydroxamic and *exo-cis*-3,6-endoxohexahydrophthalohydroxamic acids. The latter compound proved to be a powerful vesicant and contact with the skin should be avoided. This compound has a basic structure similar to cantharidine, which is a well known vesicant.

An attempt was made to prepare *o*-hydroxymethylbenzohydroxamic acid from phthalide and hydroxylamine. A small portion of the crude sodium salt of the product obtained produced a deep wine color when treated with ferric chloride in 0.1 *N* HCl which is typical of hydroxamic acids. However, treatment of an aqueous solution of the salt with carbon dioxide or hydrochloric acid

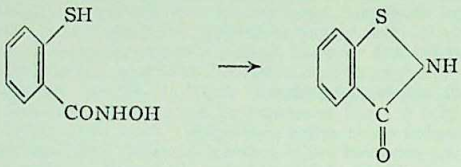
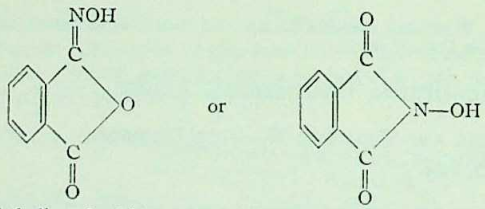
Digitized by Arya Samaj Foundation Chennai and eGangotri

yielded phthalide instead of the hydroxamic acid. Similarly, phthalide was obtained from a methanolic solution of the salt when treated with a carboxylic acid resin (IRC-50). The reaction of methyl *o*-mercaptobenzoate and hydroxylamine produced benzisothiazol-3-one (I) instead of the desired *o*-mercaptobenzohydroxamic acid. The formation of I from the ester and hydroxylamine could occur by the elimination of water from *o*-mercaptobenzohydroxamic acid formed as an intermediate.



I does not produce a color with ferric chloride in anhydrous alcohol, in contrast to hydroxamic acids, but when a drop of water was added to the light orange solution, a deep wine color was produced. This indicated that compound I may hydrolyze in water to form the desired hydroxamic acid. However, all attempts to isolate the hydroxamic acid from aqueous solution were unsuccessful.

The disodium salt of phthalohydroxamic acid when acidified yields "phthaloxime" (II) instead of the hydroxamic acid.[5]

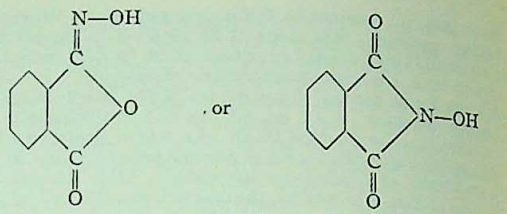


Phthalic anhydride mono-oxime (IIa)

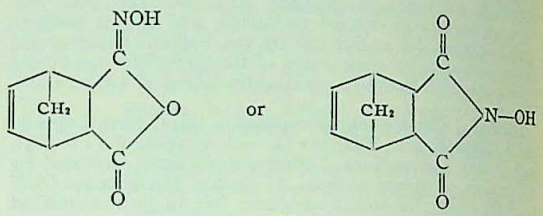
N-hydroxyphthalimide (IIb)

Since *cis*-hexahydrophthalohydroxamic acid is stable, an attempt was made to prepare the corresponding half-hydroxamic acids from the reactions of *cis*-hexahydrophthalic anhydride and *endo-cis*-3,6-endomethylene-Δ^4-tetrahydrophthalic anhydride with hydroxylamine. The products isolated, III and IV, respectively, had analyses which corresponded to the "phthaloxime" structure instead of the desired half-hydroxamic acids. The titration of these compounds with alkali gave no indication of the formation of the corresponding half-hydroxamic acids.

Brady and associates[6] formulated the structure of "phthaloxime" (II) as phthalic anhydride mono-oxime (IIa). Ames and Grey[7] reported the preparation of N-hydroxyphthalimide (IIb) by the reaction of phthalic anhydride with O-benzylhydroxylamine followed by hydrogenolysis, and this product was found to be identical with "phthaloxime." Ames and Grey believe that the correct structure is N-hydroxyphthalimide (IIb) based upon the following observations: 1. N-benzyloxy- and N-hydroxy-phthalimide show infrared



III



IV

imide absorption bands (1700–1800 cm.$^{-1}$) similar to those of N-ethylphthalimide. 2. The ultraviolet absorption spectra are also similar to those of phthalimide. 3. The pK_a value (7.0) is well outside the normal range of oximes (pK_a *ca.* 10–12).

The infrared spectra of IIb, III and IV indicated that they are structurally similar. The carbonyl absorption bands around 1700 cm.$^{-1}$ (see Table I) are clearly different from those of N-hydroxyisophthalimide (phthalic anhydride monoöxime, IIa) obtained by Carpino[8] which has the characteristic doublet at 1810 and 1825 cm.$^{-1}$. Carpino also noted that the iso derivatives lack the very broad carbonyl bands of normal phthalimides which are present in II, III and IV. III and IV have therefore been assigned the structures *cis*-N-hydroxyhexahydrophthalimide and *endo-cis*-N-hydroxy-3,6-endomethylene-Δ^4-tetrahydrophthalimide.

Experimental

o-Methoxybenzohydroxamic Acid.—A chloroform solution of 8.5 g. (0.5 mole) of *o*-methoxybenzoyl chloride was added dropwise, with stirring, to 100 ml. of a chloroform solution containing 3.8 g. (0.055 mole) of hydroxylamine hydrochloride and 10.6 g. (0.105 mole) of triethylamine. The solution was stirred for an hour to ensure complete reaction after which the solvent was vacuum distilled. The solid residue was dissolved in water and hydrochloric acid

was added with cooling to *p*H *ca.* 2, yielding a precipitate which was filtered, washed with cold water and dissolved in dilute alkali. Small pieces of Dry Ice were added to the alkaline solution and a precipitate was obtained which was recrystallized from acetone–ether, m.p. 129–131°, yield 6.4 g. (77%).

Anal. Calcd. for $C_8H_9NO_3$: C, 57.5; H, 5.5; N, 8.4. Found: C, 58.2; H, 5.8; N, 8.2.

o-Aminobenzohydroxamic Acid.—The procedure used for the preparation of the other hydroxamic acids was very similar, differing only in the quantities employed and methods of isolation. The general procedure was as follows, using *o*-aminobenzohydroxamic acid as an example. To a solution of 5.0 g. (0.03 mole) of sodium in 150 ml. of absolute methanol there was added a solution of 7.0 g. (0.1 mole) of hydroxylamine hydrochloride in 100 ml. of absolute methanol. The sodium chloride which precipitated was removed by filtration, and 15.1 g. (0.1 mole) of methyl anthranilate was added to the filtrate. The resulting solution was heated on a steam-bath for 30 minutes. Upon cooling, the sodium *o*-aminobenzohydroxamate which precipitated was filtered, dissolved in a minimum quantity of water and the solution acidified to *p*H 4 with acetic acid. The resultant precipitate was recrystallized twice from water to yield a colorless product, m.p. 142–143°, yield 3.2 g. (71%). The melting point reported in the literature is 149°.[9]

Anal. Calcd. for $C_7H_8O_2N_2$: C, 55.5; H, 5.3; N, 18.6. Found: C, 55.3; H, 5.3; N, 18.4.

o-Nitrobenzohydroxamic Acid.—When 20.0 g. (0.11 mole) of methyl *o*-nitrobenzoate was added to the alcoholic hydroxylamine solution, an orange color developed. Only a small quantity of the sodium salt precipitated using conditions described above. The solvent was removed under reduced pressure and the resulting crude solid was dissolved in water. Upon acidification a yellow precipitate was obtained which was recrystallized from hot water. The yellow needles melted at 131–133°, yield 10.0 g. (50%).

Anal. Calcd. for $C_7H_6N_2O_4$: C, 46.2; H, 3.3; N, 15.4. Found: C, 46.3; H, 3.6; N, 15.2.

o-Dimethylaminobenzohydroxamic Acid.—Only a small quantity of hydroxamic acid formed during the first hour based upon the test with ferric chloride. Heating the solution yielded products which were difficult to separate and isolate. The best procedure was to stir the ester and hydroxylamine at room temperature for 24 hr. The solvent was vacuum evaporated and the solid residue stirred with ether to remove any unreacted ester. The precipitate was filtered, dissolved in a small quantity of water and carbon dioxide bubbled into the aqueous solution. The hydroxamic acid precipitated and was recrystallized from ether, m.p. 129–131°.

Anal. Calcd. for $C_9H_{12}N_2O_2$: C, 60.1; H, 6.7; N, 15.6. Found: C, 59.5; H, 6.7; N, 15.3.

(9) A. W. Scott and B. L. Wood, *J. Org. Chem.*, **7**, 508 (1942).

***cis*-Hexahydrophthalohydroxamic Acid.**—This hydroxamic acid obtained from 10.0 g. (0.05 mole) of methyl *cis*-hexahydrophthalate was prepared and isolated exactly as above, m.p. 191–193°, yield 6.0 g. (60%).

Anal. Calcd. for $C_8H_{14}O_4N_2$: C, 47.5; H, 7.0; N, 13.9. Found: C, 47.9; H, 7.1; N, 13.3.

***exo-cis*-3,6-Endoxohexahydrophthalohydroxamic Acid.**—Treatment of the aqueous solution of the disodium salt of *exo-cis*-3,6-endoxohexahydrophthalohydroxamic acid (obtained as above) with carbon dioxide or hydrochloric acid did not produce a precipitate. The aqueous solution, after treatment with hydrochloric acid, was evaporated to dryness. The mixture was extracted with acetone in a Soxhlet extractor 4 hr., and a white crystalline product was obtained on evaporation of the acetone, m.p. 186° dec. *Care* should be exercised when handling this compound because it is a vesicant.

Anal. Calcd. for $C_8H_{12}O_5N_2$: C, 44.5; H, 5.7; N, 13.0. Found: C, 44.8; H, 5.8; N, 12.8.

N-Hydroxyhexahydrophthalimide.—A solution of 7.7 g. (0.05 mole) of *cis*-hexahydrophthalic anhydride[10] in 50 ml. of methyl alcohol was added to a solution containing 1.82 g. (0.05 mole) of hydroxylamine in 10 ml. of methyl alcohol. A red color was obtained with ferric chloride immediately. The reaction mixture was stirred for several hours at room temperature after which the solvent was vacuum removed. A colorless viscous oil was obtained which crystallized by scratching with a glass rod. The water-soluble, white crystalline product was recrystallized from chloroform–ligroin (60–90), m.p. 110–112°, yield 7.0 g. (83%).

Anal. Calcd. for $C_8H_{11}O_3N$: C, 56.7; H, 6.6; N, 8.3. Found: C, 56.7; H, 6.6; N, 8.4.

N-Hydroxy-3,6-endomethylene-Δ^4-tetrahydrophthalimide.—To a solution of 9.85 g. (0.06 mole) of *endo-cis*-3,6-endomethylene-Δ^4-tetrahydrophthalic anhydride[10] in 50 ml. of methyl alcohol there was added an equimolar mixture of hydroxylamine and sodium methoxide in methanol. A small quantity of precipitate was observed after 24 hr. at room temperature. The solvent was removed under reduced pressure after which the salt was dissolved in a minimum quantity of water and precipitated with acid. The white crystalline product was recrystallized from chloroform–ligroin (60–90) and produced a red color with ferric chloride, m.p. 165–166°, yield 8.6 g. (80%).

Anal. Calcd. for $C_9H_9O_3N$: C, 60.3; H, 5.1; N, 7.8. Found: C, 60.1; H, 5.0; N, 7.6.

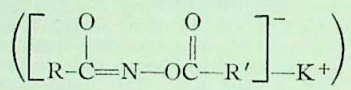
Rates of Reaction of Vicinally Substituted Hydroxamic Acids with Isopropyl Methylphosphonofluoridate (Sarin)[1]

BY MARVIN A. STOLBERG[2] AND WILLIAM A. MOSHER

RECEIVED JULY 17, 1956

The half-time of hydrolysis, pseudo-monomolecular rate constants and the specific rate constants for the reaction of certain *o*-substituted benzohydroxamic and vicinal dihydroxamic acids with isopropyl methylphosphonofluoridate (Sarin) are reported. A plot of the $\log_{10}$ of the specific rate constants *versus* the pK_a's of the hydroxamic acids coincided with the line previously established for the *p*-substituted benzohydroxamic acids. Thus, there is no marked change of the rates of reaction of hydroxamic acids with Sarin due to vicinal substitution and no alteration in the nature of the reacting group by these substituents. The most probable reactive form of the hydroxamate ion is postulated.

An exhaustive investigation of the Lossen rearrangement of acylated hydroxamic acids has been reported by Hauser and associates.[3] It was shown that the rates of decomposition of the potassium salts of a series of dibenzohydroxamates



in which R is phenyl and R′ is phenyl, containing certain *o*-, *m*- and *p*-substituents, are, with the exception of the *o*-methoxy derivative, directly related to the ionization constants of the acids corresponding to R′COOH. In a series of dibenzohydroxamates studied, where R′ is phenyl and R is phenyl, containing certain *m*- and *p*-substituents, an inverse relationship exists between the rate constants and the ionization constants. However, the rate constants of the *o*-substituted phenyl derivatives are more than 100 times greater than would be predicted.

The peculiar effects of a substituent in the *o*-position have been attributed to an *ortho* or proximity effect[4]; however, it has not been possible to estimate the relative importance of electrical effects and specific *ortho* effects for a strongly polar substituent. Generally, these effects have been attributed to steric inhibition of resonance, F strain and hydrogen bonding. The enhancement in rates of reactions by vicinal groups has been reported frequently in the literature.[5]

In the investigation of candidate drugs for the destruction of the "nerve gas" isopropyl methylphosphonofluoridate (Sarin), Hackley, *et al.*,[6] and Swidler, *et al.*,[7] have observed the rapid reaction rates of certain *p*-substituted benzohydroxamic acids with this compound. In a search for more efficacious prophylactic compounds, it was important to determine whether these reactions could be markedly accelerated by placing substituents in the *o*-position. In the accompanying paper[8] the synthesis of certain *o*-substituted benzohydroxamic and vicinal dihydroxamic acids is described.

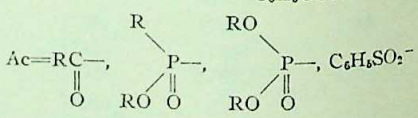
The half-times of hydrolysis of Sarin in the presence of various hydroxamic acids are reported in Table I. To assure first-order kinetics the reactions were carried out with a tenfold molar excess of hydroxamic acid over Sarin. The values were obtained by measuring the rate of addition of standard alkali consumed by the reaction mixture when maintained at a fixed *p*H by a Beckman autotitrator. A detailed discussion of the use of this instrument for studying the kinetics of the reaction of benzohydroxamic acid with Sarin was reported by Swidler and Steinberg.[9] They confirmed the validity of the use of acid production as a measure of the destruction of Sarin as well as the mechanism postulated for the reaction between hydroxamic acids and phosphoryl halides,[6] sulfonyl halides[10] or acyl halides[10a] in alkaline aqueous or inert solvents. These reactions proceed by the initial acylation of the hydroxamate ion followed by a Lossen rearrangement according to the scheme

$$(C_6H_5CONHO)^- + AcX \longrightarrow C_6H_5CONHOAc + X^-$$

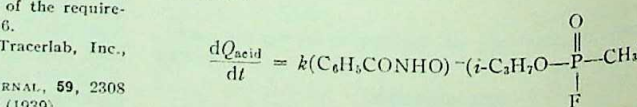
$$C_6H_5CONHOAc + OH^- \longrightarrow (C_6H_5CONOAc)^- + H_2O$$

$$(C_6H_5CONOAc)^- \longrightarrow C_6H_5NCO + Ac^-$$

$$C_6H_5NCO + (C_6H_5CONHO)^- \longrightarrow C_6H_5CONHOCONHC_6H_5$$



The rate of the reaction was found to be dependent on the concentration of the hydroxamate ion and the rate equation for the reaction was established as



Since the amount of hydroxamate ion used up in the course of the reaction is negligible in comparison

$C_8H_{14}O_4N_2$[d]	9.75	0.070	9.8	1.17	168

[a] k_{obs} = pseudomonomolecular rate constant = k-(RCONHO)$^-$. [b] k = specific rate constant. [c] *exo-cis*-3,6-Endoxohexahydrophthalohydroxamic acid. [d] *cis*-Hexahydrophthalohydroxamic acid.

with the total, the velocity equation takes the form

$$\frac{dQ_{acid}}{dt} = k_{obs}(i\text{-}C_3H_7O\text{—}\underset{\underset{F}{|}}{\overset{\overset{O}{\|}}{P}}\text{—}CH_3)$$

where $k_{obs} = k(C_6H_5CONHO^-)$.

Swidler, Plapinger and Steinberg[7] have studied the reactions of *p*-substituted benzohydroxamic acids with Sarin and have come to the following conclusions: 1. A conventional Hammett plot of log k/k_0 *vs.* σ established a ρ of -0.77 ± 0.05. This value was reported to be consistent with a gross mechanism involving the attack of an anion upon a neutral molecule and inconsistent with a rate step involving Lossen rearrangement which yielded larger negative ρ-values (ρ *ca.* -2.6).[11] The excellence of the fit of compounds over a rather wide range of σ-values attested to the apparent mechanistic unity throughout the series and the practical utility of determining the comparative reactivities of the hydroxamic acids toward Sarin by following the rate of acid production.

2. A conventional Brönsted plot of log k *vs.* pK_a of *para* substituted benzohydroxamic acids yielded a β of $+0.78$, whereas the comparable value for the line upon which the hydroxide ion lies was *ca.* $+0.5$. It was therefore postulated that the inordinate reactivity of the hydroxamic acids most probably is due to a stereospecific attack upon the Sarin molecule.

3. The hydroxamic acids could be considered as polyfunctional catalysts and react with Sarin in a manner similar to catechol.[12]

The pseudo-monomolecular rate constant (k_{obs}) and specific rate constant (k) for the reaction of Sarin with each of the *o*-substituted benzohydroxamic and vicinal dihydroxamic acids are reported in Table I. Values of log k *versus* pK_a for these compounds fell, within experimental error, on the line established for *p*-substituted benzohydroxamic acids (Fig. 1). It is obvious that a vicinal group

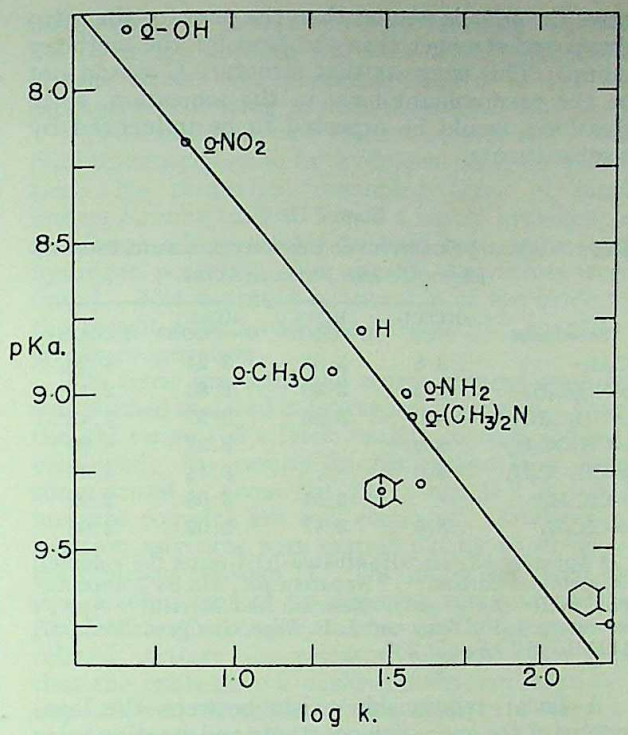

Fig. 1.—Relationship between pK_a values of certain *o*-substituted benzohydroxamic and vicinal dihydroxamic acids and log k for their reaction with Sarin. The equation for the line was obtained from a least squares plot of *p*-substituted benzohydroxamic acids.

produces no marked acceleration in the rate of reaction of a hydroxamic acid with Sarin. Changes in the rate of reaction were dependent only on the ionization constant of the hydroxamic acid. Since these derivatives adhere to a Brönsted relationship, it follows that there is no alteration of the reacting group by vicinal substituents.

The tautomeric structures of hydroxamic acids are

$$R\text{—}\underset{\underset{OH}{|}}{\overset{\overset{}{|}}{C}}\!=\!N\text{—}OH \rightleftharpoons R\text{—}\underset{\underset{O}{\|}}{\overset{\overset{H}{|}}{C}}\text{—}N\text{—}OH$$

The abstraction of a proton with base could thus provide

$$R\text{—}\underset{\underset{A}{}}{\overset{\overset{OH}{|}}{C}}\!=\!N\text{—}O^- \qquad R\text{—}\underset{\underset{B}{}}{\overset{\overset{O\ H}{\|\ |}}{C}}\text{—}N\text{—}O^-$$

$$R\text{—}\underset{\underset{}{}}{\overset{\overset{O^-}{|}}{C}}\!=\!N\text{—}OH \leftrightarrow R\text{—}\underset{\underset{C}{}}{\overset{\overset{O}{\|}}{C}}\text{—}\bar{N}\text{—}OH$$

Although absolute evidence as to which anion (A, B or C) is the reactive species cannot be provided, the *o*-derivatives yield information that enables one to postulate the most probable reactive form.

Examination of data in Table II reveals that a comparable relationship exists between the acidities of the benzohydroxamic acid and phenylpropiolic acid series, but they are quite different from the benzoic acid series. In the benzoic acid series the *ortho* isomer is markedly stronger than the *para* regardless of substituent, whereas in the former

cases the *ortho* is weaker than the *para* for the nitro group and stronger than the *para* for the methoxy group. This suggests that structure C would not be the predominant form in the ionization, since this form would be expected to be influenced by *o*-substituents.

TABLE II

p-ClC_6H_4–	8.6	3.47	3.07	3.98

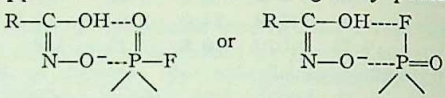
[a] Apparent pK_a's in 50% ethanol–50% water (by volume); Roberts and Carboni.[13] [b] Apparent pK_a's in 35% dioxane–65% water (by weight); Newman and Merrill.[14] [c] pK_a's in water; J. F. Dippy and J. E. Page, *J. Chem. Soc.*, 357, (1938). All pK_a's at 25°.

A linear relationship exists between the logarithms of the ionization constants and reaction rates of *o*-, *m*- and *p*-substituted phenylpropiolic acids with diphenyldiazomethane,[13] whereas ester saponification[13] and acid-catalyzed esterification[14] of *o*-substituted phenylpropiolic acids were faster than would be expected from the relationship between the rates and ionization of the *m*,*p*-substituted acids. This effect was ascribed to a decrease in the reaction site–ring distance, since both esterification and hydrolysis of esters involve attack of a nucleophilic agent at the carbonyl carbon.[13]

Since a linear relationship does exist between the logarithms of the ionization constants and the reaction rates of *o*-, *m*- and *p*-substituted benzohydroxamic acids with Sarin, it seems improbable that structure C is the reactive form because the *o*-substituents do not produce a deviation from linearity that would be expected if reaction occurred close to the ring.

Thus, tautomers A and/or B would appear to be the reactive forms of the anion in both ionization and reaction with electrophilic reagents, since both would take place at a site which is at a maximum distance from the *o*-substituent. However, if the inordinate reactivity of the hydroxamate ion (when compared to simple bases, *i.e.*, OH^-) is due to a concerted attack upon the Sarin molecule in a manner similar to catechol, the most probable reactive form is tautomer A.

Thus the interpretations presented above offer support to the mechanism originally postulated.[12c]



Experimental

Ionization Constants.—The pK_a's reported in Table I were obtained from conventional potentiometric titrations in the presence of 0.1 *M* potassium nitrate. All compounds reported except for *o*-hydroxybenzohydroxamic acid were either sufficiently soluble in water to titrate directly with standard base or stable in alkali so that excess standard base could be added and back titrated with standard acid. Due to the slight decomposition of *o*-hydroxybenzohydroxamic acid in alkali, the value reported is uncertain.

Kinetic Method.—The half-times of hydrolysis of Sarin in the presence of various hydroxamic acids are reported in Table I. The values were obtained by measuring the rate of addition of standard alkali taken up by the reaction mixture when maintained at a fixed *p*H by a Beckman autotitrator. The reaction was carried out as follows: a quantity of the hydroxamic acid was dissolved in 0.1 *M* potassium nitrate solution contained in a jacketed beaker through which water of 30.5 ± 0.2° was circulated from a thermostatically controlled bath. The final concentration of the hydroxamic acid in these experiments was 10^{-3} *M*. The solution was adjusted to *p*H 7.6 and the volume to 245 ml.

A stock solution of 0.65 ml. of Sarin (99% pure) in 100 ml. of water was prepared fresh daily. *Caution* should be exercised since Sarin is *extremely toxic* in both the liquid and vapor phase and must be handled in a hood of large capacity. In the *p*H range of 4 to 6, which the solution assumed, Sarin is resistant to hydrolysis. A 5-ml. aliquot was then added to the hydroxamic acid solution. The final concentration of the solution with respect to Sarin was 10^{-4} *M*. The quantity of standard 0.01 *N* sodium hydroxide delivered by the autotitrator *vs.* time was recorded.

Rearrangement and Decarboxylation Reactions of N,N-Dimethylglycine Oxide

BY C. C. SWEELEY AND E. C. HORNING

RECEIVED APRIL 9, 1956

Ferric ion-catalyzed reactions of dimethylglycine oxide were studied in aqueous solution over the *p*H range 2–9. It was found that two modes of N-oxide rearrangement occurred; the products were formaldehyde and sarcosine, and dimethylamine and glyoxylic acid. In addition to these rearrangement reactions, a decarboxylation reaction also occurred, with a maximum rate near *p*H 8. The products of this reaction were carbon dioxide, formaldehyde and dimethylamine; these correspond to the products of oxidative decarboxylation of an α-amino acid.

A preliminary report from this Laboratory described a ferric ion-catalyzed rearrangement reaction of *t*-amine oxides.[1] This rearrangement (reaction A) was presumed to give a carbinolamine (II); the observed reaction products were a secondary amine (through reaction B) and formaldehyde or formic acid and the *t*-amine (reaction C). The products are equivalent to those ex-

pected from a Polonovski reaction,[2] but the conditions are quite different. The Polonovski reaction is conducted in boiling acetic anhydride and is reported to occur by way of a free-radical mechanism[3]; the mechanism of the ferric ion induced reaction, which occurs in aqueous solution, is unknown.

$$\underset{\text{I}}{RCH_2N(CH_3)_2O} \xrightarrow[H_2O]{Fe^{+++}} \underset{\text{II}}{RCH_2N\begin{matrix}CH_3\\CH_2OH\end{matrix}} \quad (A)$$

$$\text{II} \longrightarrow \underset{\text{III}}{RCH_2NHCH_3} + HCHO \quad (B)$$

$$HCHO + \text{I} \longrightarrow RCH_2N(CH_3)_2 + HCOOH \quad (C)$$

The significance of reaction A lies in its relationship to what is known about biological methylation and demethylation reactions. It is known that the demethylation of drugs,[4] of N-methyltryptophan,[5] and of sarcosine and N,N-dimethylglycine[6] involves an oxidative sequence in which a methyl group is removed as formaldehyde or its cellular equivalent. It is also known that the *de novo* synthesis of the N-methyl groups of N,N-dimethylethanolamine is mediated by a folic acid derivative, in distinction from the methylation reaction which converts dimethylaminoethanol to choline and which requires methionine.[7] The methylation reactions leading to a secondary amine (N-methylethanolamine) and a tertiary amine (N,N-dimethylethanolamine) may require 5-hydroxymethyltetrahydrofolic acid.[8]

The successive steps of oxide formation, oxide rearrangement (reaction A) and hydrolytic cleavage of a methylol intermediate (reaction B) constitute a chemical model for demethylation, and methylation to a secondary or tertiary amine may be represented by the same sequence operating in a reverse direction. An enzyme-catalyzed amino acid oxide rearrangement corresponding to the transformation I → III has been observed[9] with a mouse liver homogenate for *l*-N,N-dimethyltyrosine oxide and *dl*-N,N-dimethyltryptophan oxide. These observations provide evidence that reaction A can occur as a cellular reaction in mammalian tissue, and it therefore seems likely that N-oxides are intermediates in biological methylation–demethylation reactions.

The enzymatic demethylation of N,N-dimethylglycine[6] to sarcosine and the cellular equivalent of formaldehyde is an oxidative sequence in which the amino acid is a normal component of mammalian metabolism.[10] It was therefore desirable to study the ferric ion induced reactions of N,N-dimethylglycine oxide with particular regard to the rearrangement leading to demethylation.

N,N-Dimethylglycine oxide was prepared from N,N-dimethylglycine by hydrogen peroxide oxidation. Its properties resembled those of most known *t*-amine oxides; it was a highly hygroscopic substance which tended to hold both water and hydrogen peroxide. No suitable derivatives were found. The expected relationship of the oxide to the parent amino acid was indicated by quantitative hydrogenation.

The ferric ion-catalyzed rearrangement reaction was studied in detail in two types of systems. Over the *p*H range 1–5 a ferric oxalate complex ion was employed; the results in this system have been summarized.[1] Over the *p*H range 2–9 a ferric tartrato complex ion was employed. Analyses of reaction mixtures were carried out by paper chromatography (system I). This work was aided by the development of an excellent spray procedure for detecting secondary amines in the presence of related tertiary (or primary) amines. The fact that the oxide gave a positive ninhydrin reaction[11] also allowed detection of the oxide in chromatographic analyses. Densitometer graph (B) in Fig. 1 shows a typical result obtained at *p*H 1.5, and this may be compared with (C) and (D) which represent reactions carried out at *p*H 6 and 4, respectively. The secondary amine in zone 1 was eluted from the appropriate zone in preparative runs and was identified as sarcosine by conventional biochemical procedures. Formaldehyde was detected in a usual way.[12] The secondary amine in zone 2 was found to be a volatile organic base whose concentration could be determined by a standard Kjeldahl distillation and titration procedure. The R_f value corresponded to that found for dimethylamine, but it was considered possible that this fraction might include some trimethylamine (arising by decarboxylation of the amino acid oxide to trimethylamine oxide); in separate experiments it was found that trimethylamine and/or trimethylamine oxide were not reaction products, and that therefore a direct decarboxylation to trimethylamine oxide was not occurring. A specific test procedure for glyoxylic acid[13] was applied to reaction mixtures containing the secondary amine of zone 2, and a spray procedure (adapted from the test) was used in chromatographic analyses to detect glyoxylic acid. Both sets of results indicated that glyoxylic acid and dimethylamine appeared simultaneously as reaction products when the rearrangement was carried out at *p*H 4–6; these data indicate that the ferric ion catalyzed reaction for N,N-dimethylglycine oxide occurred along both possible routes.

$$ON(CH_3)_2CH_2COOH \xrightarrow[pH\ 4\text{–}6]{Fe^{+++}} \begin{cases} \longrightarrow HOCH_2N(CH_3)CH_2COOH \longrightarrow CH_3NHCHCOOH + HCHO \\ \longrightarrow (CH_3)_2NCHOHCOOH \longrightarrow (CH_3)_2NH + \begin{matrix} CHO \\ | \\ COOH \end{matrix} \end{cases}$$

Separate experiments have provided evidence for the enzymatic formation of *t*-amine oxides[14] and for the rearrangement of N,N-dimethyltyrosine oxide and N,N-dimethyltryptophan oxide by an amino acid oxide hydroxytransferase in mouse liver.[10] From these observations, we suggest that the enzymatic demethylation of dimethylglycine described by Mackenzie[6] involves the intermediate steps of N-oxide formation and N-oxide rearrangement. This view is supported by the results presented in this paper for the non-enzymatic demethylation of dimethylglycine oxide, under conditions which approximate those of the cell.

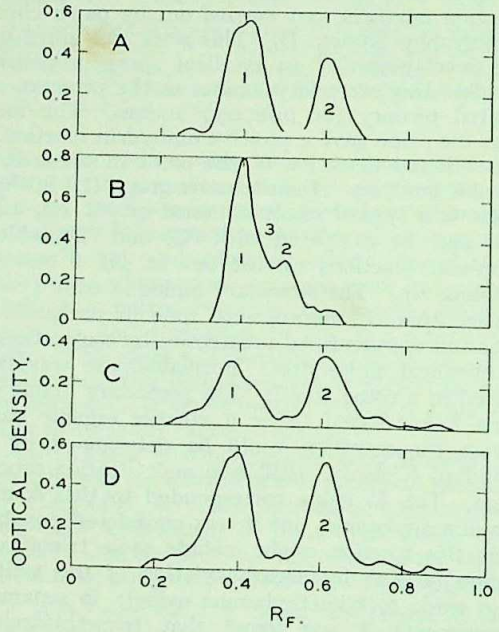

Fig. 1.—Densitometer data: A, reference compounds sarcosine (1), dimethylamine (2); B, sarcosine (1) and N,N-dimethylglycine oxide (2) in rearrangement with oxalic acid (*p*H 1.5), N,N-dimethylglycine-1-C^{14} (3) detected on radioautographs; C, sarcosine (1) and dimethylamine (2) in rearrangement reaction with tartaric acid (*p*H 6); D, sarcosine (1) and dimethylamine (2) in rearrangement reaction with tartaric acid (*p*H 4). The paper chromatograms were developed in *t*-butyl alcohol–acetic acid–water (3:1:1) and sprayed with ninhydrin reagent.

Data relating to a novel decarboxylation reaction of the oxide are in Fig. 2. This reaction was discovered when the possibility of a direct decarboxylation of the oxide to trimethylamine oxide and carbon dioxide was considered. Carbon dioxide was found as a reaction product when the oxide was subjected to ferric ion catalysis above about *p*H 5, but trimethylamine and trimethylamine oxide were found to be absent. A quantitative study of the yields of key reaction products (formaldehyde, dimethylamine and radioactive carbon dioxide) as a function of *p*H was carried out with N,N-dimethylglycine-1-C^{14} oxide. The observation that the increase in carbon dioxide yield, which rose to a maximum near *p*H 8, was paralleled by increasing yields of formaldehyde and dimethylamine, suggests strongly that the decarboxylation may be represented by

$$HO-\overset{\oplus}{N}(CH_3)_2-CH_2-C(=O)-O^{\ominus} \xrightarrow[pH\ 8]{Fe^{+++}} HO^{\ominus} + (CH_3)_2\overset{\oplus}{N}{=}CH_2 + CO_2$$

$$(CH_3)_2\overset{\oplus}{N}{=}CH_2 \xrightarrow{H_2O} (CH_3)_2NH + HCHO$$

The reaction may be represented as a β-elimination in which the concerted separation of carbon dioxide and hydroxide ion is facilitated by formation of a ferric ion–amino acid oxide complex.

In this connection, recent work on the oxidative decarboxylation of amino acids should be mentioned. Spenser, Crawhall and Smyth[15] recently proposed a new reaction pathway to explain the known effects of oxidizing agents on α-amino acids.[16]

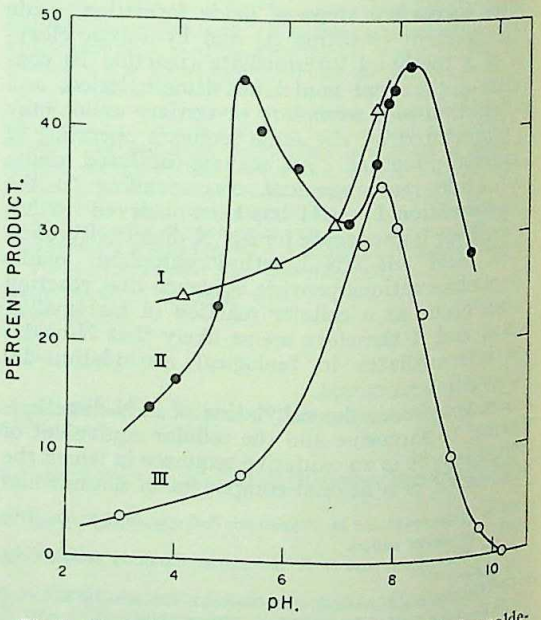

Fig. 2—Variations in yield of dimethylamine (I), formaldehyde (II) and carbon dioxide (III) with *p*H for reactions with ferric-tartrato complex ion at 22–23° for 90 minutes.

The new experimental data leading to this proposal included isotope tracer studies which showed that the hydrogen on the α-carbon atom was not involved in the reaction, and oxidation experiments with α-N-diphenylglycine in which a Schiff base was found as the reaction product. The results were interpreted in terms of an oxidative ($OH^{\oplus}$) attack on the α-carbon atom, with concurrent loss of carbon dioxide. The immediate product, a carbinolamine, would then be expected to hydrolyze to an amine and an aldehyde or ketone (the normal products of oxidative decarboxylation of an α-amino acid) or to yield a Schiff base (as found for α,N-diphenylglycine). Data cited by Spenser, Crawhall and Smyth included the fact that the reaction fails for trialkyl (betaine) structures, and that it is successively more effective with substitution on the amino group (through mono and dimethyl stages). The critical point of this hypothesis lies in the assumption that a carbinolamine must be postulated as an intermediate product. The isolation of a Schiff base supports this view only indirectly. Our experimental observations with N,N-dimethylglycine oxide suggest that an alternate explanation should be considered. The reaction may involve oxidative ($OH^{\oplus}$) attack on the amino group, followed by concurrent β-elimination and loss of carbon dioxide, and leading to hydroxide ion, carbon dioxide and a Schiff base as the products. It is not necessary to assume that carbinolamine formation is a prerequisite for Schiff base formation. This explanation is supported by the data of Spenser, Crawhall and Smyth and by the observations in this paper.

The place of oxidative decarboxylation in plant biosynthesis has been reserved by Spenser, Crawhall and Smyth for future discussion. If both oxidative decarboxylation and oxidative demethylation occur as cellular reactions *via* amino acid oxides, it may be possible to demonstrate an enzyme-catalyzed rearrangement reaction for N-oxides. This possibility is under study.

Experimental

N,N-Dimethylglycine hydrochloride was prepared in 84% yield by reductive methylation of glycine with formaldehyde,[17] using Adams platinum catalyst in a low pressure apparatus.

N,N-Dimethylglycine Oxide.—A solution of 0.80 g. of N,N-dimethylglycine hydrochloride in 15 ml. of water was adjusted to *p*H 6 with Amberlite resin (IR-45, hydroxyl phase). The resin was removed by filtration, and 14 ml. of 0.2 *M* barium hydroxide solution and 10 ml. of 15% hydrogen peroxide were added. The solution (*p*H 12) was allowed to stand at room temperature for 1.5 hours (the *p*H dropped to 8). Barium ion was removed as barium sulfate and the filtrate was concentrated under reduced pressure to 5 ml. Ethanol (20 ml.) was added and the solution was again reduced in volume to 2 ml. After the addition of 5 ml. of ethanol, 100 ml. of acetone and 100 ml. of ether, the product was allowed to crystallize. The yield (after washing with ether and drying) was 0.35 g. (40%) of the amino acid oxide.

Anal. Calcd. for $C_4H_9NO_3.0.5H_2O.0.5H_2O_2$: C, 33.10; H, 7.63; N, 9.65. Found: C, 32.95; H, 7.36; N, 9.43.

The oxide was a colorless, highly hygroscopic substance. Repeated preparative runs gave material whose melting points were identical but not sharp (68–73° dec., Kofler).

(17) D. E. Pearson and J. D. Bruton, THIS JOURNAL, **73**, 864 (1951).

The infrared spectra of these samples were identical and different from that of N,N-dimethylglycine (specific bands due to the N-oxide functional group have not been located in N-oxides under study in this Laboratory.[1,9,12] The oxide gave a positive ninhydrin reaction[11] and it was detected in chromatographic analyses in this way. All systems (Table I) gave single, well-defined areas for the oxide. The ionophoresis data (Table II) indicated that the amino acid oxide was a stronger acid than glycine or sarcosine.

TABLE I

PAPER CHROMATOGRAPHIC DATA (R_f VALUES)

Compound	Solvent systems[b] I	II	III	IV
Glycine	0.29	0.49	0.30	..
Sarcosine	.40	.58	.74	0.13
N,N-Dimethylglycine oxide	.52	.70	.95	..
Glyoxylic acid	.25	..	..	..

TABLE II

PAPER IONOPHORETIC DATA[a]

Compound	R_g[b]	Distance (cm.)
Urea	0.10	0.8
N,N-Dimethylglycine oxide	.13	1.0
Sarcosine	.76	6.2
Glycine	1.00	7.9

[a] Conditions: 300 v., 3.5 ma., 4 hours at 22–23°, with 25% aqueous acetic acid as electrolyte. [b] Ratio calculated for distance from origin.

No satisfactory derivatives were found. The chloroaurate, chloroplatinate, picrate and flavianate were not suitable derivatives. The thiouronium salt from *p*-bromobenzylthiouronium bromide retained the generally unsatisfactory physical properties of the oxide.

The formulation of the oxide as a solvate with both water and hydrogen peroxide is in accord with current knowledge of *t*-amine oxide properties. Aliphatic *t*-amine oxides often crystallize with water and/or hydrogen peroxide,[18] and one-half mole equivalent of hydrogen peroxide is not uncommon.[19] In accordance with Bodendorf and Binder,[19] the material was found to liberate iodine from potassium iodide solution. The structure of the oxide was verified by quantitative reduction to N,N-dimethylglycine. A 10-mg. quantity of Pd-C (10%) catalyst in 5 ml. of ethanol was saturated with hydrogen in a micro apparatus for quantitative hydrogenations. A solution of 70 mg. of the oxide in 30 ml. of ethanol was added, and the subsequent hydrogenation required 15.7 ml. (97% of the requirement for reduction of the oxide and peroxide of solvation) of hydrogen. This method is preferred over that of Bodendorf and Binder.[19] The product was isolated as the hydrochloride and it was found to be authentic N,N-dimethylglycine hydrochloride (infrared and m.p. data).

N,N-Dimethylglycine-1-C^{14} oxide was required for decarboxylation studies. It was prepared from N,N-dimethylglycine-1-C^{14} by the usual procedure. The infrared spectrum (Nujol) showed no changes from non-radioactive preparations, and the paper chromatographic and paper ionophoretic behavior showed no changes. The specific activity of the preparation was compared with that of the parent compound, and this was used as an experimental determination of the molecular weight of the solvated oxide: calcd. for formula above, mol. wt., 146; found 146.

Mild heating (to obtain a non-solvated product) resulted in decomposition of the oxide.

Paper Chromatographic Systems and Sprays.—Systems used for the examination of reaction mixtures and for identification of products were: (I) *t*-butyl alcohol–acetic acid–water (3:1:1); (II) propanol–acetic acid–water (10:1:9); (III) phenol–water (4:1);[20] (IV) propanol–1 *N* ammonium hydroxide (5:1). System I gave excellent results in qualitative analyses of reaction mixtures. The time required for separations was usually 16 hours at room temperature (22–23°). The papers were washed Whatman 1 and washed Whatman 3 MM.

The ninhydrin spray was a 0.2% solution in 50% aqueous pyridine. The strips were heated to develop the colored areas, and the chromatograms were preserved by spraying with a dilute cupric nitrate solution,[21] followed by exposure to ammonia to remove the excess nitric acid.

For secondary amines, the chromatogram was sprayed with a freshly prepared 1% sodium nitroprusside solution containing 10% (v./v.) of acetaldehyde. This was followed immediately by a spray with 2% sodium carbonate solution. A slowly developing deep blue spot on a light pink or colorless background constituted a positive test for secondary amines. This method was a modification of a spot test procedure for detecting secondary amines.[22] It gave no reaction with components of the reaction mixtures other than sarcosine and dimethylamine.

A spray to detect glyoxylic acid was developed from a qualitative test procedure.[13] The paper chromatogram was sprayed with a freshly prepared solution of 1% phenylhydrazine hydrochloride in 0.5 *N* hydrochloric acid. After drying (heat), the paper was sprayed with 3% hydrogen peroxide in 0.5 *N* hydrochloric acid. A red color was formed with glyoxylic acid.

Rearrangement of N,N-Dimethylglycine Oxide. A. Oxalate System.—In a typical experiment, a solution containing 3.0 mg. (20 μmoles) of N,N-dimethylglycine oxide, 200 μmoles of oxalic acid and 60 μmoles of ferric nitrate nonahydrate, in a total volume of 1.3 ml. (*p*H 1.5–2.0), was kept at 60° for 30 minutes. Paper chromatography of 50–100 μg. of organic constituents with system I, followed by a ninhydrin spray, gave a pattern as shown in the densitometer (Photovolt Model 520, 545 mμ filter) graph of Fig. 1B. Similar experiments were run at five intervals in the *p*H range 1–5; above *p*H 2 the yield of sarcosine decreased slowly.

In these experiments, the ferric ion was presumably present as an oxalato complex ion.[23] Above *p*H 5 a slow precipitation of ferric hydroxide interfered with the experiments.

B. Tartrate System.—A solution containing 1.0 mg. (6.9 μmoles) of N,N-dimethylglycine oxide, 40 μmoles of tartaric acid and 2.0 μmoles of ferric nitrate nonahydrate was adjusted to the appropriate *p*H with 10% sodium carbonate solution (final volume of 1.0 ml.). It was heated at 60° for 15 minutes. Paper chromatography, using system I with a ninhydrin spray or a secondary amine spray, was used for qualitative analysis of the reaction mixture. The densitometer records in Fig. 1C-1D were obtained with a ferric ion:oxide ratio of 0.3:1 at *p*H 6.0 and 3.0:1 at *p*H 4.0, respectively. A ninhydrin spray was used for both records.

A series of experiments were run at *p*H 2–11, with heating for 15 minutes at 60°. Visual examination of the chromatograms indicated that for runs in the *p*H range 4–8, all of the oxide was consumed, and approximately the same yield of the two secondary amines was obtained. Below *p*H 4 the yield fell, and unreacted oxide was present. At *p*H 8–9 the yield also fell, and at *p*H 10–11 there was no rearrangement.

The ferric ion was present in these solutions as a tartrato complex ion. When iron tartrate solutions of the concentrations used here were irradiated in the absence of air, an oxidation–reduction reaction occurred, and all of the iron was reduced to the ferrous state (as judged by the complete disappearance of the characteristic yellow color of ferric ion). This reaction may occur during the rearrangement, but its effect was kept at a minimum by using freshly prepared solutions for each experiment. The ferrous–tartrato complex seems to be of no great significance in these reactions. Some oxidation of the tartrate ion (by air or the amine oxide) may also occur.

Identification of Sarcosine and Dimethylamine.—A preparative run was carried through chromatography on Whatman 3MM paper. Zone 1 was eluted (water) and the amine was compared with an authentic sample of sarcosine in four solvent systems. The eluted material, sarcosine, and a mixture were run concurrently; the R_f values are in Table I, together with data for glycine and N,N-dimethylglycine oxide. Chromatographic identity was observed.

A comparison of the reaction product with sarcosine was also carried out by paper ionophoresis on washed Whatman 1 paper with 25% acetic acid as the electrolyte. The data are in Table II, with comparative values for glycine. Ionophoretic identity was observed for the authentic and eluted samples.

The reaction product gave a positive test (blue color) with a secondary amine spray; the test result was identical with that produced by authentic sarcosine.

Dimethylamine was recognized by chromatographic separation (zone 2) in system I, followed by spraying with ninhydrin or the secondary amine reagent (in alkaline systems, the amine is lost by evaporation). With system I, the R_f of dimethylamine was 0.61; chromatograms were run with the reaction mixture, an authentic sample at approximately the same concentration, and a mixture. In all cases the R_f values and the colors with both sprays were identical for these comparative runs. Quantitative determinations were also made as described.

Identification of Glyoxylic Acid.—Reaction mixtures were tested for the presence of glyoxylic acid by a spot test procedure.[13] One drop each of the mixture, 12 *N* hydrochloric acid and a freshly prepared 1% solution of phenylhydrazine hydrochloride were mixed and heated at 80° for 5 minutes. The mixture was chilled and treated with one drop each of 12 *N* hydrochloric acid and 3% hydrogen peroxide. An intense red color constituted a positive test. Blank runs, omitting the oxide, gave faint pink colors.

This procedure was modified for use as a spray, and in system I it was found that authentic glyoxylic acid (prepared from dichloroacetic acid)[24] and the reaction mixture gave corresponding colored areas (R_f 0.25).

Formaldehyde and Formic Acid Tests.—These were carried out as described in a previous study of the rearrangement of N,N-dimethyltryptamine oxide.[12] With a Fe^{+++} to oxide ratio of 0.03:1, it was found possible to detect formaldehyde directly in the reaction mixture by a chromotropic acid color test.

Metal Ions.—With two sets of standard conditions (a) an oxalate system at *p*H 2 with a metal ion to oxide ratio of 3:1, and (b) a tartrate system at *p*H 5–6 with a metal ion to oxide ratio of 0.3:1, it was found that Co^{++}, Ni^{++}, Cu^{++}, Mg^{++} and Cr^{+++} were without catalytic effect. No reaction was observed in a tartrate system at *p*H 4–6 with $[Fe(CN)_6]^{---}$ or an 8-hydroxyquinoline-5-sulfonic acid complex with ferric ion. With Fe^{++} in a 3:1 ratio, and with a tartrate system at *p*H 5, the oxide reacted as usual and the two amine products were observed in normal yield.

Quantitative Determination of Products.—In a series of experiments, conducted at 23° for 90 minutes with a 0.6:1 mole ratio of ferric ion to oxide, the *p*H of the reaction was varied. Formaldehyde, dimethylamine and carbon dioxide were determined quantitatively. The results are shown in Fig. 2.

A. Determination of Formaldehyde.—In a typical experiment, 1.0 mg. (6.9 μmoles) of N,N-dimethylglycine oxide in 1.0 ml. of water was adjusted to *p*H 5.0 with 0.1 *N* sodium hydroxide solution. A solution (1.0 ml.) of tartaric acid (50 μmoles) and ferric nitrate nonahydrate (4 μmoles) was adjusted to *p*H 5.0 with 0.1 *N* sodium hydroxide and was added to the solution of the oxide. After 90 minutes at 23° the reaction mixture was pipetted into a 50-ml. flask fitted with a distilling head and condenser. The solution was acidified with 2.0 ml. of 8.5% phosphoric acid and the mixture was distilled at atmospheric pressure into 1.0 ml. of ice-water. The tip of the condenser was immersed in the ice-water. An additional 3.0 ml. of water was added to the residue and distillation was repeated, collecting 7.0 ml. of distillate in all. Formaldehyde was determined on an aliquot of the distillate by a modified Hantzsch reaction with acetylacetone and ammonium acetate.[25] Optical density measurements were made with a Beckman DU spectrophotometer.

B. Determination of Dimethylamine.—A solution of oxide (13.7 μmoles), tartaric acid (100 μmoles) and ferric nitrate nonahydrate (8.0 μmoles), adjusted to *p*H 4.5 as described in the previous section for formaldehyde determination, was allowed to stand at 23° for 90 minutes. The solution was pipetted into a Kjeldahl still with 8.0 ml. of 20% sodium hydroxide solution. The volatile base was steam distilled for 4 minutes into 5.0 ml. of 5% boric acid

containing 3 drops of methyl red (0.1%)–brom cresol green (0.1%) indicator. The dimethylamine was determined by titration of the boric acid solution with 0.01 *N* hydrochloric acid.

In separate experiments, the volatile organic base fraction was examined for the presence of trimethylamine by the sensitive quantitative procedure of Cromwell.[26] Trimethylamine was not present. The oxide of trimethylamine was prepared; it gave a positive ninhydrin reaction[11] and it was found to be absent in chromatographic analyses of reaction mixtures at *p*H 4–8.

C. Determination of Carbon Dioxide.—A reaction mixture (*p*H 7.0), containing N,N-dimethylglycine oxide-1-C^{14} (6.9 μmoles), tartaric acid (50 μmoles) and ferric nitrate nonahydrate (4 μmoles), was prepared in the usual way and allowed to react for 90 minutes at 23° in a flask connected to a sodium hydroxide trap. The solution was acidified with 1.0 ml. of 8.5% phosphoric acid and the system was flushed with nitrogen for 15 minutes. The carbon dioxide collected in the sodium hydroxide trap was counted[27] as barium carbonate. Runs at other *p*H values were made in the same way.

N,N-Dimethylglycine hydrochloride-1-C^{14} (7.1 μmoles) and glyoxylic acid (400 μmoles) gave no carbon dioxide under similar conditions (catalyst, tartrate, 23°, 90 minutes).

D. *p*H Effects.—Over the *p*H region where decarboxylation was the primary reaction it was observed that the *p*H rose as the reaction proceeded. Initial and final *p*H values were averaged to locate the points near *p*H 8 in Fig. 2.

Some Reactions of *o*-Halophenyllithium Compounds

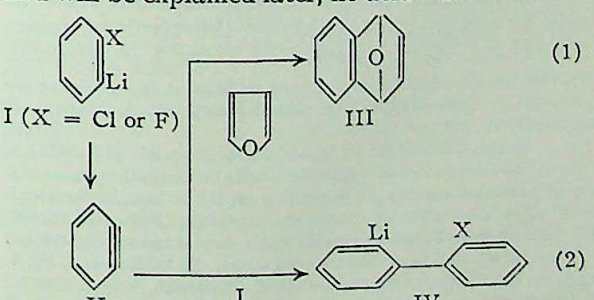
BY HENRY GILMAN AND RICHARD D. GORSICH

RECEIVED DECEMBER 7, 1956

When *o*-chloro- and *o*-fluorophenyllithium are prepared at −90 and −60°, respectively, in the presence of furan and then carbonated, the main product is 1,4-dihydronaphthalene-1,4-endoxide (III) while the corresponding 2-carboxy-2′-halobiphenyl (IV) is obtained in small yields. *o*-Dibromobenzene and *n*-butyllithium in the presence of furan also give III under modified conditions. Only III is obtained when an RLi is added to a mixture of the *o*-bromohalobenzene and furan at a temperature above that at which the *o*-halophenyllithium compound is stable. Methyllithium and phenyllithium are equally effective in reacting with an *o*-halobromobenzene in the presence of furan to give excellent yields of III. 2-Chloro-2′-(triphenylsilyl)-biphenyl has been synthesized and compared with the bromo-isomer prepared by a less ambiguous method. The results are discussed and correlated.

As a continuation of some of our earlier studies concerned with *o*-halophenyllithium compounds,[1] we have investigated further some of their reactions and possible routes by which these organometallic compounds couple to form new organolithium compounds. In order to obtain a better understanding of the various transformations, the elegant procedure of Wittig and Pohmer[2] was employed in this present work. These workers successfully interacted *o*-bromofluorobenzene with lithium amalgam in furan to obtain 1,4-dihydronaphthalene-1,4-endoxide (III), a strained molecule which has been formulated as arising *via* a Diels–Alder reaction between furan and the benzyne intermediate (II). Furthermore, the reactive species II has been postulated as being formed from *o*-fluorophenyllithium after the latter has been generated by the interaction of *o*-bromofluorobenzene and lithium amalgam.[3] In view of these results it was hoped that furan could be used in a similar fashion to trap any intermediate which might arise during the break-down of *o*-halophenyllithium compounds (I). *o*-Fluoro- and *o*-chlorophenyllithium were prepared at −60 and −90°, respectively. A relatively large excess of furan was added in each case and then the mixtures were allowed to warm to −50° for the chloro-isomer and −10° for the fluoro-isomer. Since Color Test I[4] was positive in both cases at these temperatures, the mixtures were carbonated. The run involving *o*-bromochlorobenzene afforded 41% of III and 11% of 2-carboxy-2′-chlorobiphenyl; with *o*-bromofluorobenzene the yield of III was 67% while 4% of 2-carboxy-2′-fluorobiphenyl was isolated.

A modified procedure was used with *o*-dibromobenzene since it was found in previous studies that *o*-bromophenyllithium is a short-lived intermediate.[1] Consequently, *o*-dibromobenzene was added to a mixture of furan and butyllithium. The yield of III was 68%; however, as might be expected and will be explained later, no acid was isolated.



From the foregoing results it is clear that in the case of *o*-chloro- and *o*-fluorophenyllithium some reactive intermediate is competitively reacting with furan and with I. Furthermore, evidence substantiates that such a competitive reaction occurs only when the organolithium compound is formed first independently of the other reactants. In order to ascertain that no metalation reaction

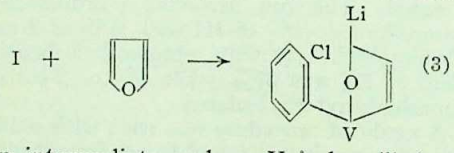
ensued between furan and I followed by another similar metalation between the halobenzene and 2-furyllithium at a warmer temperature, an attempt was made to metalate chlorobenzene under conditions used for the competitive reactions. No acid was detected after carbonation; most of the chlorobenzene was recovered.

At this time the most plausible explanation for the presence of coupling product in the competitive reaction is one involving II, although an alternate explanation has been proposed recently for a related reaction.[5] Intuitively the halide in I would not be expected to be displaced by a nucleophile because the high electron density in the position adjacent to the chlorine atom should hinder such an approach. Also, nucleophilic aromatic substitution reactions are facilitated by electron-withdrawing groups and not electron-donating substituents.[6] It is conceivable the anion of I may displace the halogen in another molecule of I either just before or during the formation of the reactive intermediate II.[7]

The rapid conversion of *o*-bromophenyllithium to II did not allow its preparation prior to the addition of furan, and, as a result, the concentration of *o*-bromophenyllithium probably was so slight that the main reaction was between II and furan.

The reaction path leading to III might involve a nucleophilic attack of I on furan or the more likely reaction of II with furan. Of the two possibilities, it appears better to rationalize on the basis of II being the key intermediate. If I is considered as being the attacking species, a reaction path (3) might be expected. Evidence indicates



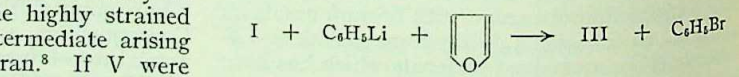
(3)

that an intermediate such as V is less likely to undergo ring closure to give the highly strained molecule III than would an intermediate arising from interaction of II with furan.[8] If V were formed as an intermediate, ring closure at such a low temperature would be doubtful in view of polar effects and formation of the strained molecule III.[6,9] The formation of V *via* I is unprecedented since there is no known instance wherein furan is attacked in such a manner. In fact under these conditions furan is inert to such an attack, and at warmer temperatures the only product formed is 2-furyllithium.[10]

On the basis of the aforementioned discussion wherein II has been visualized as the intermediate in the various reactions, it would be expected that if compound I were generated at a temperature above that at which it is stable, the concentration of I would be negligible and no coupling product (IV) should be detected. This has been verified by adding butyllithium to a mixture of furan and an *o*-bromohalobenzene at temperatures considerably higher than those at which the stability of I has been well-established. For example, when butyllithium is added to a mixture of *o*-bromochlorobenzene and a large excess of furan, only III has been isolated. No acids were found to be present. The same was found to be true for the fluoro- and bromo-isomers, although in the latter case the results are not as significant as for the former two.

Organolithium compounds other than butyllithium have been found equally suitable if not somewhat superior for generating the reactive species II at moderate temperatures. A 75% yield of III has been obtained with phenyllithium while with methyllithium yields up to 84% of III have been isolated. This is surprising because, in the past, methyllithium has been found to be very ineffective in halogen–metal interconversion reactions.[11] The unusual effectiveness in this case may be attributed to the formation of the highly reactive intermediate II.

In order to substantiate that a halogen–metal interconversion reaction was the initial step in the reaction between *o*-bromochlorobenzene and phenyllithium, the latter compound was synthesized from iodobenzene and lithium. Recovery of



bromobenzene in a good yield supports the above proposal. No attempt was made to recover methyl bromide when methyllithium was used.

A reaction between *o*-dichlorobenzene and butyllithium in the presence of furan was unsuccessful. Carbonation, after stirring at room temperature for 1 hr., afforded only 2-furoic acid. It is conceivable that conditions might be varied so as to effect a reaction since there is evidence that a reaction occurs between butyllithium and *o*-dichlorobenzene in the absence of furan.[13]

Recent related work can be correlated with the results in this communication together with pre-

(5) An ion-pair mechanism has been formulated in explaining the interaction of chlorobenzene with sodium amide; A. A. Morton, *J. Org. Chem.*, **21**, 593 (1956).

(6) J. F. Bunnett and R. E. Zahler, *Chem. Revs.*, **49**, 273 (1951).

(7) It has been shown that benzyne can be formed either *via* a stepwise or concerted mechanism depending on the halogen being eliminated when metalation reactions are involved. However, in this case these findings do not necessarily apply since it cannot be assumed that the initial step is similar in both cases; J. D. Roberts, D. A. Semenow, H. E. Simmons, Jr., and L. A. Carlsmith, THIS JOURNAL, **78**, 601 (1956); see also, J. D. Roberts, C. W. Vaughan, L. A. Carlsmith and D. A. Semenow, *ibid.*, **78**, 611 (1956).

(8) In distinguishing between the two paths, it is not pertinent whether the interaction of benzyne with furan is a polar reaction or a four-center-type reaction. Since there is no sharp line between the latter two types of reaction mechanisms, it is difficult to rationalize by which one the benzyne interacts with furan; J. Hine, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y., 1956, pp. 450–461.

(9) Previous studies (ref. 1) showed that an intermediate such as 2-(*o*-chlorophenyl)-2′-lithiobiphenyl does not undergo ring closure below approximately −50° to give the planar, non-strained system, triphenylene.

(10) In general, metalation reactions proceed smoothly only at room temperature or higher when diethyl ether is the solvent; H. Gilman and J. W. Morton, Jr., "Organic Reactions," Vol. VIII, John Wiley and Sons, Inc., New York, N. Y., 1954, Chap. 6.

(11) Methyllithium interconverts only with very reactive halides such as *o*-bromoanisole. Phenyllithium is generally more effective but has the disadvantage of occasionally participating in side-reactions (ref. 12).

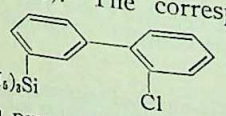
vious findings.[1] In the related work, 2,2′-diiodobiphenyl has been postulated as an intermediate in the reaction of *o*-diiodobenzene with butyllithium and lithium in non-polar solvents.[14] It is unlikely that *o*-iodophenyllithium would be present as such in any appreciable concentration in view of the instability of *o*-bromophenyllithium at −110°, and, especially since a refluxing mixture of benzene and petroleum ether (b.p. 40–60°) was employed. Since the *o*-diiodobenzene was added to butyllithium, an intermediate such as 2-iodo-2′-lithiobiphenyl (formed according to scheme 2) would be expected to react further with butyllithium to give 2,2′-dilithiobiphenyl.[15] The latter, in turn, could interact with two equivalents of II to give 2,2′-bis-(*o*-lithiophenyl)-biphenyl. This compound could partially couple with butyl iodide, formed during the interconversion reaction, to give 2,2′-bis-(*o*-*n*-butylphenyl)-biphenyl.[16] The remaining organodilithium compound would give the corresponding acid after carbonation. When lithium interacted with *o*-diiodobenzene, the major product was triphenylene. This is not too surprising since it is quite possible that in this case the intermediate, 2-iodo-2′-lithiobiphenyl, would tend to react preferentially with II instead of with lithium, and as a result one would get 2-(*o*-iodophenyl)-2′-lithiobiphenyl, a type of molecule which has been shown to undergo readily ring closure to yield triphenylene.[10]

Caution should be exercised in interpreting all reactions of *o*-bromohalobenzenes with RLi compounds as proceeding *via* the benzyne intermediate. Recent investigations infer that the solvent plays an important role in the reaction of a bromohalobenzene with an RLi compound. For example, it has been found in this Laboratory that two equivalents of *o*-dibromobenzene in tetrahydrofuran interact with one equivalent of butyllithium to give good yields of 2,2′-dibromobiphenyl. Apparently, *o*-bromophenyllithium couples with *o*-dibromobenzene rather than pass through the benzyne intermediate.[17]

2-Chloro-2′-(triphenylsilyl)-biphenyl has been prepared by allowing an ethereal solution of *o*-chlorophenyllithium to warm in the presence of triphenylchlorosilane. A small amount of triphenylene was isolated also. The former compound probably is formed *via* the organolithium compound (IV, X = Cl). The corresponding



bromo-isomer has been prepared in a less ambiguous manner by means of a monohalogen–metal interconversion reaction between 2,2′-dibromobiphenyl and butyllithium followed by reaction with triphenylchlorosilane. The infrared spectra of the two compounds compared favorably.

Experimental[18]

Reactions of *o*-Halophenyllithium Compounds in the Presence of Furan. (a) ***o*-Chlorophenyllithium.**—The *o*-chlorophenyllithium was prepared at −90° by adding a pre-cooled solution of 19.16 g. (0.10 mole) of *o*-bromochlorobenzene in 25 ml. of dry diethyl ether, during 17 min., to 80 ml. of a stirred ethereal solution containing 0.10 mole of *n*-butyllithium[19] and cooled to −100° by means of an ethanol–ether–liquid nitrogen slurry.[1] The temperature was not allowed to rise above −90° during the addition. After stirring the reaction mixture at −90° for 45 min., 48 g. of redistilled furan (Eastman) was added, and then the resulting solution was stirred between −75 and −70° for 10 min. The mixture was allowed to warm further to −50°, becoming quite milky at −65°. The reaction mixture then was stirred for 2.5 hr. at the minimum temperature afforded by a Dry Ice–acetone-bath. Subsequently the mixture was cooled to −95° and carbonated by adding powdered Dry Ice. The reaction mixture was allowed to warm to room temperature, whereupon, hydrolysis was effected with water. The aqueous layer was separated from the organic layer and was warmed to expel dissolved ether, cooled and then acidified with sulfuric acid. A brown precipitate was filtered, dissolved in ethanol, decolorized with Norit-A and then water was added slowly until the solution was slightly cloudy. On cooling, there crystallized 0.53 g. of acid melting at 139–140°. A mixed melting point with an authentic sample of 2-carboxy-2′-chlorobiphenyl obtained previously[1] showed no depression.

The organic layer was extracted with three 50-ml. portions of 5% sodium hydroxide. Acidification of the basic extract and subsequent work-up left an oil which crystallized after standing for 2 weeks. This material then was extracted with 5% sodium bicarbonate and after acidification with concentrated hydrochloric acid, there was deposited 0.72 g. of acid melting at 137–139°. The total yield of 2-carboxy-2′-chlorobiphenyl was 1.25 g. (10.7%).

The neutral organic layer was dried over anhydrous sodium sulfate, and the solvent was allowed to slowly evaporate. The resulting crystalline material was sublimed at room temperature (*ca.* 25°) and 0.005 mm. to yield 5.84 g. (40.6%) of product melting at 54–55°. The reported melting point of 1,4-dihydronaphthalene-1,4-endoxide is 55–56°.[2]

The adduct was cleaved by passing hydrogen chloride into a methanolic solution containing 2.0 g. (0.0139 mole) of 1,4-dihydronaphthalene-1,4-endoxide (III) and refluxing for about 3 hr.[2] The yield of α-naphthol melting at 94–95° was 1.61 g. (80%). A mixed melting point with an authentic specimen showed no depression.

(b) ***o*-Fluorophenyllithium.**—The *o*-fluorophenyllithium was prepared in accordance with a procedure described previously[1] from 10.0 g. (0.057 mole) of *o*-bromofluorobenzene in 30 ml. of ether and 40.5 ml. of an ethereal solution containing 0.057 mole of *n*-butyllithium at approximately −60°. To the organolithium solution cooled to about −70° was added 49 g. of redistilled furan. The temperature was not allowed to rise above −60° during the furan addition. The reaction mixture was allowed to warm slowly to −50° and was maintained between −50 and −45° for 10 min.; between −45 and −40° for 10 min.; between −35 and −30° for 10 min.; between −30 and −25° for 10 min.; and, between −15 and −10° for 25 min. Since Color Test I was positive, the reaction mixture was cooled to −65° and then poured jet-wise into a slurry of Dry Ice and ether. The carbonated mixture was worked up as described in the preceding experiment. Acidification of

(14) H. Heaney, F. G. Mann and I. T. Millar, *J. Chem. Soc.*, 1 (1956).

(15) Iodides are very reactive in interconversion reactions; see ref. 7.

(16) Alkyl iodides are more prone to be involved in coupling reactions than are other halides. For example, methyl iodide couples with 1-naphthyllithium to give a good yield of 1-methylnapthalene; H. Gilman and F. W. Moore, THIS JOURNAL, **62**, 1843 (1940); see, also, H. Gilman, C. G. Brannen and R. K. Ingham, *J. Org. Chem.*, **22**, in press (1957).

(17) This same type of reaction can be applied also to other bromohalobenzene isomers, *e.g.*, *p*-bromochlorobenzene yields 4,4′-dichlorobiphenyl. The latter reaction excludes the possibility of II being an intermediate in reactions carried out in tetrahydrofuran; H. Gilman and B. Gaj, *J. Org. Chem.*, **22**, in press (1957).

(18) All reactions involving organometallic compounds were carried out in a dry, oxygen-free nitrogen atmosphere and all melting points are uncorrected. The infrared spectra were run on a Baird Associates double beam infrared spectrometer in the sodium chloride region.

(19) H. Gilman, J. A. Beel, C. G. Brannen, M. W. Bullock, G. E. Dunn and L. S. Miller, THIS JOURNAL, **71**, 1499 (1949). The yield of butyllithium was determined according to a procedure described by H. Gilman and A. H. Haubein, *ibid.*, **66**, 1515 (1944).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the aqueous layer left needle-like crystals. These were combined with similar crystals obtained by acidification of the basic solution obtained after extracting the organic layer with 5% sodium hydroxide. Recrystallization of the 2-carboxy-2′-fluorobiphenyl from a mixture of ethanol and water yielded 0.23 g. (3.7%) of product melting at 138–140°. A mixed melting point with an authentic sample[1] of the acid showed no depression.

The organic layer on work-up as described above yielded a crystalline material which was sublimed at room temperature and 0.003 mm. to yield 5.49 g. (67%) of III melting at 54–55°.

(c) **o-Bromophenyllithium.**—A solution of 13.5 g. (0.057 mole) of *o*-dibromobenzene in 20 ml. of ether was added dropwise, during 15 min., to 70 ml. of an ethereal solution containing 0.057 mole of *n*-butyllithium and 61.5 g. of furan cooled to −110° by means of an ethanol–ether–liquid nitrogen slurry. The temperature remained between −110 and −100° during the addition. The reaction mixture was stirred at −65° for 1 hr., and, although Color Test I was negative, carbonation was effected in the same manner as described for *o*-chlorophenyllithium. Following the usual work-up no acid was isolated from the aqueous layer.

The crude adduct obtained from the organic layer was purified by sublimation at 45° and 0.005 mm. to yield 5.60 g. (68%) of pure III melting at 54.5–55.5°.

Addition of RLi to a Mixture of Furan and *o*-Bromohalobenzene. (a) ***n*-Butyllithium and *o*-Bromofluorobenzene.**—To a rapidly stirred solution of 7.00 g. (0.04 mole) of *o*-bromofluorobenzene in 15 ml. of ether and 41 g. of furan was added 30 ml. of an ethereal solution containing 0.042 mole of *n*-butyllithium. The addition funnel containing the *n*-butyllithium was jacketed and cooled by means of Dry Ice and acetone. The temperature of the reaction mixture was maintained between −30 and −25° during the addition which required 15 min. Color Test I was negative on completion of the addition. The mixture was warmed to −20° and poured into water. The organic layer was separated, dried over anhydrous sodium sulfate, filtered, and finally the ether and excess furan were distilled on a steam-bath. A small amount of *n*-butyl bromide was distilled under reduced pressure, and the remaining material was sublimed at room temperature and 0.003 mm. to yield 3.90 g. (68%) of III.

The results of the interaction of *n*-butyllithium with the *o*-chloro- and *o*-bromo-isomers are given in Table I.

(c) **Phenyllithium and *o*-Bromochlorobenzene.**—The phenyllithium was prepared by adding a solution of 11.3 g. (0.055 mole) of iodobenzene in 60 ml. of ether to a suspension of 12.1 g. of lithium wire cut into small pieces and contained in 100 ml. of ether. The mixture was cooled with an ice-bath during the addition which required 2.5 hr. The mixture was stirred in the ice-bath for 2 hr. after the addition was complete and at room temperature for another 2 hr. After concentrating the mixture to 45 ml., a single acid titration indicated the yield to be 0.053 mole; 25 ml. of this solution was added, during 7 minutes, to a stirred solution of 5.75 g. (0.03 mole) of *o*-bromochlorobenzene in 10 ml. of diethyl ether and 31 g. of furan, while maintaining the temperature between −25 and −30°. The mixture was stirred at −30° for 25 min. and then was hydrolyzed with water. The two layers were separated and the organic layer was worked up in the usual manner. After distilling the ether and excess furan, the remaining material was distilled at 155–160° (745 mm.) to give 3.33 g. (71%) of bromobenzene, n^{20}D 1.5585. The infrared spectrum was identical with that of a pure sample of bromobenzene.

Because of the high bath temperature (230°) encountered during the distillation, the adduct was converted to a dark brown material from which a trace of α-naphthol was sublimed. No other material was identified.

Three grams of III was refluxed under nitrogen for 4 hr. No adduct was recovered and the resulting product was a brown material very similar to the above material.

Attempted Metalation of Chlorobenzene in Furan with Butyllithium.—Twenty-two milliliters of an ethereal solution containing 0.03 mole of butyllithium was added, during 5 min., to a stirred solution of 3.48 g. (0.03 mole) of chlorobenzene in 15 ml. of diethyl ether and 30 g. of furan. The addition was carried out between −35 and −40° and was stirred at −30° for an additional 30 min. on completion of the addition. The mixture was cooled to −60° and carbonated in the usual manner. The aqueous layer on acidification, extraction with ether, and sublimation of the resulting solid gave 0.33 g. of 2-furoic acid, m.p. 130–132°. After distillation of solvent from the organic layer, there was obtained 2.06 g. (60%) of unreacted chlorobenzene. No Diels–Alder adduct was isolated.

2-Chloro-2′-(triphenylsilyl)-biphenyl.—An ethereal solution containing 0.10 mole of *o*-chlorophenyllithium was prepared at −70° in accordance with an earlier procedure. After stirring the organolithium solution at −70° for 1 hr., 10 g. (0.034-mole) of triphenylchlorosilane in 90 ml. of ether was added, and the reaction mixture was allowed to slowly warm to room temperature. Three hours after completion of the addition Color Test I was positive. Subsequently an additional 4.73 g. of triphenylchlorosilane in 25 ml. of ether was added, and then the mixture was allowed to stir at room temperature for 10 hr. The mixture was hydrolyzed with 5% hydrochloric acid. The ethereal layer was separated, dried over anhydrous sodium sulfate and the ether was distilled. The residue was suspended in warm petroleum ether (b.p. 60–70°) and the white solid (mostly triphenylsilanol) was filtered off. The filtrate was chromatographed on a column of alumina. Elution was effected with 100 ml. of petroleum ether followed by 400 ml. of a 1:1 mixture of petroleum ether and benzene. The white solid was then chromatographed on the same column and was eluted with a 1:1 mixture of petroleum ether and benzene. A total of

TABLE I

REACTIONS OF *o*-XC_6H_4Br WITH RLi IN THE PRESENCE OF FURAN

Run	Halide[a]	Halide, mole	RLi[b]	Temp., °C.[c]	Furan, g.[d]	Addn. time, min.	Yield of 1,4-dihydronaphthalene-1,4-endoxide, %
1	*o*-ClC_6H_4Br	0.042	*n*-C_4H_9Li	−40[e]	41	15[f]	64
2	*o*-BrC_6H_4Br	.042	*n*-C_4H_9Li	−50[e]	41	12[f]	80

5	*o*-FC_6H_4Br	.026	C_6H_5Li[i]	−30[j]	29	10	74[k]

[a] RLi was added to the halide in every run. [b] Equivalent amount of RLi was used in all runs. [c] Temperature during the addition of the RLi. [d] In all runs 15 ml. of dry diethyl ether was admixed with the furan. [e] Mixture warmed to −10° before hydrolyzing with water. [f] Negative Color Test I after addition. [g] Mixture warmed to −10° and carbonated after 10 min. [h] Color Test I was positive on completion of the addition. A negative Color Test I resulted after warming to −10°. The mixture was hydrolyzed with water. [i] C_6H_5Li prepared from C_6H_5Br. [j] Warmed to −20° before hydrolysis. [k] Recovered 1.18 g. (30%) of C_6H_5Br, n^{20}D 1.5578.

(b) **Methyllithium and *o*-Bromofluorobenzene.**—Nineteen milliliters of an ethereal solution containing 0.026 mole of methyllithium[20] was added during 7 min. to a rapidly stirred solution of 4.38 g. (0.025 mole) of *o*-bromofluorobenzene in 15 ml. of ether and 29 g. of furan. The temperature of the reaction mixture during the addition was maintained between −10 and −12°. The reaction mixture was carbonated and worked up as described previously. No acid was found in the acidified aqueous layer. The organic layer was worked up as usual, and the crude adduct was sublimed at room temperature and 0.003 mm. to yield 3.01 g. (84%) of III.

The results of the interaction of methyllithium with the *o*-chloro- and *o*-bromo- isomers are summarized in Table I.

9 fractions was collected. The oil from the second fraction when washed with ethanol gave a white solid which was crystallized from ethyl acetate to give 0.15 g. of tetraphenylsilane, identified by means of a mixed melting point with an authentic sample. Removal of the solvent from the third fraction left a yellow paste which was refluxed in petroleum ether. There was isolated 1.4 g. (13%) of product melting at 149–152°. Two additional crystallizations gave an analytical sample of 2-chloro-2′-(triphenylsilyl)-biphenyl melting at 157.5–158.5°.

Anal. Calcd. for $C_{30}H_{23}ClSi$: Si, 6.28. Found: Si, 6.23, 6.27.

Fraction four gave 0.25 g. of pale yellow plates melting at 194–196°. A mixed melting point with an authentic sample of triphenylene showed no depression.

2-Bromo-2′-(triphenylsilyl)-biphenyl.—A solution of 25 ml. (0.032 mole) of butyllithium was added over a period of 6 min. to a rapidly stirred solution of 10 g. (0.032 mole) of 2,2′-dibromobiphenyl in 100 ml. of dry ether. A temperature of −20° was maintained during the addition. After completing the addition, the mixture was stirred at −15° for 45 min. Subsequently 9.44 g. (0.032 mole) of triphenylchlorosilane dissolved in 85 ml. of ether was added at −15°, and the mixture was allowed to warm to room temperature. The mixture was stirred overnight at room temperature and then was refluxed for 7 hr. after which time Color Test I was positive. After adding 100 ml. of *n*-heptane, the resulting mixture was distilled until an internal temperature of 70° was reached, whereupon a negative color test was obtained after 20 min. The mixture was hydrolyzed with water. An insoluble material was filtered and crystallized from ethanol to give colorless needles, 1.92 g., m.p. 152–153°. Work-up of the filtrate as described in the preceding experiment yielded an additional 1.81 g. of product, m.p. 147–149°. The total yield of 2-bromo-2′-(triphenylsilyl)-biphenyl was 3.73 g. (24%). The analytical sample melted at 152.5–154°.

Anal. Calcd. for $C_{30}H_{23}BrSi$: Si, 5.71. Found: Si, 5.63, 5.45.

The infrared spectrum of the bromo-isomer as a carbon disulfide solution was very similar to that of the chloro-isomer, thus indirectly confirming the structure of the latter.

Acknowledgments.—The authors wish to express their appreciation to the Materials Laboratory, Wright Air Development Center, Wright–Patterson Air Force Base, Ohio, for financial assistance. They also are grateful to the Institute for Atomic Research, Iowa State College, and Mr. E. Miller Layton for assistance in the infrared determinations.

Reactions of Trichloromethyl-1,3,5-triazine Derivatives with Amines[1]

BY ALFRED KREUTZBERGER

RECEIVED SEPTEMBER 19, 1956

A method has been found which, by means of amines, permits the replacement by NHR-groups of all trichloromethyl groups attached to a 1,3,5-triazine ring. Use of diamines leads to longer chains of higher molecular 1,3,5-triazine compounds. In 1,3,5-triazine derivatives bearing both trichloromethyl and carbethoxy groupings, ammonia reacts first of all with one trichloromethyl group.

As is well known, the trichloromethyl groups of several organic compounds like chloral, trichloroacetic acid, trichloroacetone and others are split off upon reaction with alkali to form anions[2] which then, by combining with a proton, form chloroform. In connection with investigations on trichloromethyl-1,3,5-triazines,[3,4] especially 2-methyl-4,6-bis-trichloromethyl-1,3,5-triazine (I) and 2-phenyl-4,6-bis-trichloromethyl-1,3,5-triazine (II),[5] it was desirable to know whether these compounds reacted with bases analogously. The various replacement reactions of trichloromethyl groups attached to the 1,3,5-triazine ring by NHR-groups are described in the present article, along with some comparable observations on carbethoxytrichloro-1,3,5-triazines.

In the reaction of I or II with concentrated aqueous ammonia, only one of the two trichloromethyl groups turned out to be replaceable by the NH_2-group under very mild conditions, thus yielding 2-methyl-4-amino-6-trichloromethyl-1,3,5-triazine (III) and 2-phenyl-4-amino-6-trichloromethyl-1,3,5-triazine (IV), respectively. An attempt to replace the last trichloromethyl group by increasing the reaction temperature failed. Instead, at higher temperatures compound I yielded quantitatively 2-methyl-4-amino-6-hydroxy-1,3,5-triazine (V) upon reaction with aqueous ammonia and a mixture of III and V upon reaction with ethanolic ammonia solution.[6]

It was, however, desired to find a method by which all trichloromethyl groups attached to a triazine ring could be replaced by NHR-groups, because application of diamines would then lead to higher molecular compounds containing two or more 1,3,5-triazine rings linearly connected. This objective was achieved through working in OH-free media, like dioxane, chloroform and N,N-dimethylformamide.

Thus, by bubbling ammonia into a solution of I in N,N-dimethylformamide, 2-methyl-4,6-diamino-1,3,5-triazine (XI) was obtained. By the same

(1) This article is based on work performed under Project 116-B of The Ohio State University Research Foundation sponsored by the Ohio Mathieson Chemical Corporation, Baltimore, Md.

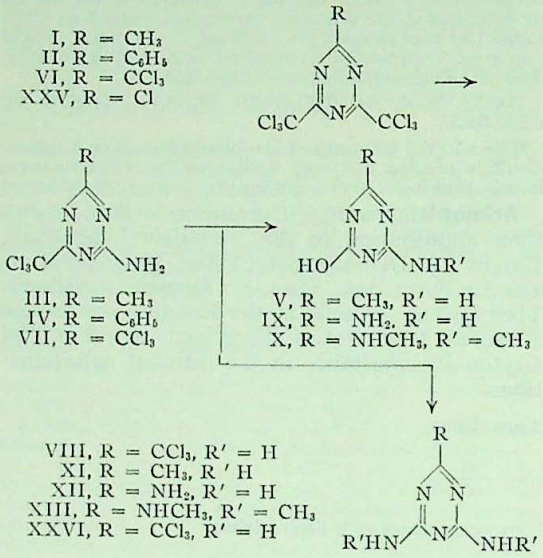
(5) K. Dachlauer, German Patent 682,391, Oct., 1939 (to I. G. Farbenindustrie A.-G.).

(6) These findings are in conformity with the results obtained from the action of concd. aqueous ammonia on 2,4,6-tris-trichloromethyl-1,3,5-triazine (VI) as reported by A. Weddige, *J. prakt. Chem.*, [2] **33**, 81 (1886). Only the first two trichloromethyl groups in VI could be replaced by the amino group with formation of 2-amino-4,6-bis-trichloromethyl-1,3,5-triazine (VII) and 2,4-diamino-6-trichloromethyl-1,3,5-triazine (VIII). Similar results were obtained when methylamine was used in place of concd. aqueous ammonia. The substitution by the NHR-group of the last trichloromethyl group in VI, however, could not even be forced under more severe conditions, and as end product only 2,4-diamino-6-hydroxy-1,3,5-triazine (IX) and 2,4-bis-methylamino-6-hydroxy-1,3,5-triazine (X), respectively, could be obtained.

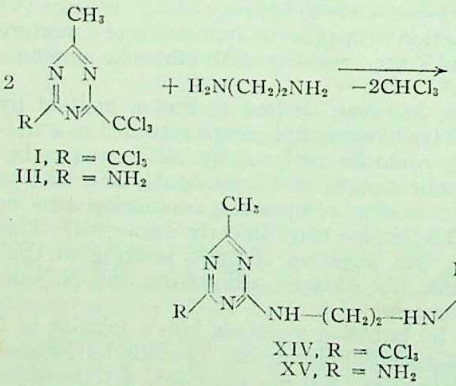
CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

procedure, the conversion of VI with ammonia into 2,4,6-triamino-1,3,5-triazine (XII) and with methylamine into 2,4,6-tris-methylamino-1,3,5-triazine (XIII) was successful.

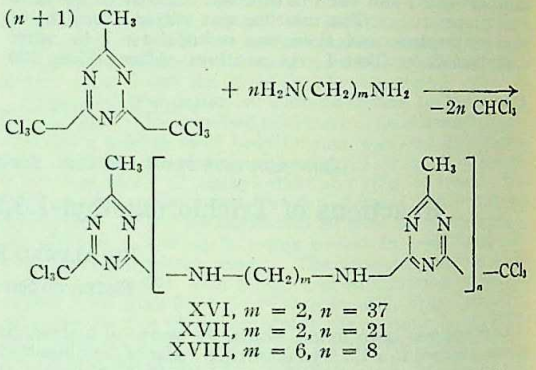


Furthermore, by the above procedure but using diamines, the linkage of two triazine rings was achieved. Thus the reaction of two molecules of I with one molecule of ethylenediamine in chloroform led to N,N′-bis-[2-methyl-4-trichloromethyl-1,3,5-triazinyl-(6)]-ethylenediamine (XIV). In addition, by the above method, the reaction of the last trichloromethyl group of the triazine ring with diamine could be brought about. Two molecules of III on reaction with one molecule of ethylenediamine in dioxane yielded N,N′-bis-[2-methyl-4-amino-1,3,5-triazinyl-(6)]-ethylenediamine (XV).



In principle by the same method, the linkage of more than two triazine rings with each other into longer chains could be brought about. In this case the molar ratio between I and the diamine had to be about 1:1 and a longer reacting time had to be allowed. At first, for the purpose of the determination of the molecular weight of these polymers, some measurements of specific viscosity were made which showed, upon comparison with the analytically found chlorine values, that the chain ends of the polymers consisted of trichloromethyl groups. That, in turn, meant that in subsequent experiments the molecular weight could be calculated simply from the analytical chlorine values. The accuracy of the chlorine analyses limits the accuracy of the calculation of the n-values for formulas XVI and XVII to ± 3.

Generally the chain length proved to be essentially dependent on the kind of diamine and the solvent used. Thus the reaction of I with ethylenediamine in m-cresol yielded a polymer XVI having a molecular weight of 5920, while the same starting materials in N,N-dimethylformamide gave the polymer XVII with a molecular weight of 3500. Using the latter solvent for the reaction between I and hexamethylenediamine, the polymer XVIII with the somewhat lower molecular weight of 1990 was obtained. All these polymers, particularly XVIII, exhibit molding properties in the molten state.



In these studies on the behavior of trichloromethyl groups attached to the 1,3,5-triazine ring, these groups were compared with carbethoxy groups as to their reactivity toward ammonia. As suitable compounds for these investigations, 2,4-bis-trichloromethyl-6-carbethoxy-1,3,5-triazine (XIX)[7] and 2-trichloromethyl-4,6-bis-carbethoxy-1,3,5-triazine (XX)[7] were chosen. Subjecting these two compounds to conditions under which in the aforementioned cases only one CCl_3 group was replaced by an NH_2 group, not only one CCl_3 group, but also one (in XIX) or two (in XX) carbethoxy groups reacted. Thus XIX was converted to 2-amino-4-trichloromethyl-6-carbamyl-1,3,5-triazine (XXI). The reaction product of XX was assigned the constitution of 2-hydroxy-4,6-bis-carbamyl-1,3,5-triazine (XXII) on the basis of the fact that it is insoluble in $NaHCO_3$, Na_2CO_3 and diluted NaOH solutions, but soluble in concd. NaOH solution. Thus, the question as to whether the CCl_3 group in XX acts toward ammonia as a "first" or "last" CCl_3 group, is to be answered in favor of the latter possibility on account of the OH-substitution.

Since under these conditions the two different functional groups of both XIX and XX reacted simultaneously, no conclusions as to their relative reactivities could be drawn. Thus milder conditions of reaction seemed indicated. It was found that when exactly equimolar amounts of ammonia and the triazine derivative were caused to react in absolute ethereal solution at 0°, only one functional

(7) H. Bosshard, H. Bohni, H. R. Mathys, R. Mitsche, E. Tschudi, H. Isler and S. Seide, *Ann.*, **577**, 84 (1952).

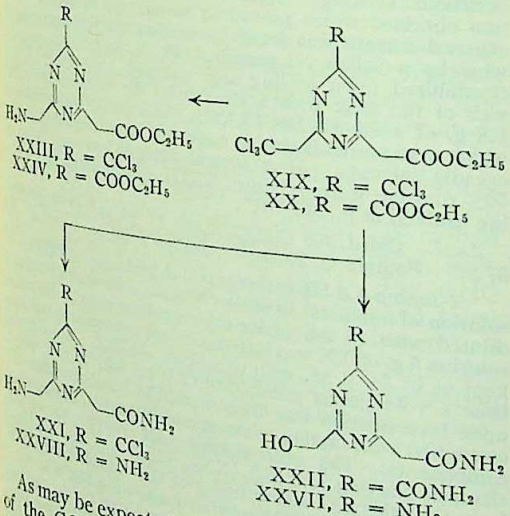
CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

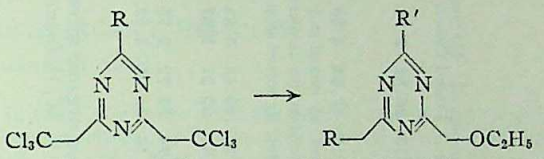
group, *viz.*, the CCl_3 group, was replaced. Thus, XIX furnished 2-amino-4-carbethoxy-6-trichloromethyl-1,3,5-triazine (XXIII) while XX yielded 2-amino-4,6-bis-carbethoxy-1,3,5-triazine (XXIV). Summarizing, it can be said that in 1,3,5-triazine derivatives containing both CCl_3 and $COOC_2H_5$ groups, the first CCl_3 is the most reactive of these functional groups toward ammonia. Second in order of activity, however, is not the second CCl_3 group but the $COOC_2H_5$ group as is evidenced by the formation of XXI.

In this connection it may be worthwhile to notice that when both CCl_3 and Cl groups are attached to the 1,3,5-triazine nucleus, the first CCl_3 group reacts most easily with ammonia. Thus 2,4-bis-trichloromethyl-6-chloro-1,3,5-triazine (XXV) reacts with ammonia to give 2-trichloromethyl-4,6-diamino-1,3,5-triazine (XXVI).[8] In this reaction no formation of the intermediate 2,4-bis-trichloromethyl-6-amino-1,3,5-triazine, which is stable under the conditions employed, was observed.

In analogy with the formation of V, the action of concentrated aqueous ammonia on XIX or XXI at elevated temperatures yielded 2-amino-4-hydroxy-6-carbamyl-1,3,5-triazine (XXVII), thus replacing the last CCl_3 group by a hydroxy rather than by an amino group. In this reaction, in addition to XXVII, only minor amounts of 2,4-diamino-6-carbamyl-1,3,5-triazine (XXVIII) were obtained. As in preceding cases, the replacement of the last CCl_3 group in XXI by NH_2 was attained by means of gaseous ammonia and N,N-dimethylformamide as solvent. In this manner, XXVIII was the sole reaction product.



As may be expected, the nucleophilic replacement of the CCl_3 group attached to the 1,3,5-triazine ring also proceeds with other suitable agents, *e.g.*, ethanol. The latter, upon reaction with trichloromethyl-1,3,5-triazine derivatives, gives principally the analogous results as ammonia. The only difference appears to be one of degree in that ethanol reacts more powerfully. Thus VI reacts with ethanol in the presence of a base to give directly 2,4,6-tris-ethoxy-1,3,5-triazine (XXIX), intermediates analogous to VII and VIII not being isolable.[9] XXIX also was obtained by the action of ethanol on XXV in the presence of sodium ethoxide, in this case the expected intermediates being isolable.[10] Another case of nucleophilic substitution of the CCl_3 group in the 1,3,5-triazine series was observed when it was attempted to dehalogenate XIX by hydrogen using ethanol as solvent, palladium-on-charcoal as catalyst and triethylamine as scavenger to bind HCl. In this reaction 2-ethoxy-4-methyl-6-carbethoxy-1,3,5-triazine (XXX) was obtained as one of the products.[11]



Acknowledgment.—The author is very much indebted to the Olin Mathieson Chemical Corporation for their generous support of this work. Furthermore he wishes to thank Dr. C. J. Grundmann of this Laboratory for his interest in the work and for stimulating discussions.

Experimental[12]

General Procedure Used for the Reaction of Trichloromethyl-1,3,5-triazine Derivatives. (A) With Concentrated Aqueous Ammonia (28%) at Room Temperature.—A suspension of 5 to 10 g. of the particular trichloromethyl-1,3,5-triazine derivative in 20 to 40 ml. of 28% aqueous ammonia was shaken for 2 to 3 hr. at room temperature, with an additional 15 to 25 ml. of the aqueous ammonia being added from time to time in smaller portions. Chloroform was evolved thereby. In some cases also heat was evolved so that cooling was necessary to maintain the suspension at room temperature. In other cases a somewhat elevated temperature (up to 50°) was necessary. The reaction product was vacuum-filtered, dried and recrystallized. Compounds III, IV, XXI and XXII in Table I were prepared by this procedure.

(B) With Aqueous Ammonia (28%) at 100°.—Batches of the type and size described under (A) were heated on a water-bath for 4 hr. Thereafter they were evaporated to dryness and the residues were recrystallized. Compounds V, IX and XXVII were produced by this procedure.

(C) With Amines in OH-free Solvents.—An amount of 5 to 10 g. of the requisite trichloromethyl-1,3,5-triazine derivative was, respectively, dissolved or suspended in N,N-dimethylformamide, chloroform or dioxane. If the amine was gaseous, it was bubbled into the reaction mixture, the temperature varying between room temperature and 165° according to the ease of the reaction. The liquid amines were added to the reaction mixture which was then shaken at a temperature chosen as explained above. The end-point of the reaction was evidenced by cessation of chloroform evolution and was usually reached after a total reaction time of 2 to 4 hours. If the reaction product remained in solution, the reaction mixture was evaporated to dryness, but if the reaction product precipitated, it was vacuum-filtered and dried. The solids were then either recrystallized or, if a suitable solvent could not be found, they were purified by extracting the impurities with ethanol, acetone and ether. Examples are listed in Table I as XI, XII, XIII, XIV, XV and XXVIII.

Polymer XVI.—Ethylenediamine (2.0 g.) was added to a solution of I (10.0 g.) in *m*-cresol (25.0 g.) and the mixture heated for 4 hr. at 205–210°. From the resulting reddish brown oil the solvent was distilled off *in vacuo* and the crude

brown remainder best purified by successive boiling out with alcohol and acetone. Thus a faintly yellow powder was obtained which was insoluble in all usual organic solvents; m.p. about 370°, yield 3.0 g. (64%).

Anal. Calcd. for $C_{223}H_{336}N_{183}Cl_6$: C, 46.24; H, 5.72; Cl, 3.59. Found: C, 46.56; H, 5.79; Cl, 3.59, 3.58.

Polymer XVII.—Ten parts by weight of I and two parts by weight of ethylenediamine were dissolved in 25 parts by weight of N,N-dimethylformamide and heated for 3 hr. at 170–180°, thereby precipitating a yellowish brown mass, the amount of which could be increased by adding acetone to the cooled suspension. Since the product obtained could not be recrystallized, the best way to purify it was by separate extractions with boiling acetone and alcohol. The yellowish powder so obtained amounted to 3.5 g. (73%) and melted at about 250°.

Anal. Calcd. for $C_{132}H_{192}N_{108}Cl_6$: C, 45.25; H, 5.52; Cl, 6.07. Found: C, 45.23; H, 5.97; Cl, 6.06, 6.21.

Polymer XVIII.—A mixture of 10.0 g. of I, 3.5 g. of hexamethylenediamine and 25 ml. of N,N-dimethylformamide was heated for 3 hr. at 160–170°. During this time the crude condensation product precipitated. After cooling, the reaction mixture was diluted with acetone, boiled for a short time and filtered. Since the solid was insoluble in lower boiling solvents like carbon tetrachloride or acetone and soluble in higher boiling ones like nitrobenzene but could not, however, be recrystallized from the latter ones, it could be purified best by successive extractions with boiling acetone, alcohol and carbon tetrachloride. The yellow powder so obtained melted at 200–201°, yield 2.5 g. (37%). Soluble also in mineral acids, XVIII could be reprecipitated from such a solution by neutralization with dilute alkali.

Anal. Calcd. for $C_{86}H_{139}N_{43}Cl_6$: C, 51.93; H, 7.05; Cl, 10.69. Found: C, 51.96, 51.76; H, 7.34, 7.42; Cl, 10.42, 10.40.

2-Amino-4-carbethoxy-6-trichloromethyl-1,3,5-triazine (XXIII).—Of a saturated solution of ammonia in ether (at 0°), 16 ml. was diluted with 15 ml. of ice-cold absolute ether. To this solution 5 g. of XIX was added in small portions and the whole reaction contents kept at 0° for 2 hr. with occasional shaking. Upon filtration, 0.3 g. of a white solid was obtained which proved to be starting material. The ethereal filtrate was freed from ether on the steam-bath whereby a yellow oil remained which, to a large extent, crystallized upon cooling and repeated scratching of the wall of the flask with a glass rod. By vacuum-filtration 1.8 g. of white needles (XXIII, yield 54%) was obtained which were insoluble only in water but soluble in all common organic solvents. After several recrystallizations from a 50% dioxane–water mixture, XXIII was obtained as glittering leaflets, m.p. 130–131°.

Anal. Calcd. for $C_7H_7Cl_3N_4O_2$: C, 29.44; H, 2.47; Cl, 37.26. Found: C, 29.39; H, 2.56; Cl, 37.40.

2-Amino-4,6-bis-carbethoxy-1,3,5-triazine (XXIV).—A solution of ammonia in ether (19 ml.), saturated at 0°, was diluted with 15 ml. of ice-cold absolute ether. Into this solution 5 g. of XX was introduced and the reaction contents kept at 0° for 3 hr. with occasional shaking. During this time a voluminous precipitate (2.9 g.) had formed which upon investigation was found not to be homogeneous. By extraction with boiling ether, it could be separated into two components. The ether-soluble part proved to be unchanged starting material (XX), which was also obtained from the ethereal mother liquor of the original precipitate. The total amount of XX recovered was 4.0 g. (80%).

The ether-insoluble portion amounted to 0.4 g., melted at 179–180° and could be obtained by recrystallization from acetone–water (1:5) as white, small leaflets melting at 182–183°.

Anal. Calcd. for $C_9H_{12}N_4O_4$: C, 45.00; H, 5.04; N, 23.23. Found: C, 44.74, 44.94; H, 5.09, 5.33; N, 23.15, 23.14.

2-Amino-4-hydroxy-6-carbamyl-1,3,5-triazine (XXVII).—Five grams of XIX was added slowly with stirring to 40 ml. of concd. aqueous ammonia at room temperature and then kept for 6 hr. on the steam-bath. The somewhat cloudy hot solution was vacuum filtered and the filtrate allowed to cool down, whereby 0.3 g. (16.9% yield) of glittering crystals came off which had no melting point up to 400° and were

Upon evaporation of the aqueous filtrate to dryness, 1.8 g. of a white substance was obtained. This substance, being insoluble in all common organic solvents and being soluble in hot water only, proved to be a hydrate of XXVII. Attempts to remove the hydrate water by heating the substance *in vacuo* resulted in partial decomposition of the material. Therefore for analysis the product was dried *in vacuo* for 1 hr. at 56°. It decomposed then in the melting point tube at 168–173°. The analysis of this sample indicated the presence of 2.5 moles of water.

Anal. Calcd. for $C_4H_5N_5O_2 \cdot 2.5H_2O$: C, 24.01; H, 5.04; N, 35.00. Found: C, 24.03; H, 5.51; N, 35.65.

1,4-Addition of Grignard Reagents to 9-Phenanthryl Ketones[1]

BY REYNOLD C. FUSON AND STANLEY J. STRYCKER

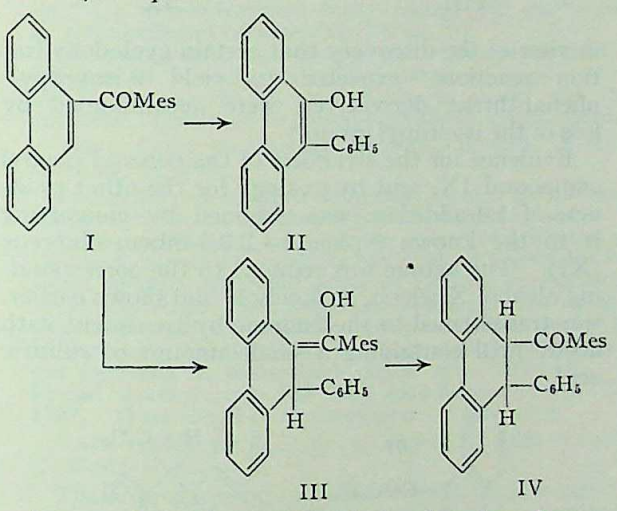
RECEIVED DECEMBER 20, 1956

It has been shown that 9-phenanthryl mesityl ketone reacts in the 1,4-manner with the methyl and phenyl Grignard reagents to give the corresponding 10-substituted 9,10-dihydrophenanthrenes. 9-Phenanthryl phenyl ketone and phenyl 9-phenanthrenecarboxylate react with phenylmagnesium bromide to yield phenyl 10-phenyl-9,10-dihydro-9-phenanthryl ketone.

The 1,4-addition of Grignard reagents to conjugated systems involving benzene rings, discovered 27 years ago by Gilman, Kirby and Kinney,[2] and almost at the same time by Kohler and Nygaard,[3] takes place more readily in the naphthalene series.[4] The difference, ascribed to the greater degree of double bond quality of the 1,2-bond in naphthalene, would be expected to be even more pronounced in suitably constituted phenanthrene derivatives; the 9,10-double bond of phenanthrene is known to have a higher order of reactivity than the bonds in naphthalene. To test this idea, we have prepared certain 9-phenanthryl ketones and subjected them to the action of Grignard reagents.

Our experiments have shown that mesityl 9-phenanthryl ketone (I) does react in the conjugate manner with the phenyl and methyl reagents. The first experiment with phenylmagnesium bromide gave an intractable oil. Chromatographic separation on an alumina-packed column yielded a small amount of the original ketone and a new compound which proved to be a phenol. It melted at 143–144° and formed an acetate (m.p. 153–155°) and benzoate (m.p. 179–180°). The melting points of the three compounds checked those given by Koelsch[5] for 9-phenyl-10-phenanthrol (II), its acetate and its benzoate. The formation of the phenanthrol is reminiscent of the production of 2-phenyl-1-naphthol in the naphthalene series[4] and similarly may be ascribed to the air oxidation of the enol III. In a subsequent experiment the expected dihydro ketones IV were isolated.

Methylmagnesium iodide behaved in a similar manner, the dihydro compound V likewise being obtained in two forms. Our belief that the methylated ketones are the expected diastereoisomers is strengthened by the observation that, when heated with a palladium-on-charcoal catalyst, the isomer having the lower melting point (109–110°) was changed to the higher-melting (154.5–155.5°) compound.



In search of a less highly hindered carbonyl compound we tried phenyl 9-phenanthroate (VI). With phenylmagnesium bromide it gave 9-benzoyl-10-phenyl-9,10-dihydrophenanthrene (VIII), presumably by way of 9-phenanthryl phenyl ketone (VII). This idea was supported by the results of experiments with the benzoyl compound VII. With the phenyl reagent it yielded the same dihydro ketone VIII obtained from the ester. We were satisfied with the structure VIII for this ketone, isolated in only one form, when we found that it could be dehydrogenated. The aromatized ketone, 9-benzoyl-10-phenylphenanthrene (IX), was obtained in small amount directly from the reaction mixture produced by the treatment of the phenyl ketone VII with phenylmagnesium bromide.

The aromatization could be effected in 76% yield by treatment of the dihydro ketone with bromine. This method was successful also in the aromatization of the methyl ketone V and the phenyl ketone IV. In the latter case, however, the dehydrogenation was accompanied by an unexpected cleavage. The cleavage product that was isolated proved to be 9-phenylphenanthrene. If mesitoic

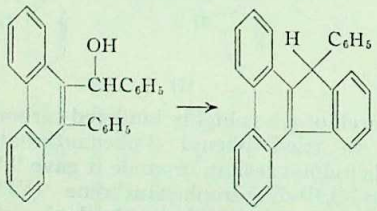
in view of the discovery that certain cyclodehydration reactions, expected to yield 9-isopropylphenanthrene derivatives, were accompanied by loss of the isopropyl group.[6]

Evidence for the structure of the benzoyl phenyl compound IX, and by analogy for the other products of 1,4-addition, was obtained by converting it to the known 9-phenyl-1,2,3,4-dibenzofluorene (XI). The ketone was reduced to the corresponding alcohol X which, as Koelsch[7] had shown earlier, was transformed to the fluorene by treatment with acetic acid containing a small amount of sulfuric acid.



X XI

9-Phenanthryl mesityl ketone was made by condensing 9-phenanthrylmagnesium bromide with mesitoyl chloride and also by the action of 9-phenanthroyl chloride on mesitylene in the presence of aluminum chloride. The preparation of 9-phenanthryl phenyl ketone from 9-cyanophenanthrene and the phenyl Grignard reagent was of especial interest since the nitrile itself might have reacted in the conjugate manner. However, chromatographic separation of the reaction mixture, after hydrolysis, gave no other phenanthrene derivative.

Experimental[8]

Phenyl 9-Phenanthroate (VI).—The procedure was similar to that employed earlier for the synthesis of phenyl 1-naphthoate.[9] A mixture of 12.9 g. of 9-phenanthroyl chloride and 5.1 g. of phenol was warmed to initiate the reaction. The evolution of hydrogen chloride continued for about 1 hr.; 60 ml. of methylcyclohexane was added and the mixture heated under reflux for 45 minutes. The hot mixture was filtered and the filtrate allowed to cool. The phenyl phenanthroate separated in the form of large clumps of colorless needles, m.p. 113.5–115.5°, yield 13.8 g. (85%). Recrystallization of the ester from ethanol raised the melting point to 115.5–116.5°.

Anal.[10] Calcd. for $C_{21}H_{14}O_2$: C, 84.54; H, 4.73. Found: C, 84.46; H, 5.01.

The infrared spectrum[11] contains absorption bands assignable to an ester function (1737 and 1200 cm.$^{-1}$) and a monosubstituted phenyl group (683 cm.$^{-1}$).

9-Benzoylphenanthrene (VII).—The procedure was patterned after that described for the preparation of 9-acetylphenanthrene.[12] A solution of 5.0 g. of 9-cyanophenanthrene in 50 ml. of dry benzene was added quickly to a Grignard reagent prepared from 19.3 g. of bromobenzene, 2.99 g. of magnesium and 200 ml. of ether. The dark, clear reaction mixture turned green and became opaque. During a 7-hr. period of reflux the color changed to a deep amber. The reaction mixture was cooled by means of an ice-bath, and an excess of dilute hydrochloric acid was added, with stirring. The initially formed yellow, fluffy precipitate changed suddenly to a milky white crystalline substance during the acidification. The precipitate was removed by filtration and warmed on a steam-bath for 4 hr. with distilled water. The crystalline material gradually changed to a clear oil, which settled to the bottom of the container. The oil, which was extracted with a mixture of ether and benzene, was subjected to chromatography. The 9-benzoylphenanthrene crystallized from high-boiling petroleum ether as colorless needles, m.p. 90–91°,[13] yield 5.3 g. (76%).

In the infrared spectrum a strongly conjugated carbonyl band appears at 1665 cm.$^{-1}$, a sharp peak at 701 cm.$^{-1}$ suggests the monosubstituted phenyl radical, and *o*-disubstitution of the phenanthrene nucleus is indicated by a sharp peak at 725 cm.$^{-1}$. A medium peak at 885 cm.$^{-1}$ may be assigned to the isolated hydrogen atom at the 10-position of phenanthrene.

9-Mesitoylphenanthrene (I). The Grignard Method.—The procedure described by Miller and Bachmann[14] for 9-acetylphenanthrene was used as a pattern. The 9-phenanthrylmagnesium bromide, prepared from 71.0 g. of 9-bromophenanthrene, was added slowly to a solution of mesitoyl chloride in 250 ml. of anhydrous benzene. An immediate precipitate appeared and the mixture became warm. After completion of the addition, which required 30 minutes, the mixture was stirred at room temperature for an additional 3 hr. The 9-mesitoylphenanthrene, isolated by usual procedures, crystallized from benzene–ethanol, yield 71 g. (80%). It was purified by sublimation at 160° (1.5 mm.), m.p. 193.0–193.5°.

Anal. Calcd. for $C_{24}H_{20}O$: C, 88.85; H, 6.21. Found: C, 88.55; H, 6.18.

The infrared spectrum has bands attributable to a conjugated carbonyl group (1662 cm.$^{-1}$) and the mesityl radical (843 cm.$^{-1}$).

9-Mesitoylphenanthrene (I). The Friedel–Crafts Method.—The procedure was similar to that described for the preparation of 2-mesitoylnaphthalene.[4] One gram of anhydrous aluminum chloride was added to a mixture of 1.0 g. of 9-phenanthroyl chloride, 1.0 g. of mesitylene and 25 ml. of pure symmetrical tetrachloroethane, and the mixture was heated gently on a steam-bath for 2 hr. The dark solution was poured carefully into dilute hydrochloric acid, and

the solvent and unchanged mesitylene were removed by steam distillation. The crude product was boiled with methanol to which decolorizing carbon had been added and the mixture filtered. The ketone separated from the filtrate in beautiful, thin plates which had a yellow tinge, m.p. 187.5–189.5°, yield 0.96 g. (71%). It melted at 193.0–193.5° after sublimation. A mixture melting point with the product from the Grignard method showed no depression.

Condensation of Phenylmagnesium Bromide with Phenyl 9-Phenanthroate.—A solution of 5 g. of the ester in 75 ml. of dry benzene was added, over a period of 40 minutes, to a Grignard reagent made from 13.1 g. of bromobenzene, 2.02 g. of magnesium and 100 ml. of anhydrous ether. The reaction did not seem to be highly exothermic, and the solution slowly developed a green color. After being heated, under reflux and with stirring, for 17 hr., the mixture was treated with a saturated solution of ammonium chloride. The two-phase system, which had a marked odor of phenol, was stirred for 3 hr. The aqueous layer was extracted once with 150 ml. of ether and the ether solution added to the original organic layer.

Extraction of the organic layer with 10% sodium hydroxide removed phenol, which was isolated as 2,4,6-tribromophenol, m.p. 94–95°.[15] Steam distillation of the organic layer served to remove solvent and biphenyl. By recourse to chromatography 9-benzoyl-10-phenyl-9,10-dihydrophenanthrene was isolated which, after recrystallization from absolute ethanol, melted at 151.5–152.5°, yield 4.35 g. (72%).

Anal. Calcd. for $C_{27}H_{20}O$: C, 89.97; H, 5.59. Found: C, 89.78; H, 5.41.

The infrared spectrum contains significant bands at 2900, 1690, 747 and 695 cm.$^{-1}$ which are consistent with the structure assigned.

9-Benzoyl-10-phenylphenanthrene.—A solution of 0.45 g. of bromine in 50 ml. of carbon tetrachloride was added to a solution of 1.0 g. of the dihydro compound VIII in 50 ml. of carbon tetrachloride. The solution was maintained at reflux for 3 hr. at the end of which time the evolution of hydrogen bromide seemed to be complete. After being washed with a 10% solution of sodium bisulfite, the solution was freed of solvent by evaporation at reduced pressure. The clear colorless oil, left as a residue, was heated for 2 hr. with 150 ml. of dimethylaniline. The crude 9-benzoyl-10-phenylphenanthrene, isolated by pouring the previously cooled reaction mixture into dilute sulfuric acid, was recrystallized from 95% ethanol, m.p. 176–177°, yield 0.76 g. (76%).

Anal. Calcd. for $C_{27}H_{18}O$: C, 90.47; H, 5.06. Found: C, 90.38; H, 5.04.

The infrared spectrum contains bands attributable to a strongly conjugated carbonyl group (1670 cm.$^{-1}$), a monosubstituted phenyl radical (698 and 759 cm.$^{-1}$) and an *o*-disubstituted phenyl segment (724 cm.$^{-1}$). Moreover, aliphatic carbon–hydrogen bonds were indicated to be absent.

9-Phenyl-1,2,3,4-dibenzofluorene (XI).—A mixture of 0.19 g. of 9-benzoyl-10-phenylphenanthrene in 25 ml. of dry ether was warmed to effect solution, and to the solution was added slowly a slurry of 0.020 g. of lithium aluminum hydride in 10 ml. of ether. The mixture was heated on a steam-bath for 2 hr. and then treated successively with wet ether, aqueous ethanol and water. The gummy, viscous oil left by removal of solvent from the organic layer did not crystallize and was dissolved in 10 ml. of glacial acetic acid by warming. To the resulting solution were added 2 drops of concentrated sulfuric acid.[5] When the mixture was heated on the steam-bath, colorless crystals began to form immediately and the mixture soon appeared to be solid. The fluorene (0.14 g., 77% yield) crystallized from ethanol–toluene in the form of colorless, fluffy needles, m.p. 212–213°. The melting point given by Koelsch is 210–211°.

Anal. Calcd. for $C_{27}H_{18}$: C, 94.70; H, 5.30. Found: C, 94.48; H, 5.38.

The infrared spectrum has peaks suggesting the presence of an aliphatic hydrogen atom (2850 cm.$^{-1}$), monosubstituted benzene ring (698, 750 cm.$^{-1}$) and *o*-disubstitution (725 cm.$^{-1}$). The ultraviolet spectrum shows maxima at 247 mμ (log ε 4.92) and 322 mμ (log ε 4.48) with shoulders at 263 and 278 mμ.

Condensation of Phenylmagnesium Bromide with 9-Mesitoylphenanthrene.—Forcing conditions were employed and the entire experiment including the hydrolysis step was conducted in an atmosphere of nitrogen. A solution of 6.48 g. of the ketone in 75 ml. of dry benzene was added slowly to a Grignard reagent made from 6.28 g. of bromobenzene, 0.96 g. of magnesium and 50 ml. of anhydrous ether. The initial deep amber color changed to a deep green and, after the mixture had been heated for 6 hr. under reflux, was a milky yellow. At the end of a total reflux period of 8 hr., 80 ml. of 3 *N* hydrochloric acid was added and the two-phase system stirred overnight at reflux to effect ketonization. The organic layer, after being washed successively with water, 10% sodium bicarbonate solution and water, was dried over sodium sulfate. Removal of the solvent at reduced pressure left a yellow, viscous oil which crystallized slowly while being allowed to cool. Methanol removed the color, leaving the 9-mesitoyl-10-phenyl-9,10-dihydrophenanthrene as colorless crystals, m.p. 196–199°, yield 4.5 g. The compound was purified by recrystallization from chloroform–methanol, m.p. 202–203°.

Anal. Calcd. for $C_{30}H_{26}O$: C, 89.51; H, 6.51. Found: C, 89.51; H, 6.69.

Infrared analysis of the compound indicates the presence of a ketone function (1703 cm.$^{-1}$), the mesityl nucleus (852 cm.$^{-1}$), a monosubstituted phenyl radical (702 cm.$^{-1}$) and an *o*-disubstituted benzene ring (739 cm.$^{-1}$).

Chromatographic separation of the residue permitted the isolation of a white crystalline substance, m.p. 140.5–141.5°, the analysis of which is also in accord with the structure, 9-mesitoyl-10-phenyl-9,10-dihydrophenanthrene.

Anal. Calcd. for $C_{30}H_{26}O$: C, 89.51; H, 6.51. Found: C, 89.84; H, 6.71.

Except for minor shifts of certain bands, the infrared spectrum is the same as that of the higher-melting isomer.

In one experiment, in which two instead of five moles of Grignard reagent were used for each mole of ketone, the reaction product underwent oxidative cleavage—presumably at the enol stage. By chromatographic separation on alumina it was possible to isolate a compound which proved to be 9-phenyl-10-phenanthrol, which crystallized from aqueous methanol as transparent plates, m.p. 143–144°. It formed an acetate, m.p. 153–155°, and a benzoate, m.p. 177–179°. These values check those given by Koelsch.[5]

Anal. Calcd. for $C_{20}H_{14}O$: C, 88.86; H, 5.22. Found: C, 88.67; H, 5.13.

The infrared spectrum indicates not only the presence of a tertiary hydroxyl group (3530 cm.$^{-1}$) and of a monosubstituted phenyl ring (700 cm.$^{-1}$) but also the absence of aliphatic hydrogen atoms, of a carbonyl group and of a mesityl nucleus.

Condensation of Methylmagnesium Iodide with 9-Mesitoylphenanthrene.—A solution of 3.0 g. of the ketone in 75 ml. of dry benzene was added to a Grignard reagent made from 4.10 g. of methyl iodide, 0.70 g. of magnesium and 75 ml. of anhydrous ether. The reaction mixture immediately became dark green, but the color was gradually discharged during the subsequent 6-hr. period of heating the mixture under reflux. The two-layer system, produced by the addition of 75 ml. of 2 *N* hydrochloric acid, was heated under reflux for 13 hr. to ensure ketonization. An atmosphere of nitrogen was maintained throughout the experiment.

The organic layer was washed with water, with 10% sodium bicarbonate solution and again with water. The clear solution, after being dried overnight with anhydrous sodium sulfate, had a magenta color. Removal of the solvent left a pale yellow, viscous material which solidified when allowed to stand, m.p. 105–135°. Trituration of this solid with ether yielded a yellow oil and 1.4 g. of a white powdery solid, m.p. 152–155°, which proved to be the high-melting form of 9-mesitoyl-10-methyl-9,10-dihydrophenanthrene (V). It was purified by recrystallization from aqueous methanol, m.p. 154.5–155.5°.

Anal. Calcd. for $C_{25}H_{24}O$: C, 88.19; H, 7.11. Found: C, 88.11; H, 7.23.

The infrared spectrum shows bands attributable to a ketone group (1700 cm.$^{-1}$), the mesityl nucleus (853 cm.$^{-1}$) and an *o*-disubstituted benzene ring (740 and 760 cm.$^{-1}$).

The low-melting form of 9-mesitoyl-10-methyl-9,10-dihydrophenanthrene was obtained by submitting the ether-soluble portion of the product to a chromatographic separation on alumina. The major part of the material was eluted with a 10:1 ratio of cyclohexane to ether. Large needles, m.p. 109–110°, separated from a cooled aqueous ethanolic solution in a yield of 1.1 g.

Anal. Calcd. for $C_{25}H_{24}O$: C, 88.19; H, 7.11. Found: C, 87.83; H, 7.39.

The infrared spectrum of this compound is nearly superimposable on that of the higher-melting isomer.

Aromatization of 9-Mesitoyl-10-methyl-9,10-dihydrophenanthrene.—A solution of 0.24 g. of bromine in 10 ml. of carbon tetrachloride was added to 0.50 g. of 9-mesitoyl-10-methyl-9,10-dihydrophenanthrene dissolved in 25 ml. of carbon tetrachloride. The evolution of hydrogen bromide continued over a period of 5 hr. The reaction mixture was washed with sodium bisulfite and with water, and the solvent was removed. Chromatography of the pale yellow oil yielded a substance, m.p. 111–112°, which crystallized from ethanol. The combustion analysis agrees with that calculated for 9-mesitoyl-10-methylphenanthrene.

Anal. Calcd. for $C_{25}H_{22}O$: C, 88.72; H, 6.55. Found: C, 88.33; H, 6.64.

The infrared analysis of this compound is consistent with this structure. A conjugated carbonyl group (1658 cm.$^{-1}$), the mesityl nucleus (854 cm.$^{-1}$) and characteristic aromatic peaks (757, 726 cm.$^{-1}$) are found in the spectrum.

Aromatization of 9-Mesitoyl-10-phenyl-9,10-dihydrophenanthrene.—A solution of 3.0 g. of 9-mesitoyl-10-phenyl-9,10-dihydrophenanthrene in 60 ml. of carbon tetrachloride was treated with 1.19 g. of bromine. The solution was heated gently until the evolution of hydrogen bromide was complete. Removal of the solvent left a dark oil, which was triturated with ethanol. Crystals separated from the cooled solution in the form of hexagonal plates, m.p. 160–161°, yield 1.7 g. This compound proved to be 9-mesitoyl-10-phenylphenanthrene.

Anal. Calcd. for $C_{30}H_{24}O$: C, 89.96; H, 6.04. Found: C, 89.67; H, 6.13.

The infrared spectrum of this compound contains peaks characteristic of a conjugated carbonyl group (1660 cm.$^{-1}$), the mesitylene radical (850 cm.$^{-1}$), *o*-disubstituted (725 cm.$^{-1}$) and monosubstituted benzene (699, 761 cm.$^{-1}$).

The ethanol filtrate yielded an oil which was subjected to chromatography. A hydrocarbon was isolated from the cyclohexane eluent. An aqueous acetic acid solution of this substance deposited a white crystalline material in the form of rosettes, m.p. 104–105°, yield 0.5 g. Its picrate melts at 113–114°. Koelsch[5] reports a melting point of 105–106° for 9-phenylphenanthrene and a melting point of 115° for its picrate.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.45; H, 5.55. Found: C, 94.51; H, 5.53.

The infrared spectrum is consistent with a hydrocarbon structure. The only significant peaks of absorption which occur indicate monosubstituted benzene (700 cm.$^{-1}$) and aromatic vibrations (745, 725 cm.$^{-1}$). The ultraviolet spectrum exhibits a maximum at 254 mμ (log ϵ 4.95) which is characteristic of the phenanthrene nucleus.

Alkylation of Benzene with Polyhalides in the Presence of Saturated Hydrocarbons and Aluminum Chloride[1]

BY LOUIS SCHMERLING, ROBERT W. WELCH AND J. P. LUVISI

RECEIVED NOVEMBER 3, 1956

The aluminum chloride catalyzed condensation of a 1,1-dihaloalkane with benzene results in the formation of a primary alkylbenzene when the reaction is carried out in the presence of a hydrogen donor, namely a saturated hydrocarbon containing a tertiary carbon atom. Thus, for example, *n*-butylbenzene and (x-methylcyclohexyl)-benzene are produced in good yield by the reaction of benzene with 1,1-dichlorobutane in the presence of methylcyclohexane. Large amounts of hydrogen transfer products are also obtained with 2,3-dibromobutane and with 1,2-dichloro-2-methylpropane but not with 1,2-dichlorobutane. The mechanisms of these reactions and of the isomerization of tertiary alkylbenzenes is discussed.

In previous papers it was shown that excellent yields of primary monoalkylbenzenes (for example, isobutylbenzene[2] and 1-phenyl-3,3-dimethylbutane)[3] are obtained by the aluminum chloride catalyzed reaction of benzene with dichloroalkanes (1,2-dichloro-2-methylpropane and 1,1-dichloro-3,3-dimethylbutane, respectively) in the presence of a saturated hydrocarbon containing a tertiary carbon atom. The present paper describes the results of an investigation of the scope of this hydrogen transfer reaction, various polyhalides and saturated hydrocarbons being studied.

1,1-Dichloroethane.—The chief product obtained by the reaction of 1,1-dichloroethane with excess benzene in the presence of aluminum chloride at 3–4° was 1,1-diphenylethane (33% yield). Ethylbenzene was obtained in no more than 2% yield.[4] When the experiment was repeated, but with the addition of methylcyclopentane, practically no diphenylethane was produced. Instead, the chief reaction products were ethylbenzene and (methylcyclopentyl)-benzene isolated in approximately equal yields (42 and 38%, respectively) in accordance with the equation

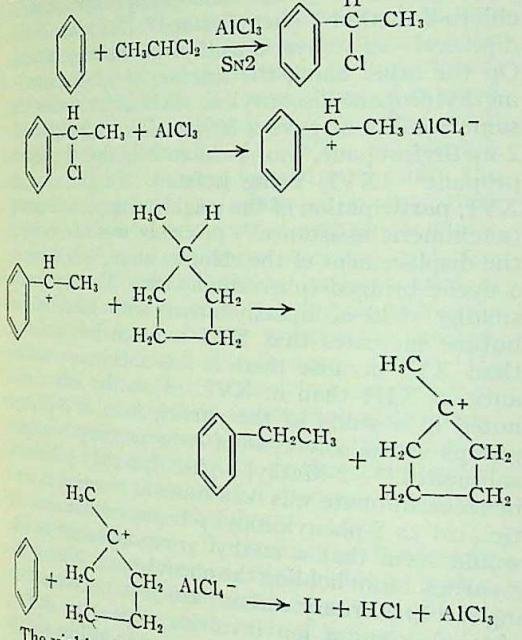
Infrared analysis showed that II contained little, if any, of the tertiary cycloalkylbenzene, (1-methylcyclopentyl)-benzene, further evidence that alkylation and cycloalkylation in the presence of aluminum chloride tends to yield secondary, rather than tertiary, alkyl and cycloalkylbenzenes.[5]

The reaction mechanism apparently involves the intermediate formation of the carbonium ion corresponding to (1-chloroethyl)-benzene, followed by the abstraction of the hydride ion attached to the tertiary carbon atom of methylcyclopentane to form ethylbenzene and the tertiary methylcyclopentyl cation, which reacts with benzene to yield II as final product.

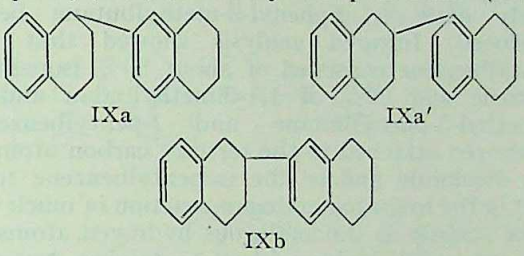


The yields of ethylbenzene and II were increased to about 60% each by carrying out the reaction at higher temperatures, 39–41°.

Use of a smaller ratio of benzene to dichloroethane (2:1 instead of 5.2:1) and of hydrogen donor (methylcyclohexane) to dichloroethane (1.6:1 instead of 4:1) resulted in the further reaction of the primary products with the formation of disubstituted benzenes. Besides ethylbenzene (42%) and methylcyclohexylbenzene (III, 31%), there was obtained diethylbenzene (9%) and (x-methylcyclohexyl)-ethylbenzene (IV, 9%).

Decahydronaphthalene was a more active hydrogen donor than methylcyclopentane. When it was used at 2–4°, phenyldecahydronaphthalene (V, chiefly the 2-phenyl isomer) was obtained in 70% yield. Ethylbenzene and a small amount (0.5%) of bis-(decahydronaphthyl)-benzene (VI) also were isolated.

1,2,3,4-Tetrahydronaphthalene served as both the aromatic hydrocarbon and the hydrogen donor when treated with 1,1-dichloroethane and aluminum chloride at 26–96°. "Self-alkylation" of the tetrahydronaphthalene occurred; tetrahydronaphthyltetrahydronaphthalene (IX) and ethyltetrahydronaphthalene (VII) were obtained in 40–45% yield. Dehydrogenation of a lower boiling fraction of IX gave 1,2′-binaphthyl, indicating that it was either or both 6-(1,2,3,4-tetrahydro-1-naphthyl)- and 5-(1,2,3,4-tetrahydro-2-naphthyl)-1,2,3,4-tetrahydronaphthalene (IXa and IXa′). The fact that alkylation of 1,2,3,4-tetrahydronaphthalene with alkyl chlorides in the presence of aluminum chloride gives 6-alkyl derivatives exclusively[6] indicates that the compound was IXa. Dehydrogenation of the higher boiling fraction, which was present in somewhat larger amount, to 2,2′-binaphthyl showed that it was 6-(1,2,3,4-tetrahydro-2-naphthyl)-1,2,3,4-tetrahydronaphthalene (IXb).



Schroeter[7] obtained a 0.5–1.0% yield of a crystalline compound (m.p. 53–54°), to which he assigned the structure IXb, by the action of 1–2% aluminum chloride on tetrahydronaphthalene at 50–70° for 6–10 hr. Attempts to crystallize the product of the present investigation were unsuccessful.

A crystalline by-product (VIII, m.p. 71–72°) of lower boiling point than IX was isolated in 0.5% yield. Analysis and dehydrogenation indicated that it was an octahydroanthracene. Schroeter[7] found that 1,2,3,4,5,6,7,8-octahydroanthracene is a major product (obtained in about 2% yield) of the action of aluminum chloride on tetrahydronaphthalene. It is apparently formed *via* ring opening of the tetrahydronaphthalene to produce 4-phenylbutyl cation which condenses with tetrahydronaphthalene forming 6-(4-phenylbutyl)-1,2,3,4-tetrahydronaphthalene which undergoes dephenylation to 4-(1,2,3,4-tetrahydro-2-naphthyl)-butyl cation, ring closure of which yields *sym*-octahydroanthracene.[8]

1,1-Dibromoethane.—When 2,3-dimethylbutane was used as hydrogen transfer agent for the alkylation of benzene with 1,1-dibromoethane, the hexylbenzene, which was isolated in 21% yield together with a 34% yield of ethylbenzene, consisted chiefly of 3-phenyl-2,2-dimethylbutane, the isomer which is also the chief product of the alkylation of benzene with either 2-chloro-2,3-dimethylbutane or 1-chloro-3,3-dimethylbutane.[5]

Dichloromethane.—Bicyclohexyl produced an 18% yield of a mixture of 3- and 4-phenylbicyclohexyl (Xa and Xb, respectively) when present in a reacting mixture of methylene chloride and benzene in the presence of aluminum chloride. Toluene was obtained in 15% yield.

1,1-Dichlorobutane.—The behavior of 1,1-dichlorobutane was similar to that of 1,1-dichloroethane. In the absence of hydrogen donor, 1,1-diphenylbutane (36%) was the principal product; butylbenzene was obtained in no more than 3%

yield. In the presence of methylcyclohexane, *n*-butylbenzene and (methylcyclohexyl)-benzene were obtained in about 63–64% yield. On the other hand, the presence of cyclohexane had no effect on the reaction; the yields of products were identical to those obtained in the absence of donor. It is obvious that cyclohexane which does not contain a tertiary carbon atom was not a hydrogen donor under the reaction conditions (2–4°).

1,1-Dichloro-3-methylbutane.—Hydrogen transfer occurred with 1,1-dichloro-3-methylbutane, even in the absence of a saturated hydrocarbon; the product consisted of pentylbenzenes (27%), relatively little 1,1-diphenyl-3-methylbutane being produced. Infrared analysis showed that the pentylbenzene consisted of about 80% isopentylbenzene and 20% of 1,1-dimethylindan and/or 2-methyl-3-phenylbutane and *t*-pentylbenzene. Hydrogen attached to the tertiary carbon atom in the dichloride and/or the isopentylbenzene took part in the hydrogen exchange reaction in much the same manner as the analogous hydrogen atoms in the saturated hydrocarbons containing tertiary carbon atoms, yielding intermediates which reacted to yield the pentylbenzene isomers and/or the dimethylindan. It was not possible to distinguish between these hydrocarbons by means of infrared. The nature of the reaction, however, makes it seem most plausible that the by-product was the indan formed by ring closure at the tertiary carbon atom of isopentylbenzene. The dichloride which lost the hydride ion attached to the tertiary carbon atom was presumably converted to unsaturated product, making up the so-called "lower layer" catalyst complex, and to high boiling by-product.

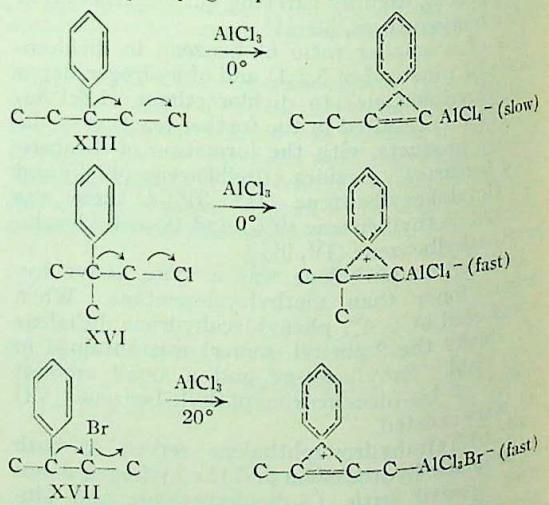
In the presence of methylcyclohexane, a higher yield (49%) of pentylbenzene (approximately 85–90% isopentylbenzene and 10–15% of other pentylbenzenes or dimethylindan) was obtained together with a 42% yield of (methylcyclohexyl)-benzene (III).

(2,2-Dibromoethyl)-cyclohexane.—Further evidence that the presence of a tertiary carbon atom in a dihalide results in comparatively high yields of monoalkylbenzene even in the absence of a saturated hydrocarbon was obtained by carrying out the reaction of 2,2-dibromoethyl)-cyclohexane with benzene in the presence of aluminum chloride. When no saturated hydrocarbon was used as a donor, 1-cyclohexyl-2-phenylethane (XII) was obtained in 37% yield. When isopentane was used, the yield of XII was 40%; there was a relatively low yield (12%) of pentylbenzene (85–90% 2-methyl-3-phenylbutane and 10–15% *t*-pentylbenzene) indicating that the hydrogen atom attached to the tertiary carbon atom in the dibromoethylcyclohexane is more readily abstracted than is that in isopentane.

1,2-Dichlorobutane.—The dihalides in the above-described experiments were those in which both halogen atoms are attached to the same carbon atom. Some dihalides in which the halogens are on adjacent carbon atoms were also tested: 1,2-dichlorobutane and 2,3-dibromobutane.

The reaction of 1,2-dichlorobutane with benzene in the presence of aluminum chloride at 4–6° resulted in a 37% yield of 1-chloro-2-phenylbutane[9] (XIII) and only 8% of diphenylbutane consisting of about 85% 1,2-diphenylbutane (XIV) and 15% of crystalline *meso*-2,3-diphenylbutane; formation of the crystalline isomer presumably involved rearrangement of XIII or XIV.

Formation of only 8% of the diphenylbutane was due apparently to the comparative inactivity of the chlorine atom attached to the primary carbon atom under the reaction conditions. This is somewhat analogous to the previously described[2] observation that the reaction of 1,3-dichloro-3-methylbutane with benzene in the presence of aluminum chloride at 2–4° produces as high a yield (28–29%) of the monophenyl compound 1-chloro-3-methyl-3-phenylbutane[10] (XV) as of the diphenyl derivative 2-methyl-2,3-diphenylbutane. On the other hand, the reaction of 1,2-dichloro-2-methylpropane (isobutylene dichloride) under the same conditions gave a 50% yield of 1,2-diphenyl-2-methylpropane, no 1-chloro-2-methyl-2-phenylpropane[11] (XVI) being isolated. In the case of XVI, participation of the neighboring phenyl group (anchimeric assistance[12]) probably was involved in the displacement of the chlorine atom,[2] resulting in a cyclic bridged (phenonium) ion. The markedly smaller yield of diphenylbutane with 1,2-dichlorobutane indicates that XIII is much less reactive than XVI because there is less anchimeric assistance in XIII than in XVI. A similar effect was noted in a study of the participation of β-phenyl groups in the solvolysis of some primary benzenesulfonates.[12] 2-Methyl-2-phenylpropyl *p*-bromobenzenesulfonate was 6.25 times as reactive in acetic acid as 2-phenylpropyl *p*-benzenesulfonate. It would seem that a methyl group attached to the β-carbon atom holding the phenyl group (thus making it a quaternary carbon) assists in the formation of a phenonium ion involving a primary carbon atom more than does hydrogen. As will be shown below, a β-phenyl group attached to a carbon atom



(9) Also named [1-(chloromethyl)-propyl]-benzene (*C. A.*).
(10) Also named (3-chloro-1,1-dimethylpropyl)-benzene (*C. A.*).

holding hydrogen does seem to participate in the reaction when the halogen is on a secondary carbon atom as in 2-bromo-3-phenylbutane.

The effect of saturated hydrocarbons on the reactions of these dihalides may be explained similarly. When the reaction of 1,2-dichlorobutane with benzene was carried out in the presence of methylcyclohexane, the hydrogen transfer reaction occurred to a relatively small extent, yielding 7% each of *sec*-butylbenzene and the cycloalkylbenzene (III). Diphenylbutane (about 93% 1,2- and 7% 2,3-isomer) and the chlorobutylbenzene XIII were obtained in approximately the same yields (7 and 50%, respectively) as in the absence of the saturated hydrocarbon. Formation of the phenonium ion from XIII was slow. The reaction was similar to that of 1,3-dichloro-3-methylbutane with benzene and methylcyclopentane or isobutane[2]; the chloropentylbenzene XV was obtained in good yields (44 and 33%, respectively) together with methylcyclopentylbenzene (II, 38%) or *t*-butylbenzene (48%) which were formed in part by the hydrogen transfer of the saturated hydrocarbon with the dihalide *before* it reacted with the benzene. On the other hand, hydrogen transfer with the intermediate chlorobutylbenzene (or ionic analog) was the chief reaction when isobutylene dichloride reacted with benzene in the presence of methylcyclohexane, yielding isobutylbenzene (57%), III (70%) and 1-(methylcyclohexyl)-4-isobutyl-benzene (14%).[2] Anchimeric assistance by the phenyl group occurred readily only with the latter chloride, there being little participation by the phenyl group in the chloropentylbenzene XV because it and the chlorine atom are not "neighbors."

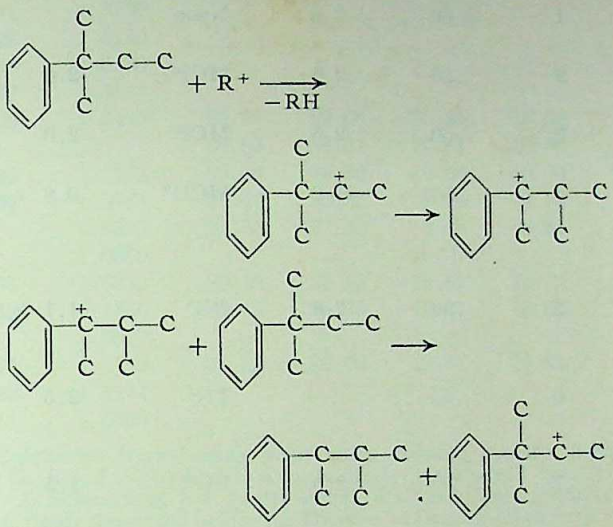
2,3-Dibromobutane.—In contrast to the results with the 1,2-dichlorobutane, high yields of hydrogen transfer product were obtained with a dihalide in which the halogen atoms were attached to adjacent secondary carbon atoms, namely 2,3-dibromobutane. In the presence of methylcyclopentane at room temperature, butylbenzene (95–96% *sec*-butylbenzene and 4–5% isobutylbenzene) and methylcyclopentylbenzene II were obtained in 68 and in 60% yield, respectively. In the absence of a saturated hydrocarbon, the chief product was *meso*-2,3-diphenylbutane (50%) together with a small amount of butylbenzene (6%).

The reaction may have involved the intermediate formation of 2-bromo-3-phenylbutane (XVII, not isolated) which under the influence of aluminum chloride and the neighboring group was converted to the cyclic bridged ion, reaction of which with benzene yielded diphenylbutane and with methylcyclopentane yielded *sec*-butylbenzene and methylcyclopentylbenzene II. The phenonium ion which is formed has been discussed in detail by Cram.[13] The small amount of isobutylbenzene which was formed can be explained by assuming a bridged ion involving the methyl group instead of the phenyl group.

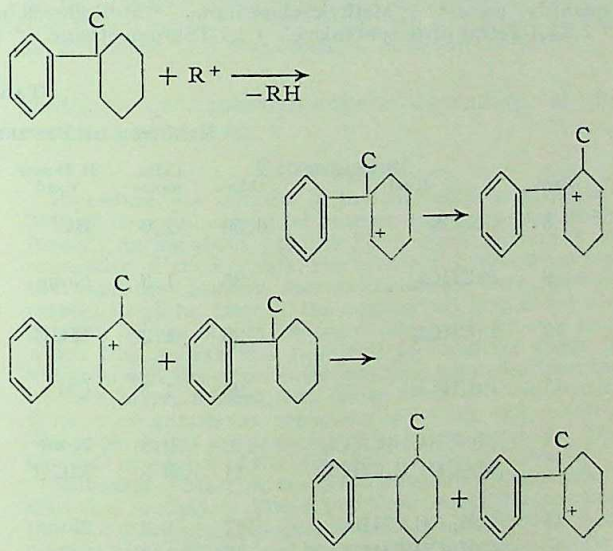
Anchimeric assistance also explains the fact that secondary, rather than tertiary, alkylbenzenes are produced in the presence of aluminum chloride.[5]

(13) D. J. Cram, THIS JOURNAL, **71**, 3863 (1949); **74**, 2129, 2137, 2139 (1952); and **75**, 332 (1953).

It has been postulated[5] that the primary product is a tertiary alkylbenzene which is isomerized to the secondary alkylbenzene by way of a chain reaction involving the formation of a resonance stabilized benzyl cation



Similarly



An objection to this type of mechanism is that hydrogen atoms attached to secondary carbon atoms are not abstracted readily under the reaction conditions. For example, cyclohexane is not a hydrogen donor in the reaction of benzene with 1,1-dichlorobutane (expt. 11). However, the objection is plausibly overcome by postulating that the neighboring phenyl group participates in the displacement of the hydride ion.

When the phenonium ion abstracts a hydride ion from the tertiary alkyl- or cycloalkylbenzene, the reaction occurs at the tertiary carbon atom of the bridged ion, yielding secondary alkyl- or cycloalkylbenzene as the final product.

1,1,2-Trichloroethane.—Good yields (58–60% each) of bibenzyl and methylcyclohexylbenzene III were obtained by the reaction of 1,1,2-trichloroethane and benzene in the presence of methylcyclohexane and aluminum chloride at 33–53°. Bimolecular nucleophilic displacement of a chlorine on each carbon atom by benzene with the resultant formation of α-chlorobibenzyl occurred, followed by hydrogen-chlorine exchange involving the active benzylic chlorine atom. Alternatively, (2-chloroethyl)-benzene may have been formed first.

Bibenzyl was also a major product of the reaction in the absence of a saturated hydrocarbon.[14] Other products included diphenylmethane and anthracene. Hydrogen transfer reactions involving intermediate products, *e.g.*, 9,10-dihydroanthracene, apparently occurred.

Carbon Tetrachloride.—Hydrogen transfer occurred when carbon tetrachloride was contacted with benzene and isopentane in the presence of aluminum chloride at room temperature. Diphenylmethane was obtained in 24% yield and pentylbenzene (65–70% 2-methyl-3-phenylbutane and 30–35% *t*-pentylbenzene) in 30% yield, based on the theoretical yield of 2 moles of pentylbenzene per mole of carbon tetrachloride.

$$CCl_4 + 4C_6H_6 + 2C_5H_{12} \longrightarrow CH_2(C_6H_5)_2 + 2C_6H_5C_5H_{11} + 4HCl$$

In the absence of saturated hydrocarbon, the principal product of the reaction of carbon tetrachloride with benzene is either triphenylchloromethane or triphenylmethane depending on the reaction conditions.[15]

Experimental

Procedure.—A solution of the polyhalide in about 20–35% of the total amount of benzene used was added slowly (usually during about 1 to 2 hr.) to a stirred mixture of the remainder of the benzene, the saturated hydrocarbon and the catalyst. Stirring was continued for from approximately 1 to 3 hr. after all the mixture had been added (depending on the rate of hydrogen chloride evolution), after which the product was permitted to stand for about 10 minutes, and the upper layer was then separated from the catalyst layer, washed with dilute alkali and with water, dried over anhydrous potassium carbonate and distilled. The experiments are summarized in Tables I and II. The physical properties of the products are given in Table III.

Materials.—Most of the polyhalides were commercially available products. The 1,1-dichloro-3-methylbutane and the (2,2-dibromoethyl)-cyclohexane were prepared by condensing vinyl chloride and bromide with isopropyl chloride[16] and cyclohexyl bromide,[17] respectively.

Identification of Products.—The well-known alkylbenzenes were identified by their physical properties and by comparison of their infrared spectra with those of the authentic compounds. These included toluene, ethylbenzene, diethylbenzene, *n*- and *sec*-butylbenzene, isopentylbenzene, *t*-pentylbenzene, 2-methyl-3-phenylbutane and 2,2-dimethyl-3-phenylbutane.[5] Diphenylmethane was similarly identified. Bibenzyl (m.p. 52–53°) and 2,3-diphenylbutane (m.p. 123–125°) were characterized by melting point and by "mixed melting point" with authentic samples.

The infrared spectra of the methylcycloalkylbenzenes II and III indicated that the tertiary compounds 1-methyl-1-phenylcyclopentane and 1-methyl-1-phenylcyclohexane were not present. It is probable that II was (3-methylcyclopentyl)-benzene mixed with a smaller amount of (2-methylcyclopentyl)-benzene. Similarly, III was presumably a mixture of (3-methylcyclohexyl)- and (4-methylcyclohexyl)-benzene. It was identical to the product of the alkylation of benzene with 1-chloro-1-methylcyclohexane or with 3- or 4-

methylcyclohexanol in the presence of aluminum chloride.[18]

The structures of several of the remaining polynuclear compounds were determined by dehydrogenation to known crystalline aromatic hydrocarbons using a platinum–alumina catalyst at 250–350°.

The **phenyldecahydronaphthalene V** yielded product, m.p. 92–95°, which on recrystallization from alcohol melted at 100–101°. 2-Phenylnaphthalene is reported to melt at 100–102°, 1-phenylnaphthalene at 84–86°.[19] Attempts to isolate product melting at about 85° by fractional crystallization were unsuccessful. Hence, V was apparently principally 2-phenyldecahydronaphthalene.

Compound VIII yielded yellow needles melting at 205–207° which did not depress the melting point of anthracene. Since analysis indicated that the formula of VIII was $C_{14}H_{18}$, it may be concluded that it was an octahydroanthracene.

The lower boiling **tetrahydronaphthyltetrahydronaphthalene (IXa)** gave yellow crystals, m.p. 73–74°. The higher boiling material (IXb) yielded product of m.p. 180–181°. The approximate melting points reported in the literature[20] for the binaphthyls are: 1,1′-, 156°; 1,2′-, 76°; and 2,2′-, 187°. Fractional crystallization of the products failed to yield any material melting near 156°. It may be concluded that IX consists of 6-(1,2,3,4-tetrahydro-2-naphthyl)-1,2,3,4-tetrahydronaphthalene and either or both 6-(1,2,3,4-tetrahydro-1-naphthyl)- and 5-(1,2,3,4-tetrahydro-2-naphthyl)-1,2,3,4-tetrahydronaphthalene. While the relative amounts of these isomers were not determined, it appeared from the fractionation data that the 6-(1,2,3,4-tetrahydro-2-naphthyl)- isomer was present in largest amount.

The phenylbicyclohexyl (Xa) liquid fraction yielded a crystalline product which on fractional crystallization gave 2 parts of white flakes, m.p. 205–206°, and 8 parts of white needles, m.p. 83–85°. Dehydrogenation of the crystalline phenylbicyclohexyl Xb yielded product, m.p. 204–205°. The literature[21] values for the melting points of 1,2-, 1,3- and 1,4-diphenylbenzene are, respectively, 55–58°, 84–89° and 205–214°. Hence, X was a mixture of 3- and 4-phenylbicyclohexyl, the latter being a crystalline compound, Xb.

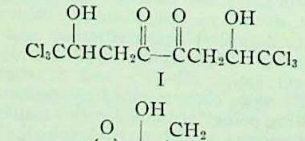
The Structure of Chloretyl, the Product of the Reaction between Chloral and Biacetyl

BY NELSON J. LEONARD, JOHN C. LITTLE[1] AND A. JERRY KRESGE[2]

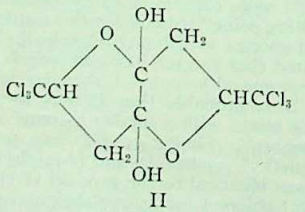
RECEIVED DECEMBER 12, 1956

Spectral and chemical evidence has been presented to establish the structure of chloretyl, the product of the reaction between chloral and biacetyl, as 3,7-di-(trichloromethyl)-2,6-dioxabicyclo[3.3.0]octane-1,5-diol (II). The stereochemical structures of the α- and β-isomers of chloretyl (racemates) have been tentatively assigned as *cis–cis–cis* (VI) and *cis–cis–trans* (VII).

In 1952, a product of molecular formula $C_8H_8Cl_6O_4$ was obtained by Schlenk[3] from the reaction of chloral with biacetyl, in 2:1 molar proportion, in the presence of piperidinium acetate. The structure of the colorless solid, m.p. 199–201° dec., was not established, and the suggested formulations of the compound as a diketone dihydrate or a monohydrate of a hydroxyketone were not fully satisfactory. The property of the compound that was difficult to accommodate in postulated structures was the absence of absorption in the ultraviolet and visible regions. We reasoned that if the initial reaction product were conceived as normal (I), simple conversion to a bis-hemiketal would provide a structural expression II, 3,7-di-(trichloromethyl) - 2,6 - dioxabicyclo[3.3.0]octane - 1,5 - diol, which would satisfy the data presented by Schlenk for the $C_8H_8Cl_6O_4$ compound. Our postulate has been confirmed by infrared absorption and nuclear magnetic resonance studies and by additional chemical evidence. Moreover, we are in a position to consider the stereochemistry of the predominant product and its isomers.



I



II

We used conditions for the reaction between chloral and biacetyl similar to those of Schlenk. However, we were able to isolate two isomeric compounds, $C_8H_8Cl_6O_4$: an α-isomer capable of existing in readily interconvertible dimorphic forms, m.p. *ca.* 206° dec. and *ca.* 175° dec., and a β-isomer, m.p. 175–177°, in lower yield. As a convenience, we wish to use the name "chloretyl" (klôrĕtĕl) for these products, or specifically, "α-chloretyl" and "β-chloretyl."

The infrared absorption spectra of the dimorphic forms of α-chloretyl were virtually identical as Nujol mulls and identical as 1% solutions in benzene. The spectrum of the β-isomer was similar but not identical to the α-chloretyl spectrum. The spectra of both isomers confirmed the absence of olefinic and carbonyl unsaturation and indicated the presence of hydroxyl. The spectrum of solid α-chloretyl showed a sharp hydroxyl band at 3480 cm.$^{-1}$ and that of β-chloretyl at 3450 cm.$^{-1}$ (Nujol mull). There were also present in the 9–11 μ region absorption bands resembling those exhibited by tetrahydrofuran. The most logical structure for chloretyl, consistent with the precursors in synthesis and the ana-

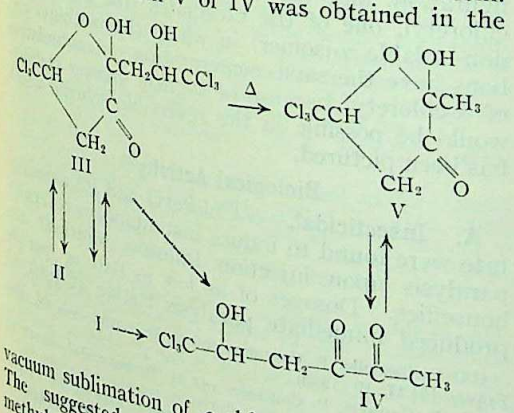
lytical and spectral data, is given by II. As further physical confirmation of this structure, the NMR spectrum, determined in dioxane solution,[4] showed clearly (Fig. 1) the ratio of 1:1:2 for the different types of hydrogen in α-chloretyl, *i.e.*, 2 hydroxyl hydrogens: 2 $CH-CCl_3$ hydrogens: 4 methylene hydrogens.

Chemical confirmation of structure II was found in the positive identification of the hemiketal hydroxyl function. Although the usual acetylation methods failed,[3] it was possible to obtain the monoacetate by prolonged heating of α-chloretyl with isopropenyl acetate in benzene solution in the presence of *p*-toluenesulfonic acid. The high frequency of the C=O stretching band (1765 cm.$^{-1}$ in the infrared spectrum of α-chloretyl monoacetate was indicative of the $-O-\overset{|}{\underset{|}{C}}-O-\overset{O}{\overset{\|}{C}}-CH_3$ system. This argument is based upon the general finding that an electronegative substituent on the α-carbon of the alcohol portion of an ester increases the carbonyl absorption frequency and the specific observation that the model compound 1,1-diacetoxypropane has a carbonyl absorption maximum at 1761 cm.$^{-1}$.[5] The mono-3,5-dinitrobenzoate of α-chloretyl also exhibited ester carbonyl absorption in this region, at 1764 cm.$^{-1}$. Attempts to combine both hemiketal hydroxyls of II in ketal formation with methanol, ethylene glycol, acetone or cyclopentanone were not successful.

The presence of an easily accessible α-diketone grouping in α-chloretyl was demonstrated in the reactions with *o*-phenylenediamine, hydroxylamine and phenylhydrazine. The quinoxaline, dioxime and osazone formed were derivatives of 6,6,6-trichlorohexan-5-ol-2,3-dione (IV). Under the usual reaction conditions chloretyl apparently reverts to the intermediate IV by losing the chloral moiety from either the acyclic I or monocyclic III form. The hemiketal form V of IV was obtained in the vacuum sublimation of α-chloretyl or β-chloretyl. The suggested structure, 2-methyl-5-trichloromethyl-1-oxacyclopentan-2-ol-3-one (V), is based mainly on analysis and spectrum. Oxidation of



chloretyl with hydrogen peroxide in acetic acid has been found to give 4,4,4-trichloro-3-hydroxybutyric acid in low yield,[3] consistent with any sequence leading to III, I or IV, followed by oxidation. The isomeric relation of α-chloretyl and β-chloretyl was shown by the production of the same quinoxaline (of IV) and the same monocyclic compound (V) from either precursor.

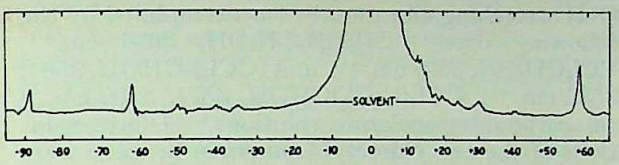


Fig. 1.—Nuclear magnetic resonance shift relative to reference (parts per million): $(H - H_r/H_r)$; frequency 30 mc.; zero of reference, dioxane.

In considering the possible stereochemical structural assignments of α- and β-chloretyl, if it is recognized that in the synthetic procedure an energetically favorable ring closure completes the formation of the bicyclic system (*e.g.*, I or III → II), it follows that forms of II having a *trans* ring juncture can be excluded on the basis of analogy with the greater stability of *cis*-bicyclo[3.3.0]octane over the *trans* isomer.[6,7] Among the possible representations of chloretyl having a *cis* ring juncture (VI, VII, VIII; one form used to designate each racemate), the *trans*–*cis*–*trans* structure VIII is the least favored, since it is the only one in which the trichloromethyl groups are in steric apposition. Moreover,

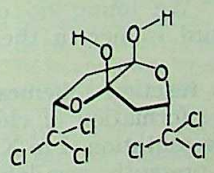
VII
CIS-CIS-TRANS



VIII
TRANS-CIS-TRANS

the infrared O–H stretching frequency exhibited by a structure like VIII should be in the normal free hydroxyl range, whereas both isomers of chloretyl which have been isolated had infrared hydroxyl bands at lower than normal frequency, suggestive of the proximity of chlorine to hydroxyl hydrogen,

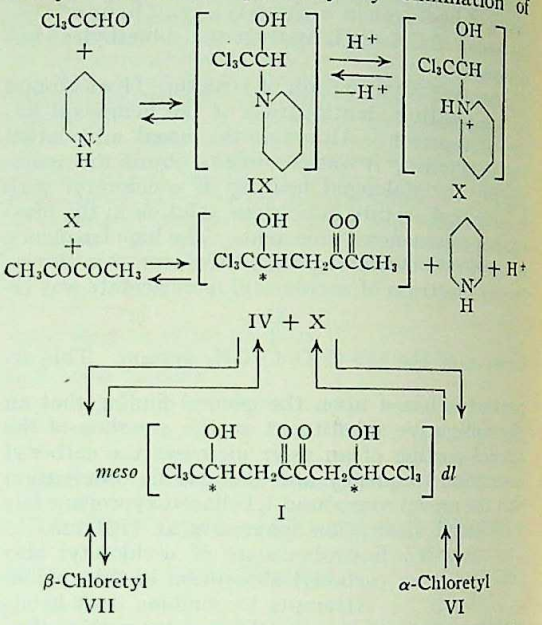
as in the examples of the chloroalcohols[8-10] and chlorophenols.[11,12]

On the basis of the foregoing arguments, the remaining problem lies in the assignment of the proper geometrically-isomeric structures, VI and VII, to α- and β-chloretyl. In our tentative assignment, reliance has been placed again upon the infrared spectral effect of an adjacent chlorine atom, which is to lower the frequency of the free hydroxyl O–H stretching vibration,[10,12] as exemplified by the following series: $CH_3CH_2CH_2OH$, 3636 cm.$^{-1}$; CCl_3CH_2OH, 3597 cm.$^{-1}$; and $(CCl_3)_2CHOH$, 3584, 3534 cm.$^{-1}$; $CCl_3(C_2Cl_5)CHOH$, 3571, 3509 cm.$^{-1}$ (in carbon tetrachloride solution).[8] Dilute solutions of the two chloretyl isomers in benzene were examined in the 3 μ region, and maxima were observed at 3550 cm.$^{-1}$ for β-chloretyl and 3510 cm.$^{-1}$ for α-chloretyl. No splitting of either band was observed. The difference is considered real and suggests that in α-chloretyl the equivalent hydroxyls are in a more electronegative environment than they are in β-chloretyl. This situation would be satisfied if α-chloretyl were assigned the *cis–cis–cis* structure (VI), with effectively two chlorines adjacent to the hydroxyls, and β-chloretyl, the *cis–cis–trans* structure (VII), with one chlorine exerting attraction for the hydroxylic hydrogens. Consistent with the infrared findings is the qualitative observation that α-chloretyl appears to be the thermodynamically more stable isomer. Thus, reactions of chloral with biacetyl which were allowed to run for 36 hr. gave approximately equal quantities, although in low yield, of α- and β-chloretyl, while reactions which were allowed to proceed to near completion (11 days) produced the α-isomer almost exclusively, in yields approaching 80%. These rough observations suggest that a rate *vs.* equilibrium process is occurring, in which the α- and β-isomers are formed randomly at first and a conversion of β- to α-chloretyl takes place subsequently and more slowly. Since a reversible process exists whereby the γ-isomer VIII could revert to VI, it is logical that VIII would not survive even if it were formed initially. We found no evidence of the presence of a third isomer in the crude reaction products.

Of the several reaction schemes which can be postulated for the formation of chloretyl, the formula diagram representation (I to X) accounts satisfactorily for the presently available facts. The intermediate IX is similar to the benzylidene-bis-piperidine intermediate proposed in condensations involving benzaldehyde and a piperidine catalyst.[13] The equilibrium between the hydroxyamine IX and the corresponding bis-amine probably lies predominantly on the side of the hydroxyamine because of the great stability of the hydroxyl group in this system, as in chloral hydrate, chloral hemiacetals and other examples.[14-20] The reaction of chloral with piperidine (or morpholine) at about 50° is vigorous and leads to the formation of the N-formyl derivative,[21] probably by elimination of



chloroform from IX. This possible side reaction in the chloretyl preparation was repressed by chilling the reaction mixture prior to the addition of piperidine. Participation of the protonated intermediate X in the aldol condensation with biacetyl is envisaged with the loss of piperidine and the formation of IV. The key step in the reaction sequence then becomes the condensation of IV with a second chloral intermediate to form either *dl*- or *meso*-I. The *meso* form is a precursor of β-chloretyl, the racemate in which the methinyl carbons are of opposite configuration, and the *dl* form is a precursor of α-chloretyl, one of the racemates (the other is the non-isolable γ-isomer) in which the methinyl carbons have the same configuration. Accumulation of α-chloretyl because of slightly greater stability would be possible in the reversible scheme which has been pictured.

Biological Activity[22]

A. Insecticidal.—α-Chloretyl and its monoacetate were found to induce instantaneous reversible paralysis upon injection (dioxane solution) into houseflies. Dosages of as low as 0.01 μg. per fly produced immediate paralysis lasting at least 45

May 20, 1957

minutes. By contrast, α-chloretyl mono-3,5-dinitrobenzoate and β-chloretyl were inactive.

B. Pharmacological. Anticonvulsant.—α-Chloretyl showed 40% protection at 400 mg./kg. by the Electroshock method and 25% protection by the Metrazol method (same dosage) upon oral administration to rats. **Hypnotic.**—Oral administration of from 400 to 900 mg./kg. to rats produced no hypnosis.

Experimental[23]

Condensation of Chloral with Biacetyl.[24]—To a chilled solution of 20.0 g. (0.233 mole) of biacetyl, 70 g. (0.48 mole) of chloral and 9.0 g. (0.15 mole) of glacial acetic acid in 70 ml. of anhydrous benzene, 8.4 g. (0.10 mole) of piperidine was added dropwise. The system was swept with nitrogen and stirred at 25° for 10 days. The precipitate was collected by filtration and washed with hexane. The crude chloretyl (37.2 g.) was dissolved in 120 ml. of warm dioxane, and the solution was diluted with water. The mixture was chilled with vigorous shaking until the chloretyl crystallized. The solid was broken into fine particles, and the mixture was filtered. After washing with cold 50% aqueous methanol and drying, the **α-chloretyl** weighed 36.5 g. (41%), m.p. *ca.* 203° dec. An analytical sample was prepared by recrystallization from benzene–hexane as colorless needles, m.p. *ca.* 206° dec. from a hot or acidic (with a trace of acetic acid) solution or m.p. *ca.* 175° dec. from a cool basic (a trace of pyridine) solution.

Anal. Calcd. for $C_5H_8Cl_6O_4$: C, 25.23; H, 2.12. Found: C, 25.24; H, 2.14.

The infrared absorption spectrum showed maxima (Nujol mull) at 3480 (OH); 1292, 1149, 1095, 1080, 1048, 1013; 814, 790 cm.$^{-1}$ (CCl_3); (1% solution in benzene) at 3510 (OH); 1392, 1294, 1250, 1135, 1106, 950, 910, 836; 812, 801 cm.$^{-1}$ (CCl_3). The compound in cyclohexane solution was transparent in the ultraviolet region, 215–400 mμ.

The mother liquor and washings from the α-chloretyl isolation were diluted with benzene. The combined liquid was washed thoroughly with water, followed by a saturated aqueous sodium chloride solution. The organic layer was dried over anhydrous magnesium sulfate and treated with decolorizing carbon. Filtration yielded a light yellow-orange solution from which the solvent was removed in vacuum to yield an orange solid. The solid was suspended in boiling hexane, and the mixture was filtered. After washing and drying, the solid obtained (14.6 g., 17%) was found to be a mixture of approximately 90% α- and 10% β-chloretyl. The latter was separated and purified by fractional crystallization from benzene–hexane, with treatment with decolorizing carbon. An analytical sample of β-chloretyl was prepared by recrystallization from benzene–hexane as colorless needles, m.p. 175–177°, different from the isomorphic form of α-chloretyl, m.p. 175° dec.

Anal. Calcd. for $C_5H_8Cl_6O_4$: C, 25.23; H, 2.12. Found: C, 25.39; H, 2.18.

The infrared absorption spectrum showed maxima (Nujol mull) at 3450 (OH); 1288, 1264, 1192, 1173, 1142, 1130, 1110–1085, 1044, 1018, 925, 903, 864, 840; 810–790 cm.$^{-1}$ (CCl_3); (1% solution in benzene) at 3550 (OH); 1395, 1368, 1320, 1270, 1205, 1145, 935, 903, 868, 837; 809 cm.$^{-1}$ (CCl_3).

Both isomers of chloretyl were instantly soluble in cold, dilute sodium hydroxide,[25] soluble in cold methanol and ethanol, somewhat soluble in benzene and insoluble in hexane and water. Chloretyl decomposed upon prolonged heating in hydroxylic solvents but appeared to be stable in crystalline form when pure.

Quinoxaline Formation.—A mixture of 0.50 g. (1.31 mmoles) of α-chloretyl and 0.16 g. (1.48 mmoles) of *o*-phenylenediamine in 15 ml. of absolute ethanol was heated under reflux for 8 hr. and then allowed to stand overnight. Dilution with water yielded 0.39 g. (97%) of red-brown platelets, m.p. 147–148°. Sublimation or recrystallization from aqueous ethanol gave ivory platelets, m.p. 148–149°.

Anal. Calcd. for $C_{12}H_{11}Cl_3N_2O$: C, 47.16; H, 3.63; N, 9.17; Cl, 34.80. Found: C, 47.22; H, 3.61; N, 9.10; Cl, 34.72.

The analysis and infrared spectrum (including maxima at 3200, 1104 and 794–810 cm.$^{-1}$) were consistent with the formulation of this product as **2-[1′-(2′-hydroxy-3′,3′,3′-trichloropropyl)]-3-methylquinoxaline.**

β-Chloretyl was converted to the quinoxaline by heating 85 mg. (2.24 mmoles) of this isomer with 27 mg. (2.5 mmoles) of *o*-phenylenediamine in 4 ml. of absolute ethanol for 6 hr. Dilution with 4 ml. of water and cooling caused the separation of 47 mg. (69%) of ivory platelets, which were recrystallized from aqueous ethanol, m.p. 147–148°, identical by the usual criteria with the product described above.

Oxime Formation.—A mixture of 1.00 g. (2.63 mmoles) of α-chloretyl, 0.42 g. (6.0 mmoles) of hydroxylamine hydrochloride, 5 ml. of absolute ethanol and 5 ml. of pyridine was heated under reflux for 12 hr. Evaporation of solvent yielded a brown residue which upon trituration with water formed heavy granular crystals, m.p. 186–187° dec. Sublimation yielded colorless crystals, m.p. 188–189° dec.

Anal. Calcd. for $C_6H_9Cl_3N_2O_3$: C, 27.35; H, 3.44; N, 10.63. Found: C, 27.93; H, 3.57; N, 10.38.

The analysis and infrared spectrum (including maxima at 3560, 3210, 3070 and 1090 cm.$^{-1}$) were consistent with the formulation of the product as **6,6,6-trichlorohexan-5-ol-2,3-dione dioxime.**

Osazone Formation.—A mixture of 0.50 g. (1.31 mmoles) of α-chloretyl, 0.35 g. (3.24 mmoles) of phenylhydrazine and a few crystals of sodium acetate in 15 ml. of 95% ethanol was heated under reflux for 3 hr., diluted with water and allowed to stand at 5° overnight. The solid which separated was recrystallized from aqueous ethanol as small orange needles, m.p. 164–165°. The infrared absorption spectrum (Nujol mull) exhibited maxima at 3300, 1608, 1575 and 1100 cm.$^{-1}$ among others.

Anal. Calcd. for $C_{18}H_{19}Cl_3N_4O$: C, 52.25; H, 4.63; N, 13.56. Found: C, 52.26; H, 4.59; N, 13.30.

On the basis of analysis and infrared spectrum, this product can be assigned the structure **6,6,6-trichlorohexan-5-ol-2,3-dione bis-phenylhydrazone.**

α-Chloretyl Monoacetate.—A mixture of 8.05 g. (21.1 mmoles) of α-chloretyl, 5.00 g. (50.0 mmoles) of isopropenyl acetate and a few crystals of *p*-toluenesulfonic acid in 50 ml. of benzene was heated under reflux for 20 hr. The solvent was removed *in vacuo*, and the residue was dissolved in 95% ethanol. The solution was treated with decolorizing carbon, filtered, and the filtrate was diluted with water. The solid α-chloretyl monoacetate was collected and dried, m.p. 91–94°, yield 6.19 g. (73%). Purification by sublimation or recrystallization from aqueous ethanol resulted in colorless crystals, m.p. 93–94°.

Anal. Calcd. for $C_{10}H_{10}Cl_6O_5$: C, 28.40; H, 2.38; Cl, 50.30; mol. wt., 422.9. Found: C, 28.55; H, 2.56; Cl, 50.88; mol. wt., 423, 444 (Rast, camphor).

The infrared absorption spectrum showed maxima (Nujol mull) at 3040 (OH); 1765 (C=O); 1255, 1210, 1184, 1125, 1085, 1053, 1016, 965, 935, 912, 897, 871, 840; 814, 805 cm.$^{-1}$ (CCl_3).

α-Chloretyl Mono-3,5-dinitrobenzoate.[26]—To 4 ml. of pyridine was added 0.22 g. (1.04 mmoles) of 3,5-dinitrobenzoic acid and 0.41 g. (2.16 mmoles) of *p*-toluenesulfonyl chloride. The mixture was cooled to 0°, and 0.20 g. (0.53 mmole) of α-chloretyl was added. The mixture was kept at 0° for 8 hr. and was then diluted with ice-water. The solid which separated was recrystallized from aqueous ethanol as a light tan powder, m.p. *ca.* 208° dec., yield 0.12 g. (30%). Repeated recrystallization from dioxane–ethanol–water yielded nearly colorless platelets, m.p. 215° dec.

(23) Melting points are corrected and boiling points are uncorrected. We are indebted to Mrs. Lucy Chang, Mrs. Ruby Ju, Mrs. R. Maria Benassi, Miss Claire Higham and Mr. Joseph Nemeth for the microanalyses and to Mrs. Louise Griffing, Mr. James Brader and Mr. Cy Portnow for determination of the infrared spectra, using a Perkin-Elmer automatic recording infrared spectrometer, model 21.

(24) All reagents were purified.

(25) Equilibration with the open form(s), I and/or III, would liberate the trichloromethylcarbinol group, which is acidic. A pK'_a value of 11.8 has been reported for trichloroethanol.[8] The cause of the solubility may also reside in a hydrolysis reaction of the trichloromethyl group, since Schlenk found chloride ion to be liberated when α-chloretyl was treated with aqueous sodium carbonate.[3]

Anal. Calcd. for $C_{15}H_{10}Cl_6N_2O_9$: C, 31.33; H, 1.75; N, 4.87; Cl, 37.00. Found: C, 31.92; H, 1.83; N, 4.68; Cl, 36.40.

The infrared spectrum showed maxima (5% in chloroform) at 1764 (C=O); 1560, 1351 (NO_2); 1274, 1161, 1130, 1082, 1020, 966; 815 cm.$^{-1}$ (CCl_3).

Decomposition of Chloretyl on Heating in Vacuum.—When either α- or β-chloretyl was sublimed at 135–140° (0.2 mm.), a small amount of unstable colorless compound, m.p. 102° dec., was obtained as the more volatile fraction. This substance was tentatively assigned the structure V, **2-methyl-5-trichloromethyl-1-oxacyclopentan-2-ol-3-one**, on the basis of analysis and infrared absorption spectrum: ν_{max}^{Nujol} 3355 (OH); 1751 (C=O); 1185, 1156, 1139, 1099, 995, 936, 911, 869; 799 cm.$^{-1}$ (CCl_3).

Anal. Calcd. for $C_6H_7Cl_3O_3$: C, 30.86; H, 3.02. Found: C, 30.89; H, 2.82.

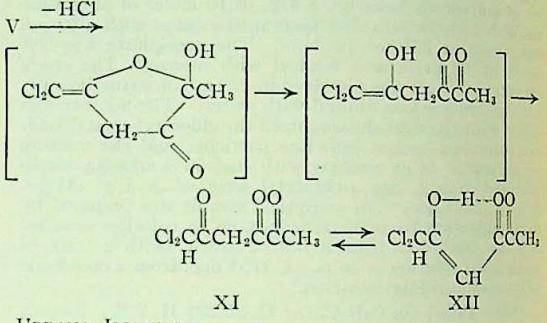
This material soon decomposed on standing at 25° to a yellow oil, with apparent loss of HCl. The infrared spectrum of the oil is consistent with the structure XI, **6,6-dichlorohexane-2,3,5-trione**, which probably exists largely as the enol XII.[27] The infrared spectrum showed maxima (5% in chloroform) at 3600–3000 (broad absorption with much fine structure, characteristic of bonded OH); 1720 (C=O); 1642 (conj. C=O); 1602 (C=C); 1423–1416, 1365, 1320, 1240–1213, 1115, 1098, 977, 840 cm.$^{-1}$.

Preparation of 2,2,2-Trichloroethyl 3,5-Dinitrobenzoate.[26]—To a cold solution of 1.42 g. (6.7 mmoles) of 3,5-dinitrobenzoic acid and 2.54 g. (13.6 mmoles) of *p*-toluenesulfonyl chloride in 20 ml. of cold dry pyridine was added 1.0 g. (6.7 mmoles) of 2,2,2-trichloroethanol. The mixture was allowed to stand at 0° for 1.5 hr. and was poured into 300 ml. of ice-water with vigorous stirring. The resultant peach-colored solid was collected by filtration and recrystallized from 95% ethanol to yield 1.55 g. (68%) of ivory platelets, m.p. 128–131°. Treatment with decolorizing carbon and repeated recrystallization from ethanol yielded an analytical sample of white platelets, m.p. 140–141°.

Anal. Calcd. for $C_9H_5Cl_3N_2O_6$: C, 31.45; H, 1.48; N, 8.15. Found: C, 31.70; H, 1.58; N, 8.33.

The infrared spectrum (5% in chloroform) showed maxima at 1755 (C=O); 1634, 1603 (aromatic); 1554, 1351 (NO_2); 1274, 1163 (C–O); 835 cm.$^{-1}$ (non-enhanced CCl_3). It will be noted that the position of the C=O maximum is at lower frequency than that exhibited by α-chloretyl mono-3,5-dinitrobenzoate.

(27) The formation of XI may be conceived as



URBANA, ILLINOIS

COMMUNICATIONS TO THE EDITOR

THE ENZYMATIC CONVERSION OF MEVALONIC ACID TO SQUALENE

Sir:

The recent isolation and identification of mevalonic acid (DL-β,δ-dihydroxy-β-methylvaleric acid, MVA) a new precursor of cholesterol[1–3] constitute an important advance in the understanding of terpene and steroid biogenesis. In this communication, we wish to report the transformation of mevalonic acid to squalene by soluble yeast enzymes and to describe experiments bearing on the mechanism of MVA utilization. Particle-free extracts of dried baker's yeast have been prepared which catalyze the conversion of DL-2-C^{14}-MVA to a radioactive lipid, shown to be squalene by alumina chromatography and by preparation of the thiourea adduct[4] and of the crystalline hexahydrochloride.[5] No sterols are synthesized from MVA under these conditions. Dialysis and treatment with charcoal to remove cofactors render the yeast extract completely inactive. Activity is restored by addition of Mn^{++}, ATP[6] and pyridine nucleotide (Table I). The reaction proceeds anaerobically as well as in air. Experiments bearing on the mechanism of the condensation process have been carried out with 2-C^{14},5-di-T-mevalonic acid. Tritium was introduced by partial reduction of β-hydroxy-β-methylglutaric acid with $LiAlT_4$. The purified product, when combined with authentic DL-2-C^{14}-MVA and recrystallized several times as the dibenzylethylenediamine salt or chromatographed on paper, showed no change in the T:C^{14} ratio. Squalene synthesized by yeast extracts from the doubly labeled MVA contained T and C^{14} in the same ratio as the precursor (Table II). From the work of Tavormina and Gibbs,[7] it is known that C_1 of mevalonic acid is lost during the conversion to cholesterol and hence the isoprenoid chain must be formed by condensations linking C_5 of one MVA residue (or a derivative thereof) to C_2 of another. The retention of T during squalene formation clearly rules out a preliminary oxidation of mevalonic acid to β-hydroxy-β-methylglutaric acid (or a derivative). Though the unchanged T:C^{14} ratio suggests that both hydrogen atoms at C_5 (δ-carbon) of MVA are

IB	1140	3380	2.97

[a] The T and C^{14} analyses were performed with a Packard Liquid Scintillation Counter by the New England Nuclear Corporation, Boston, Massachusetts. [b] The product obtained on treatment of β-hydroxy-β-methylglutaric acid with $LiAlT_4$ in dioxane was adsorbed on Dowex-1-formate and eluted with 0.1 *N* formic acid. Authentic 2-C^{14}-MVA was added and the mixture crystallized several times as the dibenzylethylenediamine salt.[1] This, after removal of the amine, was chromatographed on paper in an ethanol–ammonia system. Strips were cut separately from the slower moving section (IA) and the middle portion (IB) of the radioactive peak (R_f = 0.57), the MVA eluted with water and aliquots assayed for T and C^{14}. [c] For each experiment aliquots of the 2 fractions (IA and IB) containing 120 μg. of MVA were incubated with 15 ml. of a crude yeast extract (supernatant from 25,000 × *g* centrifugation, Table I, footnote *b*) in the presence of 9 mg. DPN, Mn^{++} 10^{-3} *M*, and 30 mg. of hexose diphosphate, for 3 hr. at 30° in air. In all expts. approximately 30% of the radioactivity was recovered in the hydrocarbon fraction. [d] Isolated and analyzed as the crystalline squalene hexahydrochloride.

retained, the possibility that the R·CH_2O–group is oxidized to R·CHO cannot be ruled out because large rate differences are known to exist for the breaking of C–H and C–T bonds.[8] In any event, these results eliminate a Claisen-type condensation mechanism and raise the distinct possibility that the condensing unit is MVA itself or a derivative of the same oxidation level. The data of Table I indicate that the reduced forms of the pyridine nucleotides are the more efficient cofactors, as would be expected from the reductive nature of the over-all transformation: 6MVA + 2H → squalene + $6H_2O$ + $6CO_2$. The concurrent participation of the oxidized nucleotides nevertheless cannot be excluded at this time. The participation of Mn^{++} is of interest since Mn^{++} is known to accelerate both enzymatic[9] and non-enzymatic[10] decarboxylations. A stimulation of cholesterol synthesis from acetate by Mn^{++} previously has been reported.[11] The dependence of the process on ATP suggests that a phosphorylation step is involved in the formation of squalene from mevalonic acid. This phosphorylation probably is not associated with the activation of carboxyl groups, since no requirement for Coenzyme A could be demonstrated.

Acknowledgments.—This work was supported by grants-in-aid from the National Science Foundation, the U. S. Public Health Service and the Life Insurance Medical Research Fund. The authors are greatly indebted to Drs. P. A. Tavormina and J. M. Sprague of the Merck, Sharp and Dohme Research Laboratories for a generous gift of DL-2-C^{11}-mevalonic acid.

PREPARATION OF A SOLUBLE MAMMALIAN TYROSINASE[1]

Sir:

Mammalian tyrosinase, unlike the soluble, highly purified,[2] well characterized[3] plant product, has been reported to be firmly bound to melanized cellular particles.[4] In view of the emphasis which has been placed on the difficulty of removing this enzyme from particulate matter,[4,5] we would like to report a relatively simple technique for the preparation of a soluble, melanin-free mammalian tyrosinase.

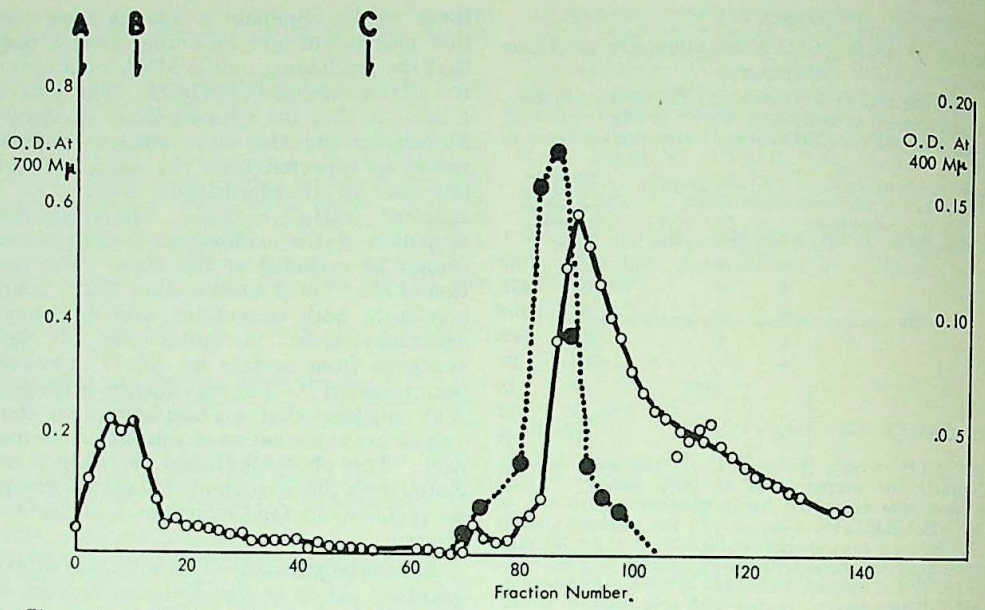

Fig. 1.—Chromatography of tyrosinase on DEAE-cellulose ion exchanger, using 3.0 g. of exchanger (capacity 0.59 meq./g.) in a column 26 × 1.2 cm. Collection after 1 hold-up volume (16 ml.), 2.1-ml. fractions. 0—0—0—0, Folin-Lowry[10] reaction with 0.1-ml. aliquots measured at 700 mμ, Coleman spectrophotometer; ●·····●·····●, tyrosinase activity of 0.1-ml. aliquots in terms of melanin produced after incubation with tyrosine in 2.7 ml., *p*H 6.8 phosphate buffer for 3 hours. O.D. measured at 400 mμ. A, 0.005 *M* phosphate buffer, *p*H 6.0, plus 0.05 *M* NaCl. B, 0.005 *M* phosphate buffer, *p*H 7.0, plus 0.05 *M* NaCl with gradient change to 0.05 *M* phosphate buffer, *p*H 8.0, through 50 ml. mixing chamber. C, Gradient change to 0.15 *M* phosphate buffer, *p*H 8.0.

Harding-Passey melanoma (415 g.) was homogenized with 2100 ml. of cold distilled H_2O in a Waring Blendor and centrifuged for one hour at 600 × *g*, and the extraction repeated. The supernatant fractions (*p*H 6.9) were combined and made 0.1 satd. with $(NH_4)_2SO_4$. An equal volume of cold acetone was added and the black precipitate was removed on a buchner funnel. These steps are critical to tyrosinase solubility which appears to depend on the ammonium sulfate salting the enzyme into the 50% acetone–water solution. Another volume of acetone was added to the clear filtrate and the precipitate was removed on a buchner, washed with acetone, and dried over P_2O_5 to yield 4.8 g. of a white powder.

The product (3.65 g.) was dissolved in 200 ml. of H_2O, the *p*H was kept at 6–7 with a few drops of 1 *N* NaOH, and was dialyzed for 24 hours against 2 liters of cold distilled H_2O. Lyophilization gave 0.96 g. of active material or 1.2% of the original dry weight of tumor. To establish the absence of cellular particles, a 1% solution of this material was subjected to centrifugation in the ultracentrifuge (Spinco model E). After 1 hour at 260,000 × *g*, the activity remained in the upper part of the cell and the fastest boundary indicated had a sedimentation constant of 3.4, although the material was not homogeneous.[6]

Tyrosinase activity was assayed manometrically against L-tyrosine plus small amounts of dopa.[4a] For the calculation of activity, the unit of Hogeboom and Adams[7] has been used but referred to the protein nitrogen content to obtain specific activity as units per mg. The original homogenate had a specific activity of 2.6 units/mg. N. The product had a specific activity of 25 units/mg. N and contained 18% of the starting activity.

Further purification was attempted by chromatography on a DEAE cellulose[8] column using differential elution.[9] The results are shown in Fig. 1.

The most highly purified fraction (S2) from the chromatogram gave a positive biuret test. The remainder of the activity peak was pooled and was shown to catalyze the oxidation of both L-dopa and L-tyrosine through some pink intermediate, presumably dopachrome, to black melanin. Heating at 100° for 30 minutes completely destroyed the activity.

Although preparations having 500 units/mg. N have been obtained, Figure 1 indicates that optimum conditions for complete chromatographic separation were not established. Experiments to improve these conditions are being carried out as rapidly as starting material becomes available.[10]

BIOSYNTHESIS OF SPHINGOSINE IN VITRO

Sir:

We wish to report the preparation of an enzyme system obtained from rat brain tissue which cata-

lyzes the incorporation of serine-C^{14} into sphingosine and to identify some of the cofactors required for this conversion. The incorporation of radioactivity from acetate-1-C^{14} and L-serine-3-C^{14} into sphingosine has been observed *in vivo*.[1,2]

Brain tissue obtained from 10–14 day old rats was homogenized with 3 volumes of isotonic sucrose or 0.1 *M* potassium phosphate buffer (*p*H 7.8), and differential centrifugation was accomplished according to Brody and Bain.[3] The enzymes required for the conversion of L-serine to sphingosine were found in the supernatant solution obtained after sedimenting the particulate matter by centrifuging at 25,000 × *g* for 30 minutes. The enzyme preparation was dialyzed for 4 hours against 100 volumes of a solution containing 0.01 *M* potassium phosphate buffer (*p*H 7.0), 0.001 *M* cysteine hydrochloride and 0.001 *M* disodium ethylenediaminetetraacetic acid.

Following incubation, the lipids were quantitatively extracted with *n*-butanol and 18 μmoles of sphingosine sulfate were added to each sample as carrier. The mixtures were refluxed for 6 hours in 85% methanol made 1.2 *M* with respect to H_2SO_4, and subsequently extracted with petroleum ether which was back-washed two times with dilute acid. The methanolic solution containing the sphingosine sulfate was concentrated under vacuum, and the sphingosine base was recovered from salt-saturated alkaline aqueous phase by extracting with 2% isoamyl alcohol in heptane.[4] The solvents were evaporated under reduced pressure and the sphingosine was recrystallized two times from petroleum ether. Approximately 80% of the carrier sphingosine was recovered with the use of this procedure. The twice recrystallized sphingosine was found to have constant specific radioactivity.

TABLE I

ENZYMATIC CONVERSION OF SERINE-3-C^{14} TO SPHINGOSINE

Except as noted, the incubation mixtures contained 1.5 ml. of dialyzed supernatant solution obtained by centrifuging a 1:3 (w./v.) cell-free preparation of rat brain tissue at 25,000 × *g* for 30 minutes, 150 μmoles of potassium phosphate buffer (*p*H 7.8), 4 μmoles of DL-serine-3-C^{14} (4 μC.), 1 μmole of pyridoxal phosphate, 5 μmoles of $MgCl_2$, 0.3 μmole of triphosphopyridine nucleotide (TPN), 20 μmoles of nicotinamide, 2 μmoles of uridine triphosphate (UTP), 0.4 μmole of cytidine triphosphate (CTP), 5 μmoles of adenosine triphosphate (ATP), and 0.1 ml. of liver kochsaft in a total volume of 2.0 ml. Incubation time, 3 hours at 38° in air.

Reactant omitted	Distribution of radioactivity in recovered sphingosine: Sphingosine, c./m./μmole	Residue after periodate degradation, c./m./μmole
None	155	26
None, heated at 100° for 10 min.	3	..
Kochsaft	11	..
Pyridoxal phosphate	35	23
$MgCl_2$	71	20
TPN	90	20
DPN	93	22
Nicotinamide	110	25
UTP	140	26
CTP	165	25
ATP	170	28

As shown in the table, the conversion of serine-3-C^{14} to sphingosine requires the presence of pyridoxal phosphate, magnesium chloride, triphosphopyridine nucleotide, diphosphopyridine nucleotide, and an as yet unidentified substance present in a kochsaft obtained from rat liver tissue. The recovered sphingosine was degraded with sodium periodate,[4,5] and the radioactivity of the residual aliphatic aldehyde was determined. It is apparent from these data that the radioactivity from the serine-C^{14} is preferentially localized in positions 1 and 2 of sphingosine and that the reaction does not represent random incorporation of radioactivity via an active one or two carbon fragment. These findings have been confirmed with the use of L-serine-U-C^{14} as substrate in this system.

A NOVEL ORGANO-CHROMIUM COMPOUND

Sir:

The known organo-chromium compounds, apart from the anionic cyanide and ethynyl complexes[1] of chromium(III) are compounds of chromium(0), chromium(I) or chromium(II)[2] which generally do not contain simple carbon–chromium bonds. We wish to report the first preparation (in solution) of a simple organo-chromium compound of the type $Cr(H_2O)_5R^{++}$ where R is benzyl. The compound has not yet been obtained crystalline, but solutions of the pure perchlorate in dilute perchloric acid solution have been obtained and are fairly stable (half-life in absence of oxygen at room temperature of about 1.5 days). The structure of the compound, benzylpentaaquochromium(III) perchlorate, can be regarded as analogous to that of the chloride complex, $Cr(H_2O)_5Cl^{++}$, of chromium(III); *i.e.*, the compound is a complex of Cr(III) with the *benzyl anion*. The remarkable stability of this organo-metallic compound in acid solution is undoubtedly related to the inertness of Cr(III) complexes to substitution.[3]

The benzylchromium compound was prepared by reducing benzyl chloride (or bromide or iodide) with aqueous 1 *M* chromous perchlorate in 1 *M* perchloric acid, either heterogeneously or in presence of alcohol or other suitable organic solvents. Countercurrent distribution of the product at 5° with the solvent system 0.01 *M* perchloric acid–butanol gave, after 70 transfers, a separation of the organo-chromium compound (partition coefficient

0.35) from $Cr(H_2O)_6^{+++}$ (mainly) and $Cr(H_2O)_5Cl^{++}$ (partition coefficient 0.13). Separation was also effected by ion-exchange chromatography on Dowex 50-X4 resin and elution with 1 *M* perchloric acid. The ion $Cr(H_2O)_5Cl^{++}$ (green) was eluted first, followed by $Cr(H_2O)_5CH_2Ph^{++}$ (yellow to orange-yellow) whilst $Cr(H_2O)_6^{+++}$ remained on the column. All the above operations were carried out in an atmosphere of oxygen-free nitrogen and as rapidly as possible.

Solutions of the benzylchromium compound were yellow to brownish-red depending on the concentration, and the spectrum of the solution had a low intensity maximum at 540 mμ and a high intensity maximum at 358 mμ. Decomposition of the complex in the absence of oxygen by heating or by keeping for several days gave bibenzyl; in the presence of oxygen benzaldehyde was the main product. The compound was decomposed very rapidly by sulfur dioxide but was stable to carbon dioxide. Hydrogenation in presence of a palladium catalyst gave toluene. Solutions of the compound reacted very quickly with aqueous mercuric chloride with *no change in pH of the solution* to give benzylmercuric chloride and $Cr(H_2O)_6^{+++}$ (not $Cr(H_2O)_5Cl^{++}$) in equimolecular amounts. Therefore the compound must contain one benzyl group per chromium atom and two positive charges. Hence it is a Cr(III) complex and its stability is best rationalized by the normal octahedral complex structure mentioned before. It differs, as might be expected, from the chloride complex in having a tendency to dissociate in a homolytic fashion to give benzyl radicals and chromous ion. An alternate structure which can be considered for the compound is a complex of the tropylium ion and Cr(I) in the manner[2] of dibenzene–Cr(I) but with only one ring involved per chromium atom, although this is somewhat unlikely on the above evidence. However, such a structure can be excluded because all the carbon atoms would then become equivalent and it was found that α-methyl, *o*-methyl- and *p*-methylbenzyl halides gave different compounds on reduction with chromous perchlorate.

Reduction of benzyl chloride with chromous chloride in hydrochloric acid gave toluene rather than an organo-metallic compound. This can be understood from the work of Taube[4] as the initially formed complex, $Cr(H_2O)_4Cl{\cdot}CH_2Ph^+$, will have chloride ion as well as water molecules in the coördination sphere and such a chlorine atom favors reduction by bridging[4] with the reducing agent. The resultant Cr(II) complex is then no longer substitution-inert and dissociates to benzyl anions which react with the solvent to give toluene. Therefore, the isolation of $Cr(H_2O)_4CH_2Ph^{++}$ in the chromous perchlorate reduction is due to the fact that this compound (like $Cr(H_2O)_6^{+++}$ but unlike $Cr(H_2O)_5Cl^{++}$ and $Cr(H_2O)_4Cl_2^+$) is reduced by Cr^{++} extremely slowly, as well as to the substitution-inertness of dipositive complexes of Cr-(III).

Allyl chloride and phenacyl chloride were readily reduced by chromous perchlorate, but without observable formation of organo-metallic compounds. Work on the reduction of halogen compounds by chromous salts is continuing.[5]

THE BIOSYNTHESIS OF SQUALENE FROM MEVALONIC ACID

Sir:

Tavormina, *et al.*,[1] have reported the incorporation of 2-C^{14}-labeled mevalonic acid (3,5-dihydroxy-3-methylvaleric acid) into cholesterol by homogenates of rat liver. These investigators have also provided evidence that the carboxyl carbon of the substrate is almost completely converted to carbon dioxide, and therefore not incorporated into cholesterol.[2]

We have confirmed the finding that 2-C^{14}-mevalonic acid[3] is converted to cholesterol, and in addition have demonstrated that it is rapidly converted to squalene by homogenates as well as by the supernatant fluid obtained from such preparations following high speed centrifugation.[4]

Employing homogenates of rat liver and 2-C^{14}-mevalonic acid, we have repeatedly isolated C^{14}-squalene into which has been incorporated 10 to 20% of the substrate. Squalene recovered from several of the experiments was combined and purified by chromatography on alumina.[4] It was subsequently chromatographed on silicic acid, eluting with an increasing gradient of benzene in petroleum ether. The latter process yields squalene as a single radioactive peak.[5]

In contrast to cruder preparations of squalene, this product is completely degraded by ozonolysis to acetone, levulinic acid and succinic acid. These substances were separated and further degraded. Acetone was converted to iodoform and acetic acid, and the acetic acid degraded by the Schmidt method.[6] The levulinic acid was converted to iodoform and succinic acid. The succinic acid was degraded by the Schmidt technique to carbon dioxide and ethylenediamine. All of the degradation products were converted to carbon dioxide and counted as barium carbonate.

The radio-analyses (Table I) demonstrated that approximately 80% of the isotopic carbon of the squalene is present in the methyl carbons of acetone and in carbon 3 of levulinic acid. The succinic acid sample, representing the central four carbons of squalene, contained only a small amount of isotope. It is clear that only one of the methylene groups of the levulinic acid was appreciably labeled.

Fig. 1.—Principal distribution of isotopic carbon in biosynthetic squalene.

The distribution of isotope in the squalene suggests that the mevalonic acid was not decarboxylated to yield a five carbon intermediate prior to condensation. If a five carbon intermediate is first produced, the compound would have to react asymmetrically to give the observed isotope distribution. This possibility has not been excluded by the data presented here. Whether mevalonic acid is or is not the biological precursor of squalene and cholesterol, there appears to be little breakdown and re-condensation prior to polymerization. It is likely that decarboxylation occurs during or after polymerization.

Complete details will be presented in a subsequent publication.

SOME ENZYMATIC REACTIONS OF 6,8-DITHIOLOCTANOIC (DIHYDROLIPOIC) ACID AND ITS ACETOACETIC THIOESTER[1]

Sir:

Evidence has been presented that AcAc[2] synthesis in soluble liver fractions from a source of Ac-S-CoA involves the intermediate formation of AcAc-S-CoA by thiolase, which catalyzes reaction 1, followed by deacylation of AcAc-S-CoA to AcAc.[3-5] However, a direct deacylation of synthetic AcAc-S-CoA is not catalyzed by these enzyme fractions.

$$2\text{Ac-S-CoA} \rightleftharpoons \text{AcAc-S-CoA} + \text{HS-CoA} \qquad (1)$$

We find that AcAc synthesis by partly purified ox or chicken liver enzyme preparations from Ac-S-CoA (generated by phosphotransacetylase from acetyl phosphate and CoA-SH[3]) requires the addition of a mono- or dithiol compound. Among active thiols, (±)-DTO[6] has the greatest activity, half maximum activation of AcAc synthesis occurring with 1×10^{-4} M (±)-DTO compared to 3.5×10^{-4} M BAL and 2×10^{-3} M GSH. These liver fractions also catalyze the reactions (2), (3)

$$(\pm)\text{-S-AcAc-DTO} + H_2O \longrightarrow \text{AcAc} + (\pm)\text{-DTO} \qquad (2)$$

$$\text{AcAc-S-Pn (or CoA)} + (\pm)\text{-DTO} \rightleftharpoons \text{Ac-S-Pn (or CoA)} + (\pm)\text{-S-Ac-DTO} \qquad (3)$$

Mono-(±)-S-AcAc-DTO was synthesized by reacting one equivalent of diketene with (±)-DTO. Presumably it is the 8-ester, since acetic anhydride and DTO have been shown to give 8-S-Ac-DTO.[7] While DTO does not give a positive nitroprusside assay for sulfhydryl,[8,9] we find the monothiol, monothioester form does. Thus, monoacylation of DTO results in the appearance of one sulfhydryl equivalent (by nitroprusside assay), as well as one thioester equivalent (measured with hydroxylamine or optically at 240 mμ). The synthesis and breakdown of mono-S-acyl-DTO compounds can therefore be measured by nitroprusside assay.

The thioesterase catalyzing reaction 2 is assayed optically by following the decrease in light absorption at λ 310 mμ or λ 240 mμ, since (±)-S-AcAc-DTO has an absorption spectrum characteristic of acetoacetyl thioesters.[10,11] It is present in liver but apparently not in other tissues. The enzyme has been purified 40-fold from chicken liver and shown to be different from AcAc-SG thioesterase.[12] It hydrolyzes S-AcAc and S-Ac esters of DTO, MTO and BAL (Table I).

As measured optically at λ 310 mμ, liver and heart enzyme fractions catalyze a disappearance of AcAc-S-Pn and AcAc-S-CoA, provided DTO (or certain mono- or dithiols) is added. With DTO, the decrease in E_{310} due to disappearance of AcAc-SR is accompanied by a simultaneous increase in E_{240}, signifying an increase in total thioester concentration. Balance studies (Table II) show that for each mole of AcAc-S-Pn disappearing, *two* moles of

TABLE I

SUBSTRATES FOR THIOESTERASE

15-fold purified chicken liver thioesterase. ~0.5 μM thioester in 0.067 M Tris–HCl buffer pH 7.0. Specific activity = $-\Delta E_{240}$ per minute per mg. protein. Values in parentheses refer to synthetic S-acetyl ester.

	Specific activity
8-S-AcAc-MTO	82
(±)-8-S-AcAc,6-ethyl-MTO	69
(±)-S-AcAc-DTO	56 (60)[a]
(±)-6-S-AcAc-MTO	17
(±)-6-S-AcAc-Decanoate	7.5
S-AcAc-BAL	310 (30)

[a] (+)-6-S-Ac-DTO was hydrolyzed at same rate as the synthetic ester.

thioester and *one* mole of thiol are formed. This stoichiometry is consistent with reaction 3 and follows from the fact that AcAc-SR does not assay as thioester by the hydroxylamine method[5] while S-Ac-DTO assays as both thiol and thioester. The Ac-S-Pn and Ac-S-DTO formed were further identified by paper chromatography. It is not yet determined whether 6- or 8-S-Ac-DTO is formed. This mixed thiolysis reaction represents a novel enzymatic synthesis of S-Ac-DTO. It differs from the synthesis of (+)-6-S-Ac-DTO from Ac-S-CoA and (−)-DTO catalyzed by DTO transacetylase[7,8] in that it involves transacetylation with a 4-carbon fragment and utilizes both (−)-DTO and (+)-DTO.[13] The enzyme(s) catalyzing reaction 3 differs from the thiolase[14,15] of the fatty acid cycle (reaction 1) in that (a) AcAc-S-Pn is more reactive than AcAc-S-CoA, (b) it is less sensitive to iodoacetamide, and (c) it is not readily reversible, if at all. Interestingly, other thiol compounds which activate AcAc synthesis (*e.g.*, BAL, GSH, cysteine) can substitute for DTO in reaction 3, yielding the corresponding S-Ac ester.

TABLE II

THIOLYSIS OF AcAc-S-Pn BY DTO

1.50 μM AcAc-S-Pn, 4.0 μM DTO, 150 μM Tris–HCl buffer pH 8.1 and 0.9 mg. ox liver protein. Incubated 13 minutes at 25°. Values in μM.

	Acetyl acceptor		
	(±)-DTO	(+)-DTO	(−)-DTO
Δ AcAc-S-Pn[a]	−1.50	−1.50	−1.50
Δ Sulfhydryl[b]	+1.43	+1.44	+1.71
Δ Hydroxamic acid	+2.99	+2.98	+2.88

[a] Measured optically at 310 mμ. [b] Nitroprusside assay.

(±)-S-AcAc-DTO is reduced by DPNH in the presence of crystalline heart β-hydroxybutyryl-S-CoA dehydrogenase.[16] Liver fractions do not catalyze a thiolysis of (±)-S-AcAc-DTO by DTO, CoA-SH, Pn-SH or GSH. Nor do they convert (+)-6-S-Ac-DTO[7] or (±)-8-S-Ac-DTO to AcAc.

Since thioesterases exist in liver for S-AcAc-DTO and AcAc-SG, the latter are possible intermediates in AcAc synthesis. However, experiments so far have failed to demonstrate their enzymatic formation, *e.g.*, by AcAc transfer from AcAc-S-CoA (or Pn). The precise role of DTO and other thiols in activating AcAc synthesis is being investigated further.

A NEW PATHWAY FOR PROPIONATE OXIDATION

Sir:

Oxidation of propionate in animal tissues occurs by a carboxylation pathway through methyl malonate to succinate.[1] Stadtman[2] has observed the formation of β-alanyl-CoA from acryl-CoA extracts of *Clostridium propionicum*. Mahler and Huennekens suggest an α-oxidative pathway.[3] In this communication evidence is presented in support of a β-oxidative pathway in peanut mitochondria.[4]

The oxidation of sodium propionate-1-C^{14} to $C^{14}O_2$ by mitochondria isolated from cotyledons of germinated peanuts[4a] is dependent upon ATP,[5] CoA, DPN, GSH and αKG; TPN and Mn^{++} stimulate the oxidation.

TABLE I

COFACTOR REQUIREMENTS FOR OXIDATION OF PROPIONATE-1-C^{14} TO $C^{14}O_2$

The complete reaction mixture contained 0.1 μmole propionate-1-C^{14} (5500 c.p.m.); 0.5 ml. mitochondria (approximately 20 mg. protein) in 0.2 M Tris- 0.5 M sucrose, pH 7.2, containing about 5×10^{-3} % BAL; 10 μmoles phosphate buffer, pH 7.1; 50 μmoles KCl; 1 μmole ATP; 0.3 μmole CoA; 0.2 μmole DPN; 0.1 μmole TPN; 5 μmoles GSH; 1 μmole αKG; 0.2 ml. 20% KOH in the center well; 0.3 ml. 10 M H_2SO_4 in the sidearm, final volume 1.7 ml. Time of incubation, 2 hr., temperature 25°. % oxidation = $BaC^{14}O_3$ (c.p.m.) × 100/substrate (c.p.m.).

Components	% Oxidation	Components	% Oxidation
Complete	24	−TPN	21
−ATP	1	−GSH	17
−CoA	2	$-MnSO_4$	20
−DPN	14	−αKG	5

Since pools of pyruvate, lactate, succinate and methyl malonate added during propionate-1-C^{14} oxidation do not acquire any label, these compounds do not appear to participate as intermediates. Furthermore, no propionate-dependent fixation of $C^{14}O_2$ can be demonstrated.

To examine the course of oxidation, propionate-1-C^{14}, -2-C^{14} and -3-C^{14}[6] were incubated with a complete reaction mixture for different periods of time and ether-extractable reaction products separated by paper chromatography. In each case a new radioactive spot (R_f 0.25 in ethanol ammonia; propionate R_f 0.42) appeared, which decreased

with time. This spot, identified as βHP, was characterized by (a) two dimensional co-chromatography with authentic βHP, (b) dichromate oxidation[7] of βHP derived from propionate-2-C^{14}, to a dicarboxylic acid which co-chromatographed with malonic acid. The dicarboxylic acid was degraded by pyrolysis[8] to radioactive acetate and CO_2 and (c) esterification of the acid with diazomethane and conversion to a hydroxamic acid (with hydroxylamine) which co-chromatographed with authentic βHP hydroxamate.

Both propionate-1-C^{14} and βHP-1-C^{14}[9] rapidly release the carboxyl-C^{14} as $C^{14}O_2$. No radioactive Krebs cycle acids are produced. The cofactor required for the oxidation of βHP-1-C^{14} to $C^{14}O_2$ is ATP.

Under the same conditions, propionate-2-C^{14} and βHP-2-C^{14}[9] slowly release C^{14} as $C^{14}O_2$, only after the appearance of radioactive citric, succinic, malic and fumaric acids. With propionate-3-C^{14} a rate of $C^{14}O_2$ release between that of propionate-1-C^{14} and of -2-C^{14} is observed with the formation of labeled Krebs cycle acids. Succinate derived from propionate-1-C^{14} is not labeled. Succinate derived from propionate-2-C^{14} is labeled exclusively in the methylene groups and succinate derived from propionate-3-C^{14} is labeled exclusively in the carboxyl groups.

The conversion of propionate-C^{14} to βHP-C^{14} is dependent on oxygen, ATP and CoA. Other cofactors were not tested.

The pathway may be formulated as[10]

$$CH_3{\cdot}CH_2\,COOH \xrightarrow{ATP,\ CoA} CH_3{\cdot}CH_2{\cdot}CO{\cdot}CoA \longrightarrow$$

$$CH_2{=}CH{\cdot}CO,\ CoA \xrightarrow{H_2O} CH_2OHCH_2{\cdot}CO{\cdot}CoA$$

$$\boxed{CH_2OH{\cdot}CH_2{\cdot}COOH}$$

$$HOOC{\cdot}CH_3 \qquad ATP$$

$$\boxed{\text{Krebs Cycle Acid}} \longrightarrow \boxed{CO_2}$$

THE STEREOSPECIFIC RADICAL ADDITION OF HYDROGEN BROMIDE TO *cis*- AND *trans*-2-BROMO-2-BUTENE[1]

Sir:

In previous work it was found that a high degree of stereospecificity is observed in the radical addition of hydrogen bromide to cyclohexene[2,3] and cyclopentene[4] derivatives. From this and other considerations it appeared possible that under favorable conditions stereospecificity might be observed with this addendum in acyclic systems. We wish to report that the radical addition of hydrogen bromide to the isomeric 2-bromo-2-butenes in liquid hydrogen bromide at −80° is indeed stereospecific and results in almost complete *trans* addition. Other radical additions which have been investigated have been found to be non-stereospecific[5] and apparently this is the first report of a stereospecific radical addition in an acyclic system.

The additions were promoted by irradiation with a quartz-jacketed Hanovia type SC-2537 lamp which fit into the reaction vessel so that the reaction mixture occupied the annular space between the walls of the lamp and reaction vessel. During the reaction the vessel was immersed in a Dry Ice–acetone bath. Mixtures of approximately 20 ml. of anhydrous liquid hydrogen bromide and 5 g. of *cis*- or *trans*-2-bromo-2-butene (shown to be homogeneous by gas chromatographic analysis[6] and physical properties) were irradiated after which the hydrogen bromide was allowed to evaporate and the composition of the residual reaction mixture determined by gas chromatographic[6] and infrared analysis.

In a typical experiment pure *cis*-2-bromo-2-butene in liquid hydrogen bromide was irradiated for 7.5 minutes. The composition of the product (gas chromatographic analysis[6]) was found to be < 0.5% 2-bromo-2-butene (largely isomerized to the *trans* isomer), 3% 2,2-dibromobutane (presumably formed by ionic addition), 92% *meso*-2,3-dibromobutane, 5% *dl*-2,3-dibromobutane and < 0.5% 1,2-dibromobutane.

Irradiation of *trans*-2-bromo-2-butene for 15 minutes under similar conditions gave a mixture consisting of 5% of unreacted *trans*-2-bromo-2-butene, 83% *dl*-2,3-dibromobutane, 8.5% *meso*-2,3-dibromobutane and 3.5% 1,2-dibromobutane. The analytical method was calibrated and confirmed using pure authentic samples of all of the components and synthetic mixtures of these. Infrared spectroscopic examination of the reaction products also showed that the *cis*-bromobutene is converted primarily to *meso*-dibromide and the

trans-bromobutene gives primarily *dl*-dibromide. These experiments were repeated several times and found to be reproducible. Increasing the reaction (irradiation) time to one hour did not result in any significant changes.

That the above additions are radical rather than ionic is clear from the orientation. When a mixture of *cis*-2-bromo-2-butene and liquid hydrogen bromide was allowed to stand in the dark at −80° for one hour the reaction mixture was found to contain 8.5% of bromobutene (mostly *trans* isomer) and 91.5% 2,2-dibromobutane. Under similar conditions using *trans*-2-bromo-2-butene the reaction mixture consisted of 10% of unreacted bromobutene, 87% 2,2-dibromobutane and 3% *dl*-2,3-dibromobutane (presumably formed by radical addition). These experiments also were found to be reproducible.

The present work demonstrates clearly that under the present conditions the radical addition involves a stereospecific *trans* addition. Assuming that the chain process involves two steps, (1) addition of a bromine atom to form an intermediate radical followed by (2) transfer with the addendum,[3,7] it is clear that different intermediate radicals are formed from the isomeric bromobutenes which undergo the transfer step faster than they are interconverted. Clearly the time interval between the two steps must be very short. A concerted process involving attack of a bromine atom on a substrate molecule complexed with hydrogen bromide has been suggested previously[3] and may be involved in the present case.

ISOPROPOXYFLUOROMETHYLENE[1]

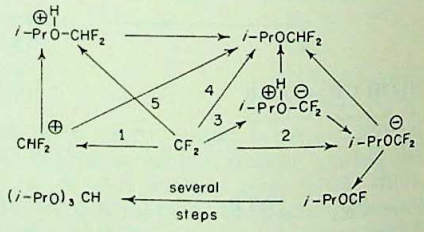
Sir:

Methylene is formed in such homolytic reactions as the decomposition of diazomethane and the photolysis of ketene,[2] and some of its derivatives apparently are formed in analogous reactions. Many of the polar reactions claimed to involve methylenes have been shown not to,[3] but the basic hydrolysis of chloroform, the reaction for which such a mechanism was first suggested,[4] does proceed through dichloromethylene.[5] The *dihalomethylenes*[6] appear to be the only ones that have been established as intermediates in polar reactions, since it is not clear just how concerted the observed α-eliminations with rearrangement are.[7] We now present evidence for the intermediate, isopropoxyfluoromethylene.

Chlorodifluoromethane reacted rapidly (k = 8×10^{-3} l. mole^{-1} sec.$^{-1}$) with potassium isopropoxide in dry isopropyl alcohol at 0° to give isopropyl difluoromethyl ether (b.p. 44.2–44.5°, d^{25}_4 0.97604, n^{25}D 1.3204, molecular refraction calcd. 22.115, found 22.404), triisopropyl orthoformate and about 1% fluoroform as the only detected organic products (no carbon monoxide or propylene[8]). The yields of the two major products were calculated from the base and chloride concentrations by stoichiometric considerations. The fraction of isopropyl orthoformate produced increased from 0.15 with 0.02 M isopropoxide to 0.30 with 0.10 M isopropoxide. The isopropyl difluoromethyl ether was inert under the reaction conditions and reacted very slowly even at 50°.

The basic decomposition of chlorodifluoromethane in methanol must involve difluoromethylene since with sodium thiophenolate the formation of phenyl difluoromethyl sulfide is powerfully catalyzed by sodium methoxide.[9] Under the more strongly basic conditions of the present case the α-dehydrochlorination is even better facilitated. The competing initial removal of hydrogen fluoride must be a negligible side reaction. While fluorine atoms increase the reactivity of haloforms from which other halogens may be removed to give fluoromethylenes, the initial removal of fluoride ions is very difficult, fluoroform being inert even to potassium *t*-amyl oxide at 50°.[10] This rules out the possibility that the orthoester is produced from chlorofluoromethylene, a hypothesis that is also incompatible with the change in orthoester yield with changing isopropoxide concentration.

The only subsequent reactions of the difluoromethylene that seem plausible are



protonation (1), coördination with isopropoxide ion (2) or isopropyl alcohol (3), or simultaneous protonation and coördination with isopropoxide (4) or alcohol (5). Reactions 1, 4 and 5 can lead reasonably only to i-PrOCHF$_2$, as do 2 and 3 if the carbanions formed thereby are protonated. Hence the isopropyl orthoformate must be formed through reaction 2 and/or 3 followed (or accompanied) by loss of a fluoride ion.[11] Reaction through the i-PrOCF$_2^-$ anion seems more reason-

able since the loss of fluoride ion should be facilitated by the unshared electron pairs of the isopropoxy group. Since isopropoxyfluoromethylene is the only intermediate in the scheme in which the inert end-product, i-PrOCHF$_2$, has been bypassed, it must be an intermediate in the formation of the isopropyl orthoformate.

GLUTAMIC ASPARTIC TRANSAMINASE

Sir:

Glutamic aspartic transaminase of pig heart has been highly purified and the presence of firmly bound pyridoxal phosphate has been confirmed. The enzyme was purified by heat denaturation (75° for 20 minutes in maleate buffer pH 6.0), ammonium sulfate fractionation (50–67%), adsorption of impurities onto calcium phosphate followed by chromatography on a calcium phosphate column[1] and a repetition of the ammonium sulfate fractionation to give an over-all yield of 30%. Sedimentation and electrophoresis studies indicate that the enzyme is 70% pure; it has an activity of 380 μM glutamate/min./mg. protein using a modification of the assay of Nisonoff, *et al.*,[2] at 37° and pH 8.5. The preparation contains one mole of pyridoxal phosphate per 67,000 grams of protein.

Figure 1 shows that the enzyme is colorless at pH 8.5 (λ_{max} 362 mμ) but turns yellow at pH 4.8 (λ_{max} 430 mμ) and in 0.1 N NaOH (λ_{max} 388 mμ). In the latter solution the prosthetic group is split off and could be isolated by use of a Dowex 1-Cl column. In 0.1 N HCl the chromophore absorbs strongly at 295 mμ. Its 2,4-dinitrophenylhydrazone, which is not extracted from acidic solution by ethyl acetate, absorbs at 478 mμ in alkali and at 415 mμ in acid. These spectra confirm the fact that the prosthetic group is a derivative of pyridoxal phosphate. It should be noted, however, that the pyridoxal phosphate has characteristically different spectra when bound to the enzyme. We believe that these spectra may be due to a pyridoxal phosphate imine, since Metzler[3] has shown that these imines absorb at 360 mμ at high pH and above 410 mμ at lower values. Matsuo and Greenberg[4] have shown that the crystallized cystathionase/homoserine dehydrase has a similar absorption band at 427 mμ.

Carbonyl reagents react with the transaminase to yield the enzyme oxime, hydrazones, cyanhydrin and complexes with thiols and bisulfite, all of which have characteristic spectra.

The addition of glutamate to the enzyme at pH 8.5 causes the absorption peak to shift to 332 mμ (see Fig. 1) a peak which is characteristic of all pyridoxine compounds including the zwitterion form of pyridoxamine. Isolation of the prosthetic group on Dowex 1-Cl, after the addition of excess glutamate, yielded pyridoxamine phosphate characterized by its absorption bands in acid (λ_{max} 293) alkali (λ_{max} 306) and at pH 5.2 (λ_{max} 326). The addition of less glutamate causes partial disappearance of the pyridoxal phosphate (measured as its 2,4-dinitrophenylhydrazone after cleavage from the enzyme by 0.1 N alkali) and the formation of an equivalent amount of α-ketoglutarate.

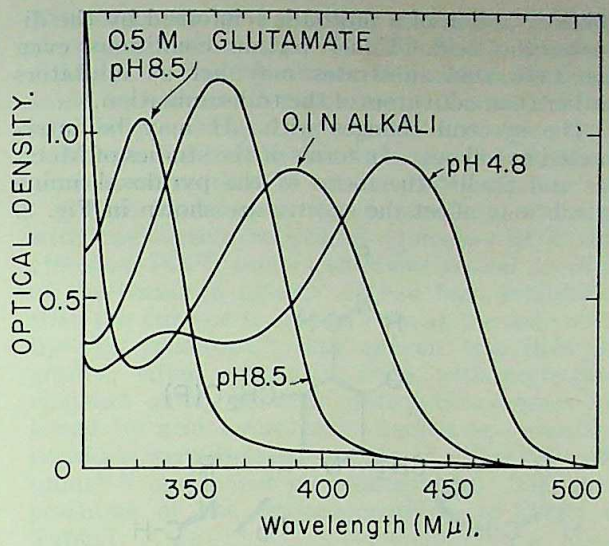

Fig. 1.—Spectra of the enzyme in 0.1 M Tris buffer pH 8.5 alone and with 0.5 M glutamate, in 0.1 N NaOH and in 0.15 M acetate buffer pH 4.8. Each cuvette contained 0.863% protein.

The reaction is reversed by increasing concentrations of ketoglutarate added to the enzyme in the presence of a constant amount of glutamate, as shown by an increase in the band at 362 mμ characteristic of the free enzyme and an increase in the band at 435 mμ ascribed to a complex of ketoglutarate with the protonated enzyme. By the use of C^{14}-glutamate rapid transamination has been confirmed in this steady-state system in which the concentrations of glutamate and ketoglutarate do not change. We believe that these experiments essentially confirm the pyridoxal-pyridoxamine hypothesis suggested on structural grounds by Snell.[5]

Dicarboxylic acids combine with the protonated form of the enzyme to produce an absorption maximum at about 435 mμ. The order of effectiveness is: glutarate > maleate > adipate > malate > ketoglutarate > oxalacetate > succinate. The fact that oxalate, malonate, pimelate, suberate, glycolate and fumarate do not interact suggests that a specific orientation of both carboxyl groups is required and that this specificity may be related to the substrate specificity of the enzyme.

These complexes may explain the apparent stabilizing effect of maleate in this purification and that of ketoglutarate in the purification of kynurenine transaminase.[6] This type of complex formation results in a new type of inhibition,[7] in which the in-

hibitory action of a proton is reinforced by the dicarboxylic acid. Under certain conditions even the keto acid substrates may act as inhibitors rather than activators of the transamination.[8]

The spectral changes with *p*H may be interpreted as follows. In terms of the studies of Metzler and Snell[3,9] the forms of the pyridoxal imine which may affect the spectra are shown in Fig. 2.

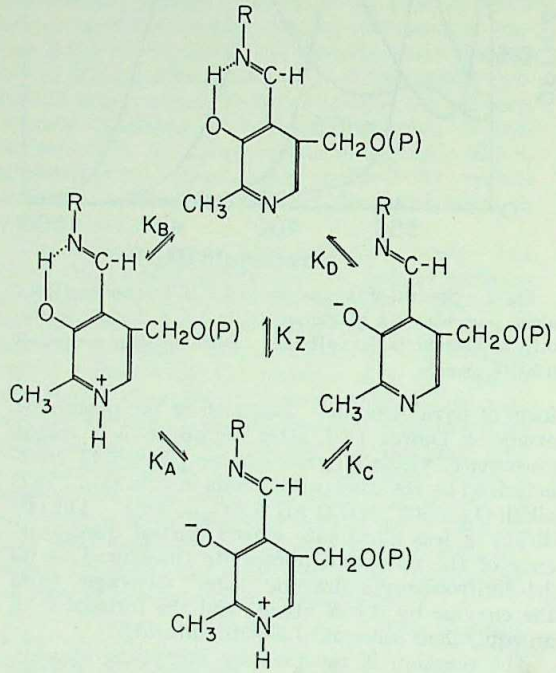

Fig. 2.—The ionization of pyridoxal phosphate imines.

These equations are based on the assumption that the yellow color may be ascribed to the hydrogen chelate ring. Rupture of this ring by a change in *p*H results in loss of color. A pK_A of 6.2 for this color change for the transaminase suggests that it is the dipolar form of the imine which occurs at neutrality, in contrast to the non-polar forms of the imines studied by Metzler[3] (pK_B = 5.9, pK_D = 10.5).

The implications of these findings with reference to the mechanism of enzymatic transamination will be discussed elsewhere.

A STABLE EQUIMOLAR COPPER(II)–ALBUMIN COMPLEX

Sir:

A simple and rapid amperometric titration technique has been developed for the determination of bovine serum albumin (BSA) with [illegible]

ammoniacal buffer at *p*H 9.2. Figure 1 shows current voltage curves of copper(II) at the rotated platinum electrode (RPE) in a buffer 0.1 *M* in ammonia and 0.1 *M* in ammonium nitrate (curve B). The first wave corresponds to the reduction of copper(II) to copper(I). No copper waves are observed when albumin is present in a molar concentration greater than that of copper (curve D). Curve E illustrates the reappearance of the copper waves when an excess of copper is present.

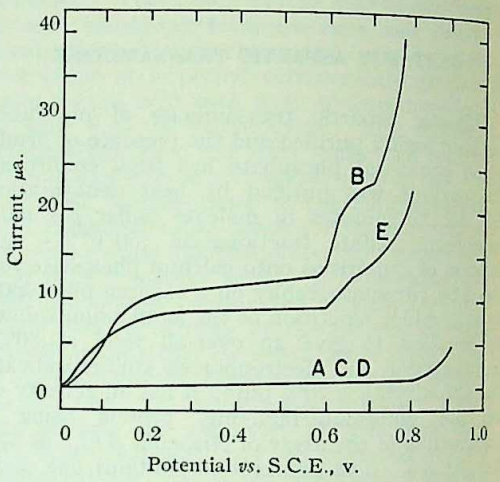

Fig. 1.—Current voltage curves at rotated platinum electrode; buffer, 0.1 *M* NH_3 + 0.1 *M* NH_4NO_3; *p*H 9.2; speed of rotation, 900 r.p.m.: A, residual; B, 4.0 × 10^{-5} *M* Cu(II); C, 7.3 × 10^{-5} *M* BSA; D, 7.3 × 10^{-5} *M* BSA + 6.5 × 10^{-5} *M* Cu(II); E, 7.3 × 10^{-5} *M* BSA + 13.0 × 10^{-5} *M* Cu(II).

By amperometric titration at the RPE in ammonia buffer at −0.4 volt, we have found that copper(II) reacts rapidly with native BSA in a mole ratio of one to one. Similar results have been obtained under proper conditions at *p*H 8 and 10. The rapid reaction is followed by a slower reaction of additional amounts of copper(II); this does not interfere with the titration. The sulfhydryl group is not involved in the reaction with copper(II). After addition of one or two moles of copper(II) per mole BSA, 0.68 mole sulfhydryl per mole BSA[1] was found by subsequent amperometric titration with mercuric chloride and/or silver nitrate.[2] Also, addition of 0.68 mole of silver nitrate or mercuric chloride per mole BSA prior to titration with copper(II) did not affect the results of this titration.

Titrations of BSA have also been carried out in a denaturing mixture which was 4 *M* in guanidine hydrochloride, 0.1 *M* in ammonia and 0.1 *M* in ammonium nitrate. A reaction ratio of copper(II) to BSA somewhat greater than unity (about 1.3) was found. This higher reaction ratio is ascribed to oxidation by copper(II)[3] of the sulfhydryl group which is oxidizable to disulfide in denatured al-

bumin. When the sulfhydryl group in denaturing medium is inactivated by addition of 0.68 mole of silver nitrate or potassium ferricyanide, the reaction ratio of copper(II) to BSA was again found to be unity.

Our experiments have been carried out under conditions quite different from those of Klotz, *et al.*,[4] and no comparison with their results is made here. Our results show that in the *p*H range 8–10, one copper(II) is bound to the BSA molecule extremely tightly, and that the sulfhydryl group is not the reactive group. It is of interest to note that nickel(II), even in very small concentrations, and also, to a lesser extent, cobalt(II) greatly interfere with the copper(II) BSA reaction while even large amounts of zinc(II) have very little effect. Thus, the group in the BSA molecule responsible for the binding of copper(II), the nature of which is at present unknown, apparently also forms stable complexes with nickel(II) and cobalt(II) but not with zinc(II). One unique site in the BSA molecule is the N-terminal aspartyl group, and further work may show whether this group is the site of copper(II) binding.

There is very little (if any) reaction between copper(II) and human γ-globulin under our conditions. The method has been applied to the determination of albumin in blood serum, and preliminary results are promising.

ENZYME CATALYSIS AND ENZYME SPECIFICITY—COMBINATION OF AMINO ACIDS AT THE ACTIVE SITE OF PHOSPHOGLUCOMUTASE[1]

Sir:

In the classical template model for enzyme action the substrate is assumed to be absorbed with a precise fit into an area called the "active site" of the protein.[2] Presumably the amino acids at this site provide not only the catalytic action but also the specificity of the enzyme. From the widely varying specificity patterns of enzymes it would be anticipated that the amino acid composition at the active site would vary to fit the particular substrate. On the other hand, stereochemical and other evidence had led to the hypothesis that a few bond-breaking mechanisms might be common to reactions of widely different specificities[3] and hence there might be some common amino acid sequences. The sequence of a portion of the active site of chymotrypsin has been established[4–6] and hence a comparison could be made if similar information could be obtained for an enzyme of very different specificity. Such an opportunity arose when it was demonstrated that the active site of phosphoglucomutase was marked by a serine phosphate.[7,8]

P^{32}-labeled enzyme was prepared by exchange with radioactive substrates (glucose-1-PO_4^{32} and glucose-6-PO_4^{32}) under conditions similar to those of the standard assay.[9] It had been established that the enzyme is labeled only at the active site by this procedure.[8] The enzyme was then degraded, either with acid alone, with proteolytic enzymes alone, or with proteolytic enzymes followed by acid hydrolysis. Radioactive phosphopeptides were isolated by use of Dowex 50 columns[10,11] and paper chromatography. The compositions of the phosphopeptides are shown in Table I.

TABLE I

P^{32}-PHOSPHOPEPTIDES ISOLATED FROM PHOSPHOGLUCOMUTASE

Peptide	Phosphopeptide obtained by treatment with	Amino acid compn.
1	Proteolytic + acid	(Asp,Ser,Gly,Glu)
2	Proteolytic + acid	(Asp,Ser,Gly,Glu,Ala)
3	Proteolytic + acid	(Asp,Ser,Gly,Glu,Ala,Val,Thr)
4	Proteolytic only	(Asp,Ser,Gly,Glu)
5	Proteolytic only	(Asp,Ser,Gly,Glu Ala,Val,Thr, Leu)
6	Acid only	(Asp,Ser,Gly,Glu,Ala)
7	Acid only	(Asp,Ser,Gly,Glu,Ala,Val Thr, Leu)

While the detailed sequence has not been completely established, it is to be noted that the composition of each peptide and the order from comparison of lower and higher peptides is in perfect agreement with the sequence for chymotrypsin which is Asp Ser Gly Glu Ala Val.[4–6] The probability that the 7 peptides isolated from phosphoglucomutase would agree with this sequence by chance alone is very small. Moreover the concordance of the acid derived and proteolytic enzyme plus acid derived peptides is strong evidence against the sequence being an artifact of the separation procedure. The data therefore indicate that the amino acid sequence of the active site for at least 6 amino acids is the same for an enzyme which specifically hydrolyzes peptide bonds and an enzyme that specifically transfers phosphate between carbohydrate molecules.

This apparently surprising result is good support for the above mentioned hypothesis that common bond-breaking mechanisms exist despite vary-

ing specificity type. It suggests further that (a) the common sequence around serine is involved in making the otherwise inert CH_2OH side chain reactive and (b) the amino acids responsible for the specificity lie further from the reactive serine, perhaps in adjacent coils. While there must be an intimate steric relation between the amino acids responsible for the catalytic action and those responsible for the specificity, these results indicate that the two may be separable. In this case common sequences related to specificity as well as to the bond-breaking action might be expected, a result which would be of enormous value in relating enzyme structure to function.

ENZYMATIC INTRODUCTION OF DOUBLE BONDS INTO STEROID RING A

Sir:

The introduction of unsaturation into ring A of steroids is of interest in connection with the aromatization involved in biosynthesis of estrogens,[1] and in the microbiological formation of Δ^1-dehydrosteroids,[2] some of which possess interesting physiological properties. *Pseudomonas testosteroni* (A.T.C.C. No. 11996)[3] can utilize certain steroids as a sole source of carbon and degrade these compounds to CO_2 and H_2O by a series of reactions catalyzed by adaptive enzymes. During the course of a study of the pathway involved in the oxidative degradation of steroids by this microörganism, it was found that early steps were the interconversion of 17β-hydroxyl and 17-ketone functions and the introduction of Δ^1-double bonds and Δ^4-double bonds into steroids of both the 5α-H and 5β-H series. Such reactions have been reported in a variety of microbiological systems.[1,2] The enzymatic interconversion of 17β-hydroxy- and 17-ketosteroids is catalyzed by the diphosphopyridine nucleotide-linked enzyme β-hydroxysteroid dehydrogenase and has been analyzed in detail.[4] The purpose of the present communication is to report on the enzymatic mechanism of the introduction of double bonds into steroids. This constitutes, to our knowledge, the first demonstration of these reactions by means of soluble enzymes.

Under suitable conditions *Ps. testosteroni* carries out efficient conversions of androstane-3,17-dione (I), testosterone, Δ^4-androstene-3,17-dione (II), Δ^1-androstene-3,17-dione (III) and etiocholan-17β-ol-3-one to principally $\Delta^{1,4}$-androstadiene-3,17-dione (IV) and to a lesser extent to $\Delta^{1,4}$-androstadien-17β-ol-3-one (V). In a typical conversion, this microörganism was grown in 450 ml. of a medium containing 0.5% sodium lactate in a mineral base, at 30° and an initial *p*H of 7.0, and at the end of 24 hours 45 mg. of II was added in 2 ml. of acetone and the incubation continued for 24 hours longer. Extraction of the culture with ethyl acetate, followed by chromatography on silicic acid, crystallization from hexane–acetone, and sublimation at 90–115° (0.0005 mm.) afforded 20.5 mg. of IV, m.p. 140.5–141° (no depression on admixture with an authentic sample); $[\alpha]^{25}D$ +123° (*c* 1.04, in $CHCl_3$); λ_{max}^{alc} 243 mμ (ϵ 16,200); sulfuric acid chromogens[5] were identical with a known sample (peaks at 265, 305 and 390 (broad) and a minimum at 288 mμ); (*Anal.* Found: C, 80.08; H, 8.46. Calcd. for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51); infrared analysis showed λ_{max}^{KBr} 5.77 μ (17-ketone), 6.04, 6.17 and 6.25 μ ($\Delta^{1,4}$-3-ketone), identical with an authentic sample. Mixed paper chromatography showed no separation from authentic IV.

In similar experiments, conversions in good yield of I and III to IV were demonstrated and the products rigorously identified by comparison paper chromatography, m.p. and infrared spectra. Evidence for the presence of small amounts of V in each case was obtained. Conversion of 19-*nor*-testosterone by the same system in 72 hours gave a 67% yield of estrone m.p. 253–256°; $[\alpha]^{25}D$ +154° (*c* 0.644, in dioxane); λ_{max}^{alc} 282 mμ (ϵ 1960); on addition of NaOH, λ_{max}^{alc} 243 mμ (ϵ 8000) and 300 mμ (ϵ 2500). The infrared spectrum showed peaks at 5.83 μ (17-ketone), 6.32, 6.18 μ (—C=C—) and 3.06 μ(OH group), and was identical with that of authentic estrone. On paper chromatography the substance migrated as estrone and gave the phenolic reaction with the Turnbull reagent.[6] Estradiol-3,17β was also found in smaller amounts.

Cell-free extracts of *Ps. testosteroni* were prepared from cultures grown on 0.5% sodium lactate as described above. After 24 hours growth, II was added to give a final concentration of 0.01% and incubation continued for 24 hours longer. Cells were harvested and washed by centrifugation. The washed cells efficiently converted I to IV. After rupture by sonic oscillation in a 9 KC Raytheon oscillator for 20 minutes, the sonicate also converted I to IV vigorously.

The unwashed residue from centrifugation of the sonicate for 20 minutes at 10,000 × *g* was also active in this conversion. The supernatant alone was inactive and its activity could be restored by adding phenazine methosulfate (PMS), an oxidation reduction dye which reacts with certain flavoprotein enzymes[7] but not by the addition of di- and triphosphopyridine nucleotides. The supernatant upon the addition of PMS still introduced Δ^1- and Δ^4-double bonds after centrifuging for 30 minutes at 105,000 × *g*. The enzymatic activities were demonstrated in a variety of ways including paper chromatographic analysis of products and ultraviolet spectrophotometry of products formed from I.

A convenient and specific assay of the Δ^1-dehydrogenase activity was the measurement of estrone formation from Δ^4-estrene-3,17-dione with the Folin

reagent.[8] Table I demonstrates the progression of this reaction with time and demonstrates the requirement for PMS.

TABLE I

CONVERSION OF Δ^4-ESTRENE-3,17-DIONE TO ESTRONE BY Δ^1-DEHYDROGENASE

	μM Phenol (as estrone) Incubation time, min. 0	45	60	90
(1) Complete system[a]	0.10	0.42	0.48	0.63
(2) Enzyme omitted[b]	.11	.10	.09	.09
(3) Estrone synthesized, (1) minus (2)	..	.32	.39	.54
(4) PMS omitted[c]	.03	.05	.04	.05
(5) Steroid omitted	.01	.02	.01	.02

[a] The reactions were carried out in air with agitation at 30° in 4 ml. systems containing 115 μM phosphate buffer, pH 7.2, and the following additions in the complete system. 0.2 ml. enzyme (supernatant from 105,000 × *g* centrifugation, see text) containing 4.3 mg. protein; 1.84 μM Δ^4-estrene-3,17-dione in 0.1 ml. acetone (or 0.1 ml. acetone only when steroid was omitted); and 3.1 μM phenazine methosulfate (added last). At the end of the reaction the mixture was acidified with 0.3 ml. of concd. HCl, extracted three times with a total of 12 ml. of CH_2Cl_2, the extract dried over Na_2SO_4, and a 5-ml. aliquot evaporated to dryness and analyzed by the Folin reaction.[8] A standard curve was prepared using estrone. [b] A small blank which did not increase on incubation was always found when PMS and steroid were mixed either in the absence of enzyme or in the presence of acid-inactivated enzyme. [c] The sample of Δ^4-estrene-3,17-dione was found to be contaminated with about 1–2% phenol, presumably estrone.

It is believed that at least two and probably three separate enzymes are involved in these dehydrogenating reactions (Δ^1-, Δ^4-5α- and Δ^4-5β-dehydrogenases), and that probably these enzymes are flavoproteins.

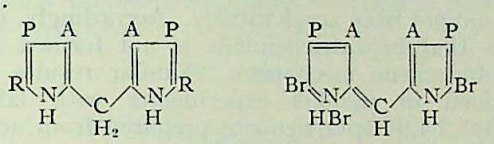
DIPYRRYLMETHANES

Sir:

Although dipyrrylmethane itself and nuclear carboxy, acyl, and hydroxy derivatives are known, those without such groups or their vinylogs are not, being presumed to be very unstable.[1] It now appears that some dipyrrylmethanes of the latter type, which may be intermediates in the biosynthesis of porphyrins, may be obtained by and undergo conventional pyrrole reactions without fission or oxidation at the bridge.

For example, I (R = H) forms nearly colorless micro-prisms without visible absorption, m.p. 199° dec., Ehrlich's reaction strongly positive cold. (Calcd. for $C_{19}H_{22}N_2O_8$: C, 56.15; H, 5.46; N, 6.89; eq. wt., 101.6. Found: C, 56.35; H, 5.57; N, 6.80; eq. wt., 103.2.) It was obtained in 80% yield from I (R = COOH)[2] with 10% sodium hydroxide for four hours at 170°, and also from II[2] with sodium amalgam. Diazomethane converted I (R = H) into its tetramethyl ester III, m.p. 105°, (Calcd. for $C_{23}H_{30}N_2O_8$: C, 59.73; H, 6.54; N, 6.06. Found: C, 59.58; H, 6.59; N, 6.10) which gave IV (80%), the ester of I (R = CHO), m.p. 203°, with hydrogen cyanide and hydrogen chloride (Calcd. for $C_{25}H_{30}N_2O_{10}$: C, 57.91; H, 5.83; N, 5.40. Found: C, 57.85; H, 5.73; N, 5.34).



I II

A = CH_2·COOH; P = CH_2CH_2·COOH

Uroporphyrin II[2] was obtained from I (R = H) with formic acid and hydrogen bromide–acetic acid at 100° (∼ 20%, methyl ester, m.p. *ca.* 310°, degraded to coproporphyrin II methyl ester, m.p. 284–286°) and also from III with IV in methanolic hydrogen bromide at 20° followed by warming with aqueous sodium hydroxide (∼ 25%, methyl ester, m.p. *ca.* 313–315°, degraded to coproporphyrin II methyl ester, m.p. 285–286°). Under these last conditions neither III nor IV separately gave any porphyrin.

A MECHANISM STUDY OF THE 2,4,6-HEPTATRIENENITRILE SYNTHESIS FROM ACRYLONITRILE AND ACETYLENE

Sir:

The existence of transition-metal complexes of cyclobutadiene as intermediates in reactions of acetylene has been suggested recently.[1] For example, it was proposed that the cycloöctatetraene synthesis from acetylene in the presence of nickel cyanide catalyst involves the intermediate complex $Ni(CN)_2 \cdot C_4H_4$. As an extension of this concept, it seemed reasonable to postulate that the heptatrienenitrile synthesis from acrylonitrile and acetylene[2] could be pictured as

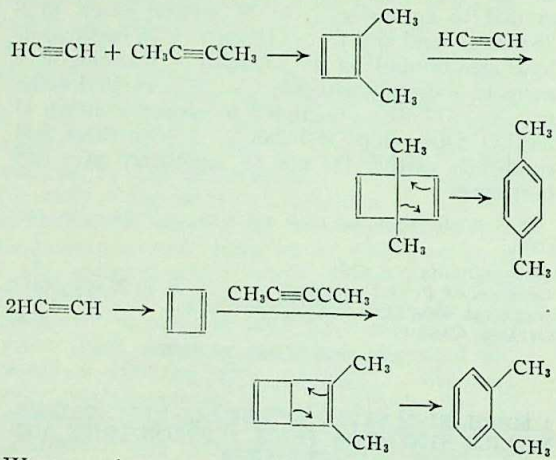
This reaction sequence necessitates having the terminal methylene group of the heptatrienenitrile derived from the acrylonitrile rather than from the acetylene. A tracer study was carried out to test this hypothesis.

For this purpose, C^{14}-labeled 2,4,6-heptatrienenitrile was prepared by the reaction of labeled acrylonitrile ($\overset{*}{C}H_2=\overset{*}{C}H$-CN) with acetylene in the presence of a nickel carbonyl/triphenylphosphine catalyst. The terminal methylene group in the heptatrienenitrile was then removed by ozonolysis and found to contain virtually no C^{14}. This result affords strong evidence that the terminal methylene group in heptatrienenitrile is derived from acetylene and not from acrylonitrile. Accordingly, it appears that heptatrienenitrile is not formed by a cyclobutadiene mechanism. Similar results were obtained in parallel experiments with labeled methyl 2,4,6-heptatrienoate prepared from acetylene and labeled methyl acrylate.

Another extension of the cyclobutadiene mechanism would suggest that some *p*-xylene, as well as *o*-xylene, should be formed in the cotrimerization of dimethylacetylene with acetylene.



We were, however, unable to detect any *p*-xylene by ultraviolet or infrared analyses.

The labeled acrylonitrile (rel. molar activity 3.8 × 10^5 dis./min.) was prepared by pyrolysis of labeled lactonitrile acetate at 555–560°. The acetate was made by heating labeled vinyl acetate, hydrogen cyanide and potassium cyanide catalyst.[3] Labeled 2,4,6-heptatrienenitrile (rel. molar activity 3.9 × 10^5 dis./min.) was prepared by injecting acetylene into the labeled acrylonitrile.[2] The heptatrienenitrile was ozonized in methylene chloride by the procedure of Clemo and Macdonald.[4] The crude formaldehyde containing other ozonolysis products was converted into the dinitrophenylhydrazone (m.p. 151–158° after recrystallization from methanol (0.19 g., 13%), rel. molar activity 0.4 × 10^5, or a drop in activity of 89.7%). The dinitrophenylhydrazone recovered from the mother liquor (0.14 g., 10%) had a relative molar activity of 0.3 × 10^5, or a drop in activity of 92.3%. The derivative appeared to be essentially pure dinitrophenylhydrazone of formaldehyde based on infrared analysis.

Tagged methyl heptatrienoate (rel. molar activity 60 × 10^4 dis./min.) was prepared from tagged methyl acrylate and acetylene.[2] Ozonolysis gave formaldehyde whose dinitrophenylhydrazone showed a drop in relative molar activity of 98%.

In the dimethylacetylene/acetylene cotrimerization, the reactants were heated with a $Ni(CO)_2[(C_6H_5)_3P]_2$ catalyst in tetrahydrofuran at 80–165° under a bomb gage pressure of 5–15 atm. for 3 hr. Benzene, styrene and *o*-xylene were identified as products. There was no indication of the presence of even small amounts of *p*-xylene (based largely on infrared and ultraviolet spectral data).

THE SYNTHESIS OF D-GULOSAMINE

Sir:

A new aminosugar has been isolated recently from streptothricin and streptolin B and the structure of a 2-aminosugar, D-gulosamine, has been proposed for it.[1] This appears to be the first reported isolation of a naturally occurring 2-aminohexose other than the well known D-glucosamine and D-galactosamine. It is also the first isolation of a naturally occurring sugar with the gulose configuration.

We wish to report the synthesis of a 2-aminohexose, possessing the D-gulosamine configuration and also having identical properties to the naturally isolated compound described above. Methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside[2] treated with methanesulfonyl chloride in pyridine solution gave an 86% yield of methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methylsulfonyl-α-D-galactopyranoside (I), m.p. 219–220°, $[\alpha]^{24}D$ +169° (*c* 1.12, $CHCl_3$). *Anal.* Calcd. for $C_{17}H_{23}O_8NS$: C, 50.86; H, 5.77; S, 7.99. Found: C, 50.93; H, 5.86; S, 7.90. Hydrolysis of I with 60% acetic acid afforded a quantitative yield of methyl 2-acetamido-2-deoxy-3-*O*-methylsulfonyl-α-D-galactopyranoside (II), m.p. 179–180°, $[\alpha]^{22}D$ +132° (*c* 0.88, CH_3OH). *Anal.* Calcd. for $C_{10}H_{19}O_8NS$: C, 38.33; H, 6.11. Found: C, 38.48; H, 6.22. It was characterized by the 4,6-di-*O*-acetyl derivative, m.p. 163–164°, $[\alpha]^{24}D$ +96° (*c* 0.83, $CHCl_3$). *Anal.* Calcd. for $C_{14}H_{23}O_{10}NS$: C, 42.31; H, 5.83. Found: C, 42.22; H, 5.79. A solution of II in methyl cellosolve heated in the presence of sodium acetate[3] gave a product, subsequently acetylated with pyridine and acetic anhydride. After purification by chromatography, a 56% yield of methyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-gulopyranoside (III) was obtained;

m.p. 123–124°, $[\alpha]^{21}D$ +76° (*c* 0.91, $CHCl_3$). *Anal.* Calcd. for $C_{15}H_{23}O_9N$: C, 49.86; H, 6.42. Found: C, 49.71; H, 6.45. Catalytic deacetylation of III with barium methylate afforded methyl 2-acetamido-2-deoxy-α-D-gulopyranoside (yield 72%) (IV), m.p. 79–82°, $[\alpha]^{25}D$ +72° (*c* 0.74, CH_3OH). *Anal.* Calcd. for $C_9H_{17}O_6N$: C, 45.95; H, 7.29. Found: C, 45.80; H, 7.22. A crystalline *O*-benzylidene derivative was prepared, m.p. 111–114°, $[\alpha]^{25}D$ +71° (*c* 0.90, CH_3OH). *Anal.* Calcd. for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55. Found: C, 59.08; H, 7.07. 2-Amino-2-deoxy-D-gulose hydrochloride (D-gulosamine hydrochloride) (V) was obtained in a 66% yield by treatment of IV with hydrochloric acid, 150–170° dec., $[\alpha]^{22}D$ +6.1° (10 min.) → −17.9° (36 hr.) (*c* 0.90, H_2O). *Anal.* Calcd. for $C_6H_{14}O_5NCl$: C, 33.26; H, 6.48; N, 6.50; Cl, 16.44. Found: C, 33.47; H, 6.56; N, 6.32; Cl, 16.52. A crystalline derivative was prepared, 2-deoxy-2-(2′-hydroxynaphthylidenamino)-D-gulose, m.p. 186–188° dec., $[\alpha]^{22}_{5461}$ − 150° (at equilibrium, *c* 0.60, methyl cellosolve). *Anal.* Calcd. for $C_{17}H_{19}O_6N$: C, 61.26; H, 5.75. Found: C, 61.16; H, 5.86. The structure of V was ascertained by degradation with ninhydrin in presence of pyridine[4] to D-xylose, identified by paper chromatography. Chromatographed on paper in the mixture *n*-propanol–ammonia 1% 70:30, V migrated 1.18, compared to D-glucosamine 1.00, D-galactosamine 0.91, and D-allosamine[5] 1.03. Treatment of V with pyridine and acetic anhydride, followed by reflux with methanolic hydrochloric acid and subsequent reacetylation of the crude product with pyridine and acetic anhydride, gave a compound, m.p. 116–119°, $[\alpha]^{23}D$ −54° ($CHCl_3$) to which the structure of a methyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-gulopyranoside (VI) was attributed on the basis of the sequence of reactions, rotation and analysis. Found: C, 49.69; H, 6.58.

A sample of natural gulosamine,[6] chromatographed on paper had the same R_f value as V. Submitted to the above described treatment, it gave a compound, m.p. 116–119°, $[\alpha]^{23}D$ −53°, showing no depression of the m.p. in admixture with VI.

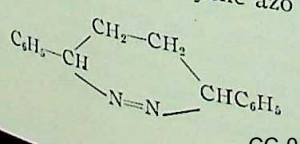
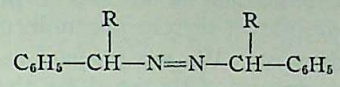
Sir:

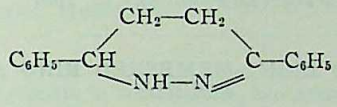
We wish to report the preparation and decomposition of the six-membered cyclic azo compound (I)



a potential source of the biradical 1,4-diphenyl-1,4-butadiyl (II) $C_6H_5\dot{C}HCH_2C\dot{C}H_2HC_6H_5$ which is of interest as possibly being formed by interaction of two molecules of styrene monomer during thermal polymerization. Compound I is analogous to the acyclic azo compounds[1] (III) R = CH_3 or



C_2H_5, which lead to styrene-type radicals. Attempts to prepare a six-membered cyclic azo compound analogous to azo-bis-iso-butyronitrile[2] failed, apparently because of thermal instability. A previously reported[3] synthesis of I had in fact led to the hydrazone-type tautomer[4] (IV)



λ_{max} 292 mμ, log ε 4.19.

Compound I was prepared by (1) addition of diethyl azo-dicarboxylate to 1,4-diphenylbutadiene-1,3, forming the adduct, 1,2-dicarboethoxy-3,6-diphenyl-1,2,3,6-tetrahydropyridazine, 95% yield, m.p. 134–136°, reported[5] 132°; (2) hydrogenation of the adduct to the hexahydro derivative, 70% yield, m.p. 85–87°, reported[5] 87°; (3) saponification with potassium hydroxide and decarboxylation in boiling methanol under nitrogen, and autoxidation during concentration of the dried ether extract, 22% yield, decomposing with vigorous gas evolution when placed in a bath at 120°, λ_{max} 287 mμ, log ε 3.49, λ_{max} 387 mμ, log ε 2.89. *Anal.* Calcd. for $C_{16}H_{16}N_2$: C, 81.30; H, 6.82; N, 11.85. Found: C, 81.48; H, 6.92; N, 11.75. The absorption due to the azo linkage is displaced from its normal position at about 350 to 387 mμ, apparently because of the *cis* configuration of I, acyclic aliphatic azo compounds normally having the *trans* configuration about the azo-linkage. Compound I is tautomerized readily to IV, by heat or by polar solvents.

Thermal decomposition of I in dilute solution in decalin at 135 and 100°, in ethylbenzene at 100°, and in 3.46 moles/l. styrene in ethylbenzene at 100° and at 80° leads to essentially quantitative evolution of nitrogen. Thermal decomposition of solid I leads to partial isomerization to IV; styrene is formed as one of the products of decomposition of solid I, identified as the dibromide, m.p. and mixed m.p. 68–70°, reported[6] 72–73°. The decomposition in solution at 80° had a half-life of about 20 minutes and appeared about 100 times as fast as that of the acyclic analog[1] III, due apparently to the *cis* nature of the cyclic compound and possibly in part due to concomitant formation of the styrene. A large (24-membered) ring bis-

azo compound[7] has been reported, with ultraviolet absorption maximum and rate of decomposition quite similar to those of the acyclic analogs,[1] the size of the ring apparently allowing the azo linkages to assume the *trans* configuration. Decomposition of 0.036 mole/l. of I in 3.46 moles/l. styrene in ethylbenzene at 80° led to polymerization of 8.5 molecules of styrene per molecule of I.

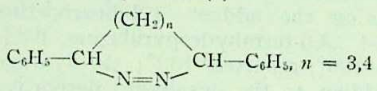
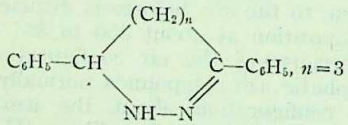
SEVEN- AND EIGHT-MEMBERED RING AZO COMPOUNDS

Sir:

We wish to report the synthesis and decomposition of the azo compounds (I)



Decomposition of these cyclic azo compounds should provide biradicals of the benzyl type. The preparation of the six-membered ring analog is also described in this issue.[1] A method for the preparation of the hydrazine precursor of I, $n = 3$, by reduction of the azine with lithium aluminum hydride has been reported previously.[2] As a preparative method, this procedure is unsatisfactory owing to the formation of the hydrazone (II)



λ_{max} 290 mμ, log ϵ 3.73, from incomplete reduction of the azine and from isomerization of the azo compound obtained by autoxidation of the hydrazine under the conditions of isolation. Quantitative reduction of the cyclic azine[2] with hydrogen over 10% palladium-on-charcoal followed by immediate oxidation of the crude hydrazine with mercuric oxide gives 29.4% of I, $n = 3$, m.p. 115°, with gas evolution, λ_{max} 290 mμ, log ϵ 2.21, λ_{max} 389 mμ, log ϵ 2.03. *Anal.* Calcd. for $C_{17}H_{18}N_2$: C, 81.56; H, 7.25; N, 11.19. Found: C, 81.51; H, 7.01; N, 11.23. Air oxidation of the crude hydrazine has also yielded the azo compound. The normal azo absorption found in acyclic azo compounds at approximately 350 mμ,[3] has been displaced to 389 mμ, presumably due to the *cis* configuration forced on the azo link in I, $n = 3$. Thermal decomposition of I, $n = 3$, in xylene solution at 100.2° gives first-order kinetics, half-life 2.9 minutes, with a 94% evolution of nitrogen after 31 minutes. Decomposition of I in xylene at 80° gave a half-life of 27.1 minutes with only a 71.5% evolution of nitrogen. These decomposition rates are over 100 times faster than the corresponding linear *trans*[3] azo compounds. Analysis of products of the decomposition at 80° indicates the presence of the hydrazone II, $n = 3$, λ_{max} 290 mμ, log ϵ 3.60. Analysis of the ultraviolet spectrum of I, $n = 3$, has shown that I slowly isomerizes to the hydrazone II, $n = 3$, in ethanol at room temperature.

The synthesis of the eight-membered ring azo compound I, $n = 4$, was carried out by preparing the appropriate cyclic azine by a modification of the method of Overberger and Lapkin,[4] m.p. 136–137°, λ_{max} 268 mμ, log ϵ 4.45. *Anal.* Calcd. for $C_{18}H_{18}N_2$: C, 82.42; H, 6.92; N, 10.68; mol. wt., 262. Found: C, 82.64; H, 6.90; N, 10.43; mol. wt. 281 (ebullioscopic in butanol). Quantitative reduction of the azine followed by immediate oxidation with mercuric oxide yielded 57% of I, $n = 4$, m.p. 88–90°, λ_{max} 368 mμ, log ϵ 1.65. *Anal.* Calcd. for $C_{18}H_{20}N_2$: C, 81.77; H, 7.63; N, 10.60; mol. wt., 264. Found: C, 81.60; H, 7.47; N, 10.73; mol. wt., 297 (ebullioscopic in butanol).[5] The infrared absorption for both I, $n = 3,4$, are almost identical, show no hydrazone absorptions and confirm the conclusions made from ultraviolet data.

Acknowledgment.—We wish to thank the National Science Foundation for the support of a portion of this work, Grant NSF-1453.

BOOK REVIEWS

Magnetochemistry. Second Edition. Completely Revised and Rewritten. By PIERCE W. SELWOOD, Professor of Chemistry, Northwestern University. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, N. Y. 1956. xii + 435 pp. 16 × 23.5 cm. Price, $11.50.

The subject of magnetochemistry has proliferated in the thirteen years since the first edition of this monograph appeared and the second edition, which has been revised, expanded and brought up-to-date, is a most welcome addition to the literature. The author states that about one-half of the available references, covering the literature through 1955 *Chemical Abstracts*, have been included in this edition. The present volume is unique in providing a modern survey of the applications of magnetic measurements to chemical problems since the treatises by Klemm and by Bhatnagar and Mathur are now quite out-of-date. The author has largely avoided repetition of material adequately covered elsewhere and his treatment complements those in other books on magnetism by Van Vleck, Stoner, Bates and Bozoroth, all of which represent the viewpoint of the physicist.

The first three chapters of the new edition are devoted to experimental methods of measuring average susceptibilities, principal susceptibilities and specific magnetization; these provide a practical guide to current practice which should be studied by anyone contemplating experimental work of this type. A nine-page chapter on resonance methods and a chapter on diamagnetic anisotropy are new. The chapters covering diamagnetism of molecules, diamagnetism of atoms, paramagnetism of atoms, paramagnetism of molecules and ferromagnetism have been partly rewritten, numerous references added and many helpful tables of data inserted. A new chapter reviews applications of atomic paramagnetism, particularly to glasses, irradiated solids and luminescent solids. Antiferromagnetism not even listed in the index to the first edition, now receives a separate chapter. The applications of ferromagnetism and antiferromagnetism to structural inorganic chemistry are stressed rather than the technological applications. The chapter on metallic diamagnetism and paramagnetism has been completely rewritten and the book concludes with an interesting account of magnetochemistry and heterogeneous catalysis, a subject to which Selwood and his students have made extensive contributions.

The most disappointing features of the new edition to this reviewer are the scanty treatment accorded to resonance methods and to theoretical developments. Nuclear magnetic resonance and paramagnetic resonance are already important tools for investigating chemical problems and each already has an extensive literature. Although many references to specific applications have been inserted through the text, in addition to the brief chapter introducing the methods, the reader must turn elsewhere for an adequate review of experimental methods or of results. Important theoretical developments often receive no attention. Thus Pauling's theory of the magnetic properties of metals and the band theory each receive only a reference. Since readable introductions to many of these topics are rare the casual reader will no doubt often fail to gain an understanding of the physical bases of the phenomena. However, by exclusion of such material it has undoubtedly been possible to keep down the size and cost of the book.

Although emphasis throughout is on experimental methods and results it avoids being a mere compendium of references. Brief summaries of pertinent theoretical work provide, in many cases, the background for understanding and interpreting the data. References have been chosen which for the most part offer either a theoretical or practical advance with the result that nearly every application of magnetism to chemistry is at least mentioned. The treatment of experimental articles is critical and, reflecting the wide experience of the author, many doubtful results are questioned (such as the "superparamagnetism" of Kobozev, *et al.*). Direct or implied suggestions for research abound and should stimulate workers in a variety of fields to apply magnetochemical methods to their problems.

The new edition will be indispensable to workers in the field particularly in view of the fact that the two-thousand listed references come largely from journals not usually read by the chemist and often not available. The volume is highly recommended as a comprehensive guide to "classical" magnetochemistry to anyone interested in structural chemistry, solid state physics or the application of magnetic measurements in chemistry. The style is clear and readable, the organization good and the background required of the reader very modest.

Die Polarographie in der Medizin, Biochemie und Pharmazie. By M. BŘEZINA and P. ZUMAN, Polarographisches Institut der Tschechoslowakischen Akademie der Wissenschaften, Prag. Akademische Verlagsgesellschaft, Geest und Portig K.-G., Sternwartenstrasse 8, Leipzig C 1, Germany. 1956. 800 pp. 17.5 x 25 cm. Price, DM 48.

This monograph, which is a "revised and enlarged translation" of the first (1952) Czech edition, deals with the use of the polarograph in analyzing not only biological, clinical and pharmaceutical materials, but virtually every other kind of organic sample as well. Most of its pages are devoted to the determination of organic substances, but there is also a quite comprehensive treatment of the determination of inorganic constituents. Its subject is thus both important and broad, and one cannot but welcome this extensive treatment by two well-known contributors to the polarographic literature.

The nature and scope of the treatment may be illustrated by the contents of the section dealing with the determination of lead. Here, within twenty pages, are given descriptions of methods for dealing with thirty different kinds of samples, including, for example, blood, fingernails, tin cans, cadavers and port wine. Most of the procedures are given in enough detail to permit their practical execution without the necessity of consulting the original literature: this should be especially valuable to the busy clinical analyst. Where two or more procedures for analyzing similar samples have been proposed, all are usually described in about equal detail. This has the advantage of placing at the reader's disposal an extensive summary of the work in this field up to about 1954, and especially of that portion of it which is due to the authors and their Czech colleagues. However, it will be regretted that room could not be found for a critical evaluation of the merits of the various procedures or for some description of the chemical and electrochemical processes on which they are based.

Though the authors have succeeded in giving an admirably thorough presentation of their own country's achievements in polarographic analysis, there are some noteworthy gaps in their coverage of the remainder of the literature. Derivative polarography (attributed to Vogel and Říha alone) is discussed at some length, though without reference either to an important paper by Lingane and Williams or to the related and no less meritorious technique of polarography with superimposed a.-c. On the other hand, rotating solid metal electrodes are dismissed very briefly, and such other techniques as electro-separations at controlled potential and coulometry at controlled current are not even mentioned. Nor is any reference made to the fundamental work of Elving, *et al.*, on the influence of ionic strength in organic polarography.

Although the extensive table of "the most important" half-wave potentials of inorganic and organic substances will be gladly received by those concerned with descriptive polarography, it is marred by a number of errors and other defects. The errors may be typified by two examples. The value given (+0.67 for the half-wave potentials of the "copper(I)–copper(II)" couple in sulfate and citrate media are

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

evidently derived from the work of Kalousek, which actually involved mixed potentials and had nothing to do with copper(I). On p. 665 $E_{1/2}$ is given as − 0.54 v. *vs.* N.C.E. for the process Re(I)→Re(II) in 1 *M* perchloric acid: though no reference is given, the only possible source known to this reviewer is a paper by Lingane which gives a different half-wave potential, a different oxidation state of the starting material, and a different concentration of the supporting electrolyte, and also describes three additional waves of which no mention is made in the table. In the organic section of the table, the consistent use of trivial rather than systematic names of organic compounds is regrettable, as is the frequent failure to give full details concerning supporting electrolyte composition. As in the remainder of the book, American sources are poorly represented in this table—the reviewer sought in vain for any mention of a long and important series of papers by Elving, *et al.*—and over half of those which are listed are over ten years old.

Fortschritte der Chemie Organischer Naturstoffe (Progress in the Chemistry of Organic Natural Products). Volume XIII. Edited by L. ZECHMEISTER, California Institute of Technology, Pasadena. Springer-Verlag, Mölkerbastei 5, Wien 1, Austria. 1956. xii + 624 pp. 16.5 × 23.5 cm. Price, $24.75; Ganzleinen, $25.60.

Earlier volumes in this series have presented comprehensive reviews by leading workers on topics which, while of current interest, have not become hackneyed by repeated reviewing. The present volume continues this valuable tradition, although some of the chapters have been anticipated to a greater or less degree by reviews published elsewhere.

The chapter on infrared spectra of natural products by A. R. H. Cole discusses instrumentation, and then considers numerous applications to problems in the structure of natural products, principally of steroids and terpenoids. Cole wisely does not attempt to duplicate the comprehensive collections of information about infrared spectra of organic compounds which are available in the writings of Bellamy and of Norman Jones, but his chapter is interesting and useful.

O.Th. Schmidt's review of gallotannins and related compounds gives a good summary of a field with which most organic chemists are probably not very familiar; the reader should note that "genetisch" in this chapter is apparently synonymous with the word "biogenetic" in English.

The cardiac drugs have offered one of the most complex structural problems in the whole steroid field, and in spite of many outstanding researches, particularly the classical studies of W. L. Jacobs, the structural problems are not all solved. Ch. Tamm gives a comprehensive and timely review of the chemistry of the glycosides and the aglycones.

Tropolone chemistry is reviewed by one of its most active exponents, Nozoe; the coverage is not as comprehensive as that in the recent review article by Pauson, but Nozoe's paper contains some new material and is a readable summary.

J. R. Price contributes an interesting and well-written chapter on alkaloids which can be considered to be related to anthranilic acid; the alkaloids considered include those of the quinoline, acridine, furoquinoline and quinazoline types.

The chemistry and pharmacology of the Rauwolfia alkaloids are discussed by Chatterjee, Pakrashi and Werner; this paper is comprehensive, is admirably up to date (Woodward's total synthesis of reserpine is included) and will undoubtedly be very useful to the many workers in this field. The section on pharmacology is particularly well done.

The great advances made in method of polypeptide synthesis in the last decade, and the large amount of work currently going on in the field of protein structure, make the last chapter, by Grassmann and Wünsch, particularly timely. They present a comprehensive and valuable, although occasionally rather uncritical, survey of methods of synthesis of the peptide bond; the chapter is, as far as the reviewer knows, the most complete and up to date discussion available.

In summary, all of the chapters will be useful to the specialist, and they all make instructive and broadening reading to the organic chemist who is interested in structural and theoretical problems. The emphasis of the whole book is on structural organic chemistry; possibly a chapter or two of more biological and biochemical nature, such as have appeared in earlier volumes of the series, would have provided some welcome variety.

Reactions of Gaseous Ions. II. Acetylene

BY F. H. FIELD, J. L. FRANKLIN AND F. W. LAMPE

RECEIVED JANUARY 23, 1957

The gas phase reactions of several organic positive ions with acetylene have been identified and their rates measured. The rates are in approximate agreement with values calculated theoretically. Appearance potentials of several primary ions have been measured to provide energy data necessary for interpretation of certain secondary reactions.

In a recent paper[1] we reported on studies of the reactions of ions from methane and ethylene in a mass spectrometer ion source. The present paper reports the results of studies of the reactions of ions from acetylene. Hinkle, Roberts and Hamner[2] have reported secondary ions from several acetylenes but did not identify the reactions or measure the reaction rates. In this paper we describe experiments by which the reactions leading to the formation of several secondary ions from acetylene were determined and their rates measured.

Results and Discussions

A typical mass spectrum of acetylene at a reservoir pressure of 10.3 mm. is given in Table I. The important secondary peaks are those having m/e ratios of 51, 50, 49, 37 and 38. All of these peaks exhibited an approximately second-order pressure dependence and so could not be attributed to impurities. Further, their variation in intensity with repeller voltage clearly showed them to be secondary ions.

TABLE I

MASS SPECTRUM OF ACETYLENE AT 10.3 MM. RESERVOIR PRESSURE ($N = 11 \times 10^{13}$ MOLECULES/CC.) ($V_R = 1$ V.)

m/e	Intensity, arbitrary units	m/e	Intensity, arbitrary units
12	510	37	44
13	1590	38	21
14	70	39	4
24	1530	49	55
25	5800	50	750
26	38000	51	930
27	750	52	≈12

In order to identify the reactions by which these secondary products were formed, their appearance potentials were measured in the Westinghouse Type LV mass spectrometer using the techniques described in the previous paper. Firm data have not previously been obtained for the appearance potentials and heats of formation of certain of these ions. In order to interpret the results of our secondary reactions, it was necessary to determine the heats of formation of these ions by measuring their appearance potentials as primary decomposition products. Accordingly, we determined the appearance potentials of the C_3H^+ and C_4H^+ ions from 1,3-butadiene, 1-butyne and vinylacetylene and of the $C_4H_2^+$ and $C_4H_3^+$ ions from vinylacetylene. In addition, for purposes of calibration we measured the appearance potential of the CH^+, C_2^+ and C_2H^+ ions from acetylene. The appearance potentials of these primary ions and the corresponding heats of formation are given in Table II.

Our value for C_2H^+ is in sufficiently good agreement with the value of 17.8 v. reported by Coats and Anderson[3] and Kusch, Hustrulid and Tate.[4] Also, our appearance potential for CH^+ agrees within the accuracy of the measurements with the value of 22.3 v. reported by the latter workers.

We found three values for the appearance potential of the C_2^+ ion from acetylene. The low value of about 13 v., which is quite approximate, is probably attributable to a small amount of pyrolysis on the filament. There were also two quite definite

	$\rightarrow C_4H^+ + 3H$	17.02	301
50	$C_4H_4 \rightarrow C_4H_2^+ + H_2$	12.84	361
51	$C_4H_4 \rightarrow C_4H_3^+ + H$	12.59	303

[a] Calculated using heats of formation taken from the API tables.[5] The heat of formation of vinylacetylene was estimated by the method of group equivalents[6] assuming a resonance energy of 4 kcal/mole.

discontinuities in the ion intensity curves, one at 18.2 v. and the other at 22.7 v. The higher value corresponds within experimental accuracy to the 23.3 and 23.9 v. values of Coats and Anderson and Kusch, Hustrulid and Tate. This we attribute to the reaction

$$C_2H_2 \longrightarrow C_2^+ + 2H$$

The lower appearance potential 18.2 v. differs from the higher by almost exactly $D(H_2)$ and accordingly it is reasonable to attribute it to the reaction

$$C_2H_2 \longrightarrow C_2^+ + H_2$$

We are concerned that other investigators have not observed this appearance potential, but in our instrument it was definite and we think the interpretation is a reasonable one.

It was surprising to find the lower appearance potentials for the C_3H^+ ion from 1,3-butadiene and 1-butyne so small. The values appear real, however, and we have no choice but to accept them. In each case we have interpreted the appearance potential as corresponding to the reaction giving the highest heat of formation for C_3H^+. Although there is a discrepancy of 17 kcal./mole between the results from the two sources, the heat of formation nevertheless appears to be in the neighborhood of 290 kcal./mole. Further, the higher appearance potentials, if interpreted as corresponding to the formation of hydrogen atoms instead of H_2, give approximate agreement with this heat of formation of C_3H^+. The literature gives very few measurements of the appearance potential of C_3H^+. The only one capable of unequivocal interpretation is that of Field[7] from cyclopropane. His value of 15.0 v. leads to a heat of formation of C_3H^+ of 307 kcal./mole if one assumes the reaction

$$\text{Cyclo-}C_3H_6 \longrightarrow C_3H^+ + 2H_2 + H$$

More extensive atomization of hydrogen would give unreasonably low heats of formation of C_3H^+. Coats and Anderson[3] obtained a value of 18.4 v. from propyne which would lead to a heat of formation of 416 or 312 kcal./mole depending upon whether the decomposition reaction involved the formation of $H_2 + H$ or 3H. Hissel[8] measured the appearance potential of C_3H^+ from pyrrole, furan and thiophene. The results can be interpreted as corresponding to a heat of formation of C_3H^+ in the neighborhood of 300 kcal./mole, but since the reactions are complicated, any interpretation would be equivocal. It appears then, from all of the available measurements, that a value for the heat of formation of C_3H^+ in the neighborhood of 300 kcal./mole is correct although it is indeed lower than would have been anticipated.

The appearance potentials of the C_4H^+ ion similarly lead to surprisingly low values for the ion's heat of formation. Although again close agreement is not obtained amongst the heats of formation from various sources, we must conclude that the heat of formation of C_4H^+ is in the neighborhood of 300 kcal./mole. Unfortunately, we know of no reliable measurement for the appearance potential from other sources.

In an earlier paper, Franklin and Field[9] reported the appearance potential of $C_4H_2^+$ from vinylacetylene as 12.88 v. Partly for purposes of calibration we remeasured this appearance potential and found excellent agreement with the previous value. This leads to a heat of formation of 361 kcal./mole which is in fair agreement with that which one calculates from ionization potentials reported by Price and Walsh.[10]

Our value for the heat of formation of the $C_4H_3^+$ ion is appreciably lower than that obtained from Coats and Anderson's[3] value as determined from butyne-2. We are inclined to prefer our value since it corresponds to a simpler decomposition.

In Table III, we compare the appearance potentials of ions formed in acetylene by secondary processes with that of the primary ion formed from acetylene by a primary process. From this, it is evident that $C_4H_3^+$ and $C_4H_2^+$ are formed by reaction of $C_2H_2^+$ with acetylene. Further, these two peaks are by far the most intense in the secondary spectrum and undoubtedly correspond to reaction of a very abundant primary ion.

It is of interest that two appearance potentials for the C_4H^+ ion were found. These correspond approximately to the two appearance potentials of C_2^+ from acetylene at 18.2 and 22.7 v. We did not observe a C_4H^+ appearance potential at around 13 v., but this is not surprising since the amount of

[a] Calculated using heats of formation of ions taken from the compilation of Field and Franklin[11] and heats of formation of neutral molecules taken from the API tables.[3]

pyrolysis was so small that even the primary C_2^+ peak corresponding to it was very difficult to measure.

The appearance potentials of both the 37 and 38 peaks in the secondary spectrum agree most closely with that of CH^+ and we conclude, therefore, that both of these ions are formed by the reaction of CH^+ with acetylene. Both processes would be exothermic. Further, these secondary peaks are comparatively small and would be expected to arise from a comparatively weak precursor.

In the previous paper,[1] we showed that where two secondary ions arise from a common primary, the reaction can be best interpreted as involving the decomposition of a common activated complex. This is also true of the ions from acetylene. Thus, comparison in Table IV of the relative intensities of $C_4H_3^+$ and $C_4H_2^+$ ions formed as primary decomposition products of C_4H_4 and as secondary products from the reaction of $C_2H_2^+$ and C_2H_2, shows very close agreement. The C_4H^+ is also formed as a primary product from C_4H_4, but appearance potentials indicate that it is not formed in appreciable amounts from the reaction of $C_2H_2^+$. Since this reaction is slightly exothermic, the absence of C_4H^+ as a secondary product of the reaction of $C_2H_2^+$ suggests that some activation energy is involved.

TABLE IV

COMPARISON OF PRIMARY AND SECONDARY MASS SPECTRA (BASED ON LARGEST OF PEAKS COMPARED)

Ion	Relative intensities Primary from C_4H_4	Sec. from $C_3H_3^+ + C_2H_2$	Ion	Relative intensities Primary from C_4H_2	Sec. from $C_2^+ + C_2H_2$
$C_4H_3^+$	100	100	C_4H^+	100	100
$C_4H_2^+$	83	81	C_4^+	24	45 ?
C_4H^+	13	6			

It is interesting also that the primary mass spectrum of C_4H_2 and the secondary spectrum of $C_2^+ + C_2H_2$ show approximate agreement for the C_4H^+ and C_4^+ ion intensities. The C_4^+ ion intensity was too small to permit a detailed study, but it seems reasonable that it might be formed from the reaction of C_2^+ ions.

As in the previous paper,[1] we measured the variation in ion intensities at a series of pressures while holding the repeller voltage constant and from this the rate constants for the various reactions at fixed voltage have been calculated by means of the equations (see ref. 1).

$$\frac{I_{S_j^+}}{I_{P^+} + \sum_j I_{S_j^+}} = \frac{k_{S_j^+}}{\sum_j k_{S_j^+}} k_1 [M] \tau_{P^+} \quad (1)$$

$$\tau_{P^+} = \frac{1}{2A}\sqrt{B^2 + 2Ad_0} + \frac{d_0}{2B} \ln \frac{\sqrt{B^2 + 2Ad_0} + B}{\sqrt{B^2 + 2Ad_0} - B} \quad (2)$$

$A = ev/m$

$B = \sqrt{8kT/\pi m}$

d_0 = distance from electron beam to the ion exit slit

v = ionization chamber field strength

In Table V, the rate constants are given at a field strength of 10 volts/cm. It is of interest that, as in the previous studies, the rate constants for the various reactions differ by a comparatively small amount.

TABLE V

RATE CONSTANTS FROM PRESSURE STUDIES (FIELD STRENGTH = 10 VOLTS/CM.)

	$\left(\frac{k_{S_j^+}}{\Sigma k_{S_j^+}}\right) k_1 \times 10^{10}$ (cc./molecule sec.)	$k_1 \times 10^{10}$ (cc./molecule sec.)
$C_2H_2^+ + C_2H_2 \rightarrow C_4H_3^+ + H$	5.0	
$C_2H_2^+ + C_2H_2 \rightarrow C_4H_2^+ + H_2$	3.9	
$C_2H_2^+ + C_2H_2 \rightarrow (C_4H_4^+)$		8.9
$C_2^+ + C_2H_2 \rightarrow C_4H^+ + H$	7.3	7.3
$CH^+ + C_2H_2 \rightarrow C_3H_2^+ + H$	3.5	
$CH^+ + C_2H_2 \rightarrow C_3H^+ + H_2$	6.9	
$CH^+ + C_2H_2 \rightarrow (C_3H_3^+)$		10.4

The rate constants were also measured at different field strengths while holding the pressure constant. Table VI gives the average rate constants for the various reactions at several field strengths. In accordance with previous experience, all of these values tend to go through a maximum in the neighborhood of 8 to 20 volts per cm. Such discrepancies as are to be found between Tables V and VI are to be attributed to experimental error.

Equation (3) relates rate constant to reaction cross section, σ

$$k = f\sigma Q'/\bar{\tau} \quad (3)$$

where

$$Q'/\bar{\tau} = \frac{A\bar{\tau}}{2} + \frac{B^2}{A\bar{\tau}}\left[\frac{247}{382} + \frac{1}{3}\ln\frac{2A\bar{\tau}}{\sqrt{B^2 + 3A^2\bar{\tau}^2}}\right] \quad (4)$$

f is an efficiency factor, and other terms are defined above. Values of $f\sigma$ have been calculated from the measured rate constants and the results are given in Table VII.

In the previous paper we have shown that σ can be calculated from the equation

$$\sigma = \frac{e\pi\sqrt{\alpha}}{\sqrt{6kT + 2/3eVd_0}} \quad (5)$$

where α is the polarizability. Values of σ have been calculated from equation 4 using $\alpha = 3.88 \times 10^{-24}$ from Landolt-Börnstein[12] and the results are given

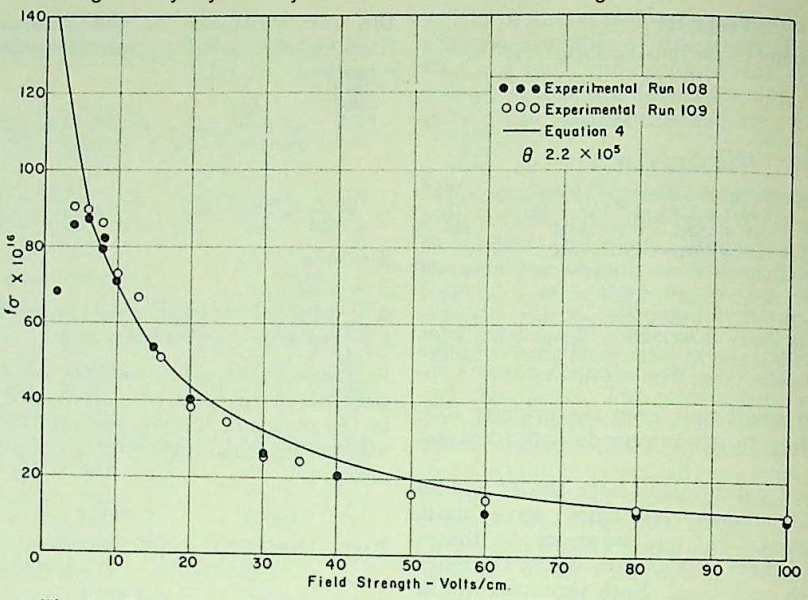

Fig. 1.—Typical plot of $f\sigma$ *vs.* field strength for $C_2H_2^+ + C_2H_2 \rightarrow [C_4H_4^+]$.

in Table VII. The agreement amongst the experimental cross sections for the various reactions is rather close as would be expected from theory.

As in the previous paper[1] rate constants and reaction cross sections for thermal speed ions were obtained by extrapolation from the more reliable higher field strength measurements. It was shown that the reaction cross section could be represented by

$$f\sigma = {}^1/_2\left(\frac{m_1(m_1+m_2)}{m_2}\right)^{1/2}\frac{\theta e\pi\alpha^{1/2}}{\left(3kT+\frac{eVd_0}{3}\right)} \quad (6)$$

where the indices 1 and 2 refer to the ion and molecule, respectively, and with θ determined from the slope of a plot of $f\sigma$ *vs.* $1/(3kT + eVd_0/3)$. That equation 4 represents quite nicely the variation of $f\sigma$ with field strength is shown in Fig. 1. The rate constant for thermal speed ions was shown to be

$$k_{v=0} = \frac{\theta e}{6}\left(\frac{8\pi\alpha}{kT}\right)^{1/2}\left(\frac{m_\alpha + m_\beta}{m_\beta}\right)^{1/2} \quad (7)$$

where the index α always refers to the lighter reactant.

previously.[1] In studying reaction rates a Consolidated Electrodynamics Corporation (CEC) Model 21-620 cycloidal focusing mass spectrometer was used. In calibrating the ion source for pressure, the ionization cross section of acetylene was determined as $5.6_0 \times 10^{-16}$ cm.² in reasonably good agreement with the value of 4.98×10^{-16} cm.,² reported by Massey and Burhop.[14] Appearance potentials were measured on a Westinghouse Type LV mass spectrometer. The acetylene used in these studies was commercial tank material obtained from Matheson Chemical Company and purified by repeated condensation at liquid nitrogen temperatures. The 1,3-butadiene was Phillips research grade having a stated purity of 99.51% and the 1-butyne was an API standard sample of 99.87% purity. Both were used without further purification. The vinylacetylene was obtained from the du Pont Company and was used without treatment since a mass spectrum indicated it to be of satisfactory purity.

Acknowledgment.—We wish to express our appreciation to Mr. B. L. Clark for his help in making the measurements and calculations.

Electronic and Vibrational States of the Nitrite Ion. I. Electronic States[1]

BY JEROME W. SIDMAN[2]

RECEIVED AUGUST 16, 1956

The lowest absorption transition of the nitrite ion has been studied in the crystalline state at 77°K. and at 4°K., using single crystals of $NaN^{14}O_2$ and $NaN^{15}O_2$ in polarized light. The corresponding fluorescence transition also has been studied. The spectra are sharp, and can be analyzed in considerable detail to yield vibrational and lattice frequencies for both the ground and excited electronic states. From the intensity dichroism and vibrational structure, it is concluded that the weak absorption transition of $NaN^{14}O_2$ with origin at 25977 cm.$^{-1}$ at 4°K. (25977 cm.$^{-1}$ for $NaN^{15}O_2$ at 4°K.) is allowed by symmetry and is polarized perpendicular to the plane of the NO_2^- ion ($^1B_2 \leftarrow {}^1A_1$). Comparisons with theory and with previous work are made wherever possible. The effect of environment on the electronic spectrum of NO_2^- is discussed. The NO_2^- spectra also are compared with the spectra of other 18-valence electron molecules, such as O_3, SO_2, HCO_2^-, ONCl, etc. The simplest LCAO–MO treatment appears to give a qualitatively correct description of the excited electronic states of NO_2^-.

Introduction

Within the last few years, considerable progress has been made toward understanding the electronic spectra of polyatomic molecules. Although much attention has been given to large aromatic hydrocarbons, a survey of the literature reveals that relatively few triatomic molecular electronic spectra have been completely analyzed. The vapor spectra of triatomic molecules are sometimes sharp enough to permit analysis of the rotational fine structure, from which the transition moment direction and the geometry change can be deduced. However, even in such cases, there may be so many closely spaced bands present in the spectrum that the vibrational analysis is made difficult. Furthermore, if the molecule is very different from a symmetric top, the rotational analysis becomes quite difficult. In the cases in which the bands are broadened by predissociation, less information can be obtained.

The study of crystal and mixed crystal spectra has provided exact information about symmetry properties and vibrational structure of the electronic transitions of large, complex molecules. In this paper and in the following one, the results of such a study are reported for the lowest singlet-singlet electronic transition of the NO_2^- molecule-ion. Although it has been known since 1934 that the spectra of crystalline $NaNO_2$ and KNO_2 are sharp at low temperatures,[3] a complete analysis has not yet been given. The recent polarization studies of Trawick and Eberhardt[4] have provided additional information, which, together with the vibrational analysis presented in this work, lead to conclusions about the nature of the ground and lowest excited electronic states of this molecule. These results should also be applicable to other related molecules which possess the same number of valence electrons and similar geometry, and comparisons and predictions will therefore be made where possible.

Experimental

Mallinckrodt Analytical Reagent Grade $NaNO_2$ was further purified by recrystallization from water. Single crystals of suitable thickness were prepared readily by crystallization from molten $NaNO_2$ between quartz disks. The experimental arrangement used to record the absorption and fluorescence spectra of single crystals at low temperature has been described in a previous publication.[5] In this work, a tungsten filament lamp was the source for the absorption experiments, and a medium-pressure Hg arc with a Corning 5860 filter was used to excite the fluorescence of $NaNO_2$. All spectra were recorded on Kodak

Discussion and Interpretation

(A) **Assignment of the Electronic Transitions.**—The determination of the symmetry properties of the combining states in an electronic transition of a polyatomic molecule is as important as the determination of the energy and transition probability. Until recently, the direct determination of this property has been quite difficult. It has often been difficult or impossible to determine correctly the electronic symmetry properties from polarized spectra of single crystals, due to intermolecular coupling between identical molecules in the crystal.[8,9] Such effects are absent in the polarized absorption spectra of dilute mixed crystals, and considerable data are now available for the electronic assignments of the aromatic hydrocarbons from mixed crystal studies.[10]

The crystals which have been studied previously are molecular crystals, in which the molecule and its nearest neighbors are identical. $NaNO_2$ is an ionic crystal, and the nearest neighbors of the NO_2^- ions are Na^+ ions, which shield the NO_2^- ions from each other. Consequently, effects due to intermolecular coupling, such as dichroic splitting of the 0–0 band and/or formation of trapped excitons,[9,11] should be much less prominent in $NaNO_2$, which may be regarded as a concentrated (50%) mixed crystal in which there is order with respect to the position and orientation of both the solute (NO_2^-) and solvent (Na^+).

Trawick and Eberhardt[4] have studied the polarization properties of the electronic transitions of single crystals of $NaNO_2$ at 77°K. They have found that the origin of the lowest absorption band at λ 3851.4 Å. is polarized perpendicular to the plane of the NO_2^- ion. The results of this investigation are in agreement with Trawick and Eberhardt's work. However, thicker crystals at wave lengths shorter than λ 3851.4 Å. show that there is weak but definite absorption for light polarized in the plane of the NO_2^- ion (Fig. 1). This will be discussed in further detail in section (C).

The polarization of the crystal absorption spectrum does not in itself lead to an unambiguous electronic assignment, since it is possible that the electronic transition might be forbidden by symmetry and that its appearance might be due to a vibrational or to a lattice perturbation, or both. However, an unambiguous determination often can be made if the same electronic transition appears in fluorescence. Excitation of crystalline $NaNO_2$ with the λ 3660 Å. Hg group produces a weak but detectable fluorescence spectrum, which nearly is the mirror image of the absorption spectrum.[12] Although lines from the Hg arc interfere in the region near λ 3851.4 Å., the vibrational analyses of the absorption and the fluorescence spectra leave no doubt that the lowest absorption band at λ 3851.4 Å. is the 0–0 band of an electronic transition which is allowed by symmetry and which is polarized perpendicular to the plane of the NO_2^- ion. Since the molecular point group, molecular site group in the crystal, and crystallographic space group are all C_{2v}, the polarization results of the crystal spectra should be directly applicable to the free ion.

The crystal structure of $NaNO_2$ has been extensively and carefully investigated.[13–15] A diagram of the crystal and molecular structure is shown in Fig. 3. The crystallographic axes are labeled according to Ziegler's notation.[13]
